Locks are a handy tool to synchronize access to data. Using them properly is the key to safe shared data. Unfortunately, locks aren't without their dangers. Consider the following code:

```
use Thread qw(async yield);
$a = 4;
$b = "foo";
async {
    lock($a);
    yield;
    sleep 20;
    lock ($b);
};
async {
    lock($b);
```

```
        yield;
        sleep 20;
        lock ($a);
    };
```

This program will probably hang until you kill it. The only way it won't hang is if one of the two async() routines acquires both locks first. A guaranteed-to-hang version is more complicated, but the principle is the same.

The first thread spawned by async() will grab a lock on $a then, a second or two later, try to grab a lock on $b. Meanwhile, the second thread grabs a lock on $b, then later tries to grab a lock on $a. The second lock attempt for both threads will block, each waiting for the other to release its lock.

This condition is called a deadlock, and it occurs whenever two or more threads are trying to get locks on resources that the others own. Each thread will block, waiting for the other to release a lock on a resource. That never happens, though, since the thread with the resource is itself waiting for a lock to be released.

There are a number of ways to handle this sort of problem. The best way is to always have all threads acquire locks in the exact same order. If, for example, you lock variables $a, $b, and $c, always lock $a before $b, and $b before $c. It's also best to hold on to locks for as short a period of time to minimize the risks of deadlock.

51.8.5 Queues: Passing Data Around

A queue is a special thread-safe object that lets you put data in one end and take it out the other without having to worry about synchronization issues. They're pretty straightforward, and look like this:

```
    use Thread qw(async);
    use Thread::Queue;

    my $DataQueue = new Thread::Queue;
    $thr = async {
        while ($DataElement = $DataQueue->dequeue) {
            print "Popped $DataElement off the queue\n";
        }
    };

    $DataQueue->enqueue(12);
    $DataQueue->enqueue("A", "B", "C");
    $DataQueue->enqueue(\$thr);
    sleep 10;
    $DataQueue->enqueue(undef);
```

You create the queue with new Thread::Queue. Then you can add lists of scalars onto the end with enqueue(), and pop scalars off the front of it with dequeue(). A queue has no fixed size, and can grow as needed to hold everything pushed on to it.

If a queue is empty, dequeue() blocks until another thread enqueues something. This makes queues ideal for event loops and other communications between threads.

51.9 Threads And Code

In addition to providing thread-safe access to data via locks and queues, threaded Perl also provides general-purpose semaphores for coarser synchronization than locks provide and thread-safe access to entire subroutines.

51.9.1 Semaphores: Synchronizing Data Access

Semaphores are a kind of generic locking mechanism. Unlike lock, which gets a lock on a particular scalar, Perl doesn't associate any particular thing with a semaphore so you can use them to control access to anything you like. In addition, semaphores can allow more than one thread to access a resource at once, though by default semaphores only allow one thread access at a time.

Basic semaphores

Semaphores have two methods, down and up. down decrements the resource count, while up increments it. down calls will block if the semaphore's current count would decrement below zero. This program gives a quick demonstration:

```
use Thread qw(yield);
use Thread::Semaphore;
my $semaphore = new Thread::Semaphore;
$GlobalVariable = 0;

$thr1 = new Thread \&sample_sub, 1;
$thr2 = new Thread \&sample_sub, 2;
$thr3 = new Thread \&sample_sub, 3;

sub sample_sub {
    my $SubNumber = shift @_;
    my $TryCount = 10;
    my $LocalCopy;
    sleep 1;
    while ($TryCount--) {
        $semaphore->down;
        $LocalCopy = $GlobalVariable;
        print "$TryCount tries left for sub $SubNumber (\$GlobalVariable is $GlobalVariable)\n
        yield;
        sleep 2;
        $LocalCopy++;
        $GlobalVariable = $LocalCopy;
        $semaphore->up;
    }
}
```

The three invocations of the subroutine all operate in sync. The semaphore, though, makes sure that only one thread is accessing the global variable at once.

Advanced Semaphores

By default, semaphores behave like locks, letting only one thread down() them at a time. However, there are other uses for semaphores.

Each semaphore has a counter attached to it. down() decrements the counter and up() increments the counter. By default, semaphores are created with the counter set to one, down() decrements by one, and up() increments by one. If down() attempts to decrement the counter below zero, it blocks until the counter is large enough. Note that while a semaphore can be created with a starting count of zero, any up() or down() always changes the counter by at least one. $semaphore->down(0) is the same as $semaphore->down(1).

The question, of course, is why would you do something like this? Why create a semaphore with a starting count that's not one, or why decrement/increment it by more than one? The answer is resource availability. Many resources that you want to manage access for can be safely used by more than one thread at once.

For example, let's take a GUI driven program. It has a semaphore that it uses to synchronize access to the display, so only one thread is ever drawing at once. Handy, but of course you don't want any thread to start drawing until things are properly set up. In this case, you can create a semaphore with a counter set to zero, and up it when things are ready for drawing.

Semaphores with counters greater than one are also useful for establishing quotas. Say, for example, that you have a number of threads that can do I/O at once. You don't want all the threads reading or writing at once though, since that can potentially swamp your I/O channels, or deplete your process' quota of filehandles. You can use a semaphore initialized to the number of concurrent I/O requests (or open files) that you want at any one time, and have your threads quietly block and unblock themselves.

Larger increments or decrements are handy in those cases where a thread needs to check out or return a number of resources at once.

51.9.2 Attributes: Restricting Access To Subroutines

In addition to synchronizing access to data or resources, you might find it useful to synchronize access to subroutines. You may be accessing a singular machine resource (perhaps a vector processor), or find it easier to serialize calls to a particular subroutine than to have a set of locks and semaphores.

One of the additions to Perl 5.005 is subroutine attributes. The Thread package uses these to provide several flavors of serialization. It's important to remember that these attributes are used in the compilation phase of your program so you can't change a subroutine's behavior while your program is actually running.

51.9.3 Subroutine Locks

The basic subroutine lock looks like this:

```
    sub test_sub :locked {
    }
```

This ensures that only one thread will be executing this subroutine at any one time. Once a thread calls this subroutine, any other thread that calls it will block until the thread in the subroutine exits it. A more elaborate example looks like this:

```
    use Thread qw(yield);

    new Thread \&thread_sub, 1;
    new Thread \&thread_sub, 2;
    new Thread \&thread_sub, 3;
    new Thread \&thread_sub, 4;

    sub sync_sub :locked {
        my $CallingThread = shift @_;
        print "In sync_sub for thread $CallingThread\n";
        yield;
        sleep 3;
        print "Leaving sync_sub for thread $CallingThread\n";
    }

    sub thread_sub {
        my $ThreadID = shift @_;
        print "Thread $ThreadID calling sync_sub\n";
        sync_sub($ThreadID);
        print "$ThreadID is done with sync_sub\n";
    }
```

The `locked` attribute tells perl to lock sync_sub(), and if you run this, you can see that only one thread is in it at any one time.

51.9.4 Methods

Locking an entire subroutine can sometimes be overkill, especially when dealing with Perl objects. When calling a method for an object, for example, you want to serialize calls to a method, so that only one thread will be in the subroutine for a particular object, but threads calling that subroutine for a different object aren't blocked. The method attribute indicates whether the subroutine is really a method.

```
    use Thread;

    sub tester {
        my $thrnum = shift @_;
        my $bar = new Foo;
        foreach (1..10) {
            print "$thrnum calling per_object\n";
            $bar->per_object($thrnum);
            print "$thrnum out of per_object\n";
            yield;
            print "$thrnum calling one_at_a_time\n";
            $bar->one_at_a_time($thrnum);
            print "$thrnum out of one_at_a_time\n";
            yield;
        }
    }

    foreach my $thrnum (1..10) {
        new Thread \&tester, $thrnum;
    }

    package Foo;
    sub new {
        my $class = shift @_;
        return bless [@_], $class;
    }

    sub per_object :locked :method {
        my ($class, $thrnum) = @_;
        print "In per_object for thread $thrnum\n";
        yield;
        sleep 2;
        print "Exiting per_object for thread $thrnum\n";
    }

    sub one_at_a_time :locked {
        my ($class, $thrnum) = @_;
        print "In one_at_a_time for thread $thrnum\n";
        yield;
        sleep 2;
        print "Exiting one_at_a_time for thread $thrnum\n";
    }
```

As you can see from the output (omitted for brevity; it's 800 lines) all the threads can be in per_object() simultaneously, but only one thread is ever in one_at_a_time() at once.

51.9.5 Locking A Subroutine

You can lock a subroutine as you would lock a variable. Subroutine locks work the same as specifying a `locked` attribute for the subroutine, and block all access to the subroutine for other threads until the lock goes out of scope. When the subroutine isn't locked, any number of threads can be in it at once, and getting a lock on a subroutine doesn't affect threads already in the subroutine. Getting a lock on a subroutine looks like this:

```
    lock(\&sub_to_lock);
```

Simple enough. Unlike the `locked` attribute, which is a compile time option, locking and unlocking a subroutine can be done at runtime at your discretion. There is some runtime penalty to using lock(\&sub) instead of the `locked` attribute, so make sure you're choosing the proper method to do the locking.

You'd choose lock(\&sub) when writing modules and code to run on both threaded and unthreaded Perl, especially for code that will run on 5.004 or earlier Perls. In that case, it's useful to have subroutines that should be serialized lock themselves if they're running threaded, like so:

```
    package Foo;
    use Config;
    $Running_Threaded = 0;

    BEGIN { $Running_Threaded = $Config{'usethreads'} }

    sub sub1 { lock(\&sub1) if $Running_Threaded }
```

This way you can ensure single-threadedness regardless of which version of Perl you're running.

51.10 General Thread Utility Routines

We've covered the workhorse parts of Perl's threading package, and with these tools you should be well on your way to writing threaded code and packages. There are a few useful little pieces that didn't really fit in anyplace else.

51.10.1 What Thread Am I In?

The Thread->self method provides your program with a way to get an object representing the thread it's currently in. You can use this object in the same way as the ones returned from the thread creation.

51.10.2 Thread IDs

tid() is a thread object method that returns the thread ID of the thread the object represents. Thread IDs are integers, with the main thread in a program being 0. Currently Perl assigns a unique tid to every thread ever created in your program, assigning the first thread to be created a tid of 1, and increasing the tid by 1 for each new thread that's created.

51.10.3 Are These Threads The Same?

The equal() method takes two thread objects and returns true if the objects represent the same thread, and false if they don't.

51.10.4 What Threads Are Running?

Thread->list returns a list of thread objects, one for each thread that's currently running. Handy for a number of things, including cleaning up at the end of your program:

```
# Loop through all the threads
foreach $thr (Thread->list) {
    # Don't join the main thread or ourselves
    if ($thr->tid && !Thread::equal($thr, Thread->self)) {
        $thr->join;
    }
}
```

The example above is just for illustration. It isn't strictly necessary to join all the threads you create, since Perl detaches all the threads before it exits.

51.11 A Complete Example

Confused yet? It's time for an example program to show some of the things we've covered. This program finds prime numbers using threads.

```
#!/usr/bin/perl -w
# prime-pthread, courtesy of Tom Christiansen

use strict;

use Thread;
use Thread::Queue;

my $stream = new Thread::Queue;
my $kid    = new Thread(\&check_num, $stream, 2);

for my $i ( 3 .. 1000 ) {
    $stream->enqueue($i);
}

$stream->enqueue(undef);
$kid->join();

sub check_num {
    my ($upstream, $cur_prime) = @_;
    my $kid;
    my $downstream = new Thread::Queue;
    while (my $num = $upstream->dequeue) {
        next unless $num % $cur_prime;
        if ($kid) {
           $downstream->enqueue($num);
                 } else {
           print "Found prime $num\n";
               $kid = new Thread(\&check_num, $downstream, $num);
        }
    }
    $downstream->enqueue(undef) if $kid;
    $kid->join()         if $kid;
}
```

This program uses the pipeline model to generate prime numbers. Each thread in the pipeline has an input queue that feeds numbers to be checked, a prime number that it's responsible for, and an output queue that it funnels numbers that have failed the check into. If the thread has a number that's failed its check and there's no child thread, then the thread must have found a new prime number. In that case, a new child thread is created for that prime and stuck on the end of the pipeline.

This probably sounds a bit more confusing than it really is, so lets go through this program piece by piece and see what it does. (For those of you who might be trying to remember exactly what a prime number is, it's a number that's only evenly divisible by itself and 1)

The bulk of the work is done by the check_num() subroutine, which takes a reference to its input queue and a prime number that it's responsible for. After pulling in the input queue and the prime that the subroutine's checking (line 20), we create a new queue (line 22) and reserve a scalar for the thread that we're likely to create later (line 21).

The while loop from lines 23 to line 31 grabs a scalar off the input queue and checks against the prime this thread is responsible for. Line 24 checks to see if there's a remainder when we modulo the number to be checked against our prime. If there is one, the number must not be evenly divisible by our prime, so we need to either pass it on to the next thread if we've created one (line 26) or create a new thread if we haven't.

The new thread creation is line 29. We pass on to it a reference to the queue we've created, and the prime number we've found.

Finally, once the loop terminates (because we got a 0 or undef in the queue, which serves as a note to die), we pass on the notice to our child and wait for it to exit if we've created a child (Lines 32 and 37).

Meanwhile, back in the main thread, we create a queue (line 9) and the initial child thread (line 10), and pre-seed it with the first prime: 2. Then we queue all the numbers from 3 to 1000 for checking (lines 12-14), then queue a die notice (line 16) and wait for the first child thread to terminate (line 17). Because a child won't die until its child has died, we know that we're done once we return from the join.

That's how it works. It's pretty simple; as with many Perl programs, the explanation is much longer than the program.

51.12 Conclusion

A complete thread tutorial could fill a book (and has, many times), but this should get you well on your way. The final authority on how Perl's threads behave is the documentation bundled with the Perl distribution, but with what we've covered in this article, you should be well on your way to becoming a threaded Perl expert.

51.13 Bibliography

Here's a short bibliography courtesy of Jürgen Christoffel:

Chapter 52

perlport

Writing portable Perl

52.1 DESCRIPTION

Perl runs on numerous operating systems. While most of them share much in common, they also have their own unique features.

This document is meant to help you to find out what constitutes portable Perl code. That way once you make a decision to write portably, you know where the lines are drawn, and you can stay within them.

There is a tradeoff between taking full advantage of one particular type of computer and taking advantage of a full range of them. Naturally, as you broaden your range and become more diverse, the common factors drop, and you are left with an increasingly smaller area of common ground in which you can operate to accomplish a particular task. Thus, when you begin attacking a problem, it is important to consider under which part of the tradeoff curve you want to operate. Specifically, you must decide whether it is important that the task that you are coding have the full generality of being portable, or whether to just get the job done right now. This is the hardest choice to be made. The rest is easy, because Perl provides many choices, whichever way you want to approach your problem.

Looking at it another way, writing portable code is usually about willfully limiting your available choices. Naturally, it takes discipline and sacrifice to do that. The product of portability and convenience may be a constant. You have been warned.

Be aware of two important points:

Not all Perl programs have to be portable

There is no reason you should not use Perl as a language to glue Unix tools together, or to prototype a Macintosh application, or to manage the Windows registry. If it makes no sense to aim for portability for one reason or another in a given program, then don't bother.

Nearly all of Perl already *is* portable

Don't be fooled into thinking that it is hard to create portable Perl code. It isn't. Perl tries its level-best to bridge the gaps between what's available on different platforms, and all the means available to use those features. Thus almost all Perl code runs on any machine without modification. But there are some significant issues in writing portable code, and this document is entirely about those issues.

Here's the general rule: When you approach a task commonly done using a whole range of platforms, think about writing portable code. That way, you don't sacrifice much by way of the implementation choices you can avail yourself of, and at the same time you can give your users lots of platform choices. On the other hand, when you have to take advantage of some unique feature of a particular platform, as is often the case with systems programming (whether for Unix, Windows, Mac OS, VMS, etc.), consider writing platform-specific code.

When the code will run on only two or three operating systems, you may need to consider only the differences of those particular systems. The important thing is to decide where the code will run and to be deliberate in your decision.

The material below is separated into three main sections: main issues of portability (§52.2, platform-specific issues (§52.4, and built-in perl functions that behave differently on various ports (§52.5.

This information should not be considered complete; it includes possibly transient information about idiosyncrasies of some of the ports, almost all of which are in a state of constant evolution. Thus, this material should be considered a perpetual work in progress (`<IMG SRC="yellow_sign.gif" ALT="Under Construction">`).

52.2 ISSUES

52.2.1 Newlines

In most operating systems, lines in files are terminated by newlines. Just what is used as a newline may vary from OS to OS. Unix traditionally uses `\012`, one type of DOSish I/O uses `\015\012`, and Mac OS uses `\015`.

Perl uses `\n` to represent the "logical" newline, where what is logical may depend on the platform in use. In MacPerl, `\n` always means `\015`. In DOSish perls, `\n` usually means `\012`, but when accessing a file in "text" mode, STDIO translates it to (or from) `\015\012`, depending on whether you're reading or writing. Unix does the same thing on ttys in canonical mode. `\015\012` is commonly referred to as CRLF.

A common cause of unportable programs is the misuse of chop() to trim newlines:

```
# XXX UNPORTABLE!
while(<FILE>) {
    chop;
    @array = split(/:/);
    #...
}
```

You can get away with this on Unix and Mac OS (they have a single character end-of-line), but the same program will break under DOSish perls because you're only chop()ing half the end-of-line. Instead, chomp() should be used to trim newlines. The Dunce::Files module can help audit your code for misuses of chop().

When dealing with binary files (or text files in binary mode) be sure to explicitly set $/ to the appropriate value for your file format before using chomp().

Because of the "text" mode translation, DOSish perls have limitations in using `seek` and `tell` on a file accessed in "text" mode. Stick to `seek`-ing to locations you got from `tell` (and no others), and you are usually free to use `seek` and `tell` even in "text" mode. Using `seek` or `tell` or other file operations may be non-portable. If you use `binmode` on a file, however, you can usually `seek` and `tell` with arbitrary values in safety.

A common misconception in socket programming is that `\n` eq `\012` everywhere. When using protocols such as common Internet protocols, `\012` and `\015` are called for specifically, and the values of the logical `\n` and `\r` (carriage return) are not reliable.

```
print SOCKET "Hi there, client!\r\n";      # WRONG
print SOCKET "Hi there, client!\015\012";  # RIGHT
```

However, using `\015\012` (or `\cM\cJ`, or `\x0D\x0A`) can be tedious and unsightly, as well as confusing to those maintaining the code. As such, the Socket module supplies the Right Thing for those who want it.

```
use Socket qw(:DEFAULT :crlf);
print SOCKET "Hi there, client!$CRLF"      # RIGHT
```

When reading from a socket, remember that the default input record separator `$/` is `\n`, but robust socket code will recognize as either `\012` or `\015\012` as end of line:

```
while (<SOCKET>) {
    # ...
}
```

Because both CRLF and LF end in LF, the input record separator can be set to LF and any CR stripped later. Better to write:

```
use Socket qw(:DEFAULT :crlf);
local($/) = LF;      # not needed if $/ is already \012

while (<SOCKET>) {
    s/$CR?$LF/\n/;   # not sure if socket uses LF or CRLF, OK
#   s/\015?\012/\n/; # same thing
}
```

This example is preferred over the previous one–even for Unix platforms–because now any \015's (\cM's) are stripped out (and there was much rejoicing).

Similarly, functions that return text data–such as a function that fetches a web page–should sometimes translate newlines before returning the data, if they've not yet been translated to the local newline representation. A single line of code will often suffice:

```
$data =~ s/\015?\012/\n/g;
return $data;
```

Some of this may be confusing. Here's a handy reference to the ASCII CR and LF characters. You can print it out and stick it in your wallet.

```
LF  eq  \012  eq  \x0A  eq  \cJ  eq  chr(10)  eq  ASCII 10
CR  eq  \015  eq  \x0D  eq  \cM  eq  chr(13)  eq  ASCII 13

        | Unix | DOS  | Mac  |
    ---------------------------
    \n   |  LF  |  LF  |  CR  |
    \r   |  CR  |  CR  |  LF  |
    \n * |  LF  | CRLF |  CR  |
    \r * |  CR  |  CR  |  LF  |
    ---------------------------
    * text-mode STDIO
```

The Unix column assumes that you are not accessing a serial line (like a tty) in canonical mode. If you are, then CR on input becomes "\n", and "\n" on output becomes CRLF.

These are just the most common definitions of \n and \r in Perl. There may well be others. For example, on an EBCDIC implementation such as z/OS (OS/390) or OS/400 (using the ILE, the PASE is ASCII-based) the above material is similar to "Unix" but the code numbers change:

```
LF  eq  \025  eq  \x15  eq  \cU  eq  chr(21)  eq  CP-1047 21
LF  eq  \045  eq  \x25  eq           chr(37)  eq  CP-0037 37
CR  eq  \015  eq  \x0D  eq  \cM  eq  chr(13)  eq  CP-1047 13

```

52.2.2 Numbers endianness and Width

Different CPUs store integers and floating point numbers in different orders (called *endianness*) and widths (32-bit and 64-bit being the most common today). This affects your programs when they attempt to transfer numbers in binary format from one CPU architecture to another, usually either "live" via network connection, or by storing the numbers to secondary storage such as a disk file or tape.

Conflicting storage orders make utter mess out of the numbers. If a little-endian host (Intel, VAX) stores 0x12345678 (305419896 in decimal), a big-endian host (Motorola, Sparc, PA) reads it as 0x78563412 (2018915346 in decimal). Alpha and MIPS can be either: Digital/Compaq used/uses them in little-endian mode; SGI/Cray uses them in big-endian mode. To avoid this problem in network (socket) connections use the `pack` and `unpack` formats `n` and `N`, the "network" orders. These are guaranteed to be portable.

You can explore the endianness of your platform by unpacking a data structure packed in native format such as:

```
print unpack("h*", pack("s2", 1, 2)), "\n";
# '10002000' on e.g. Intel x86 or Alpha 21064 in little-endian mode
# '00100020' on e.g. Motorola 68040
```

If you need to distinguish between endian architectures you could use either of the variables set like so:

```
$is_big_endian   = unpack("h*", pack("s", 1)) =~ /01/;
$is_little_endian = unpack("h*", pack("s", 1)) =~ /^1/;
```

Differing widths can cause truncation even between platforms of equal endianness. The platform of shorter width loses the upper parts of the number. There is no good solution for this problem except to avoid transferring or storing raw binary numbers.

One can circumnavigate both these problems in two ways. Either transfer and store numbers always in text format, instead of raw binary, or else consider using modules like Data::Dumper (included in the standard distribution as of Perl 5.005) and Storable (included as of perl 5.8). Keeping all data as text significantly simplifies matters.

The v-strings are portable only up to v2147483647 (0x7FFFFFFF), that's how far EBCDIC, or more precisely UTF-EBCDIC will go.

52.2.3 Files and Filesystems

Most platforms these days structure files in a hierarchical fashion. So, it is reasonably safe to assume that all platforms support the notion of a "path" to uniquely identify a file on the system. How that path is really written, though, differs considerably.

Although similar, file path specifications differ between Unix, Windows, Mac OS, OS/2, VMS, VOS, RISC OS, and probably others. Unix, for example, is one of the few OSes that has the elegant idea of a single root directory.

DOS, OS/2, VMS, VOS, and Windows can work similarly to Unix with `/` as path separator, or in their own idiosyncratic ways (such as having several root directories and various "unrooted" device files such NIL: and LPT:).

Mac OS uses `:` as a path separator instead of `/`.

The filesystem may support neither hard links (`link`) nor symbolic links (`symlink`, `readlink`, `lstat`).

The filesystem may support neither access timestamp nor change timestamp (meaning that about the only portable timestamp is the modification timestamp), or one second granularity of any timestamps (e.g. the FAT filesystem limits the time granularity to two seconds).

The "inode change timestamp" (the `-C` filetest) may really be the "creation timestamp" (which it is not in UNIX).

VOS perl can emulate Unix filenames with `/` as path separator. The native pathname characters greater-than, less-than, number-sign, and percent-sign are always accepted.

RISC OS perl can emulate Unix filenames with `/` as path separator, or go native and use `.` for path separator and `:` to signal filesystems and disk names.

Don't assume UNIX filesystem access semantics: that read, write, and execute are all the permissions there are, and even if they exist, that their semantics (for example what do r, w, and x mean on a directory) are the UNIX ones. The various UNIX/POSIX compatibility layers usually try to make interfaces like chmod() work, but sometimes there simply is no good mapping.

If all this is intimidating, have no (well, maybe only a little) fear. There are modules that can help. The File::Spec modules provide methods to do the Right Thing on whatever platform happens to be running the program.

```
    use File::Spec::Functions;
    chdir(updir());        # go up one directory
    $file = catfile(curdir(), 'temp', 'file.txt');
    # on Unix and Win32, './temp/file.txt'
    # on Mac OS, ':temp:file.txt'
    # on VMS, '[.temp]file.txt'
```

File::Spec is available in the standard distribution as of version 5.004_05. File::Spec::Functions is only in File::Spec 0.7 and later, and some versions of perl come with version 0.6. If File::Spec is not updated to 0.7 or later, you must use the object-oriented interface from File::Spec (or upgrade File::Spec).

In general, production code should not have file paths hardcoded. Making them user-supplied or read from a configuration file is better, keeping in mind that file path syntax varies on different machines.

This is especially noticeable in scripts like Makefiles and test suites, which often assume `/` as a path separator for subdirectories.

Also of use is File::Basename from the standard distribution, which splits a pathname into pieces (base filename, full path to directory, and file suffix).

Even when on a single platform (if you can call Unix a single platform), remember not to count on the existence or the contents of particular system-specific files or directories, like */etc/passwd*, */etc/sendmail.conf*, */etc/resolv.conf*, or even */tmp/*. For example, */etc/passwd* may exist but not contain the encrypted passwords, because the system is using some form of enhanced security. Or it may not contain all the accounts, because the system is using NIS. If code does need to rely on such a file, include a description of the file and its format in the code's documentation, then make it easy for the user to override the default location of the file.

Don't assume a text file will end with a newline. They should, but people forget.

Do not have two files or directories of the same name with different case, like *test.pl* and *Test.pl*, as many platforms have case-insensitive (or at least case-forgiving) filenames. Also, try not to have non-word characters (except for `.`) in the names, and keep them to the 8.3 convention, for maximum portability, onerous a burden though this may appear.

Likewise, when using the AutoSplit module, try to keep your functions to 8.3 naming and case-insensitive conventions; or, at the least, make it so the resulting files have a unique (case-insensitively) first 8 characters.

Whitespace in filenames is tolerated on most systems, but not all, and even on systems where it might be tolerated, some utilities might become confused by such whitespace.

Many systems (DOS, VMS) cannot have more than one `.` in their filenames.

Don't assume > won't be the first character of a filename. Always use < explicitly to open a file for reading, or even better, use the three-arg version of open, unless you want the user to be able to specify a pipe open.

```
    open(FILE, '<', $existing_file) or die $!;
```

If filenames might use strange characters, it is safest to open it with `sysopen` instead of `open`. `open` is magic and can translate characters like >, <, and |, which may be the wrong thing to do. (Sometimes, though, it's the right thing.) Three-arg open can also help protect against this translation in cases where it is undesirable.

Don't use `:` as a part of a filename since many systems use that for their own semantics (Mac OS Classic for separating pathname components, many networking schemes and utilities for separating the nodename and the pathname, and so on). For the same reasons, avoid `@`, `;` and |.

Don't assume that in pathnames you can collapse two leading slashes `//` into one: some networking and clustering filesystems have special semantics for that. Let the operating system to sort it out.

The *portable filename characters* as defined by ANSI C are

```
 a b c d e f g h i j k l m n o p q r t u v w x y z
 A B C D E F G H I J K L M N O P Q R T U V W X Y Z
 0 1 2 3 4 5 6 7 8 9
 . _ -
```

and the "-" shouldn't be the first character. If you want to be hypercorrect, stay case-insensitive and within the 8.3 naming convention (all the files and directories have to be unique within one directory if their names are lowercased and truncated to eight characters before the `.`, if any, and to three characters after the `.`, if any). (And do not use `.`s in directory names.)

52.2.4 System Interaction

Not all platforms provide a command line. These are usually platforms that rely primarily on a Graphical User Interface (GUI) for user interaction. A program requiring a command line interface might not work everywhere. This is probably for the user of the program to deal with, so don’t stay up late worrying about it.

Some platforms can’t delete or rename files held open by the system, this limitation may also apply to changing filesystem metainformation like file permissions or owners. Remember to `close` files when you are done with them. Don’t `unlink` or `rename` an open file. Don’t `tie` or `open` a file already tied or opened; `untie` or `close` it first.

Don’t open the same file more than once at a time for writing, as some operating systems put mandatory locks on such files.

Don’t assume that write/modify permission on a directory gives the right to add or delete files/directories in that directory. That is filesystem specific: in some filesystems you need write/modify permission also (or even just) in the file/directory itself. In some filesystems (AFS, DFS) the permission to add/delete directory entries is a completely separate permission.

Don’t assume that a single `unlink` completely gets rid of the file: some filesystems (most notably the ones in VMS) have versioned filesystems, and unlink() removes only the most recent one (it doesn’t remove all the versions because by default the native tools on those platforms remove just the most recent version, too). The portable idiom to remove all the versions of a file is

```
    1 while unlink "file";
```

This will terminate if the file is undeleteable for some reason (protected, not there, and so on).

Don’t count on a specific environment variable existing in `%ENV`. Don’t count on `%ENV` entries being case-sensitive, or even case-preserving. Don’t try to clear %ENV by saying `%ENV = ();`, or, if you really have to, make it conditional on `$^O ne 'VMS'` since in VMS the `%ENV` table is much more than a per-process key-value string table.

Don’t count on signals or `%SIG` for anything.

Don’t count on filename globbing. Use `opendir`, `readdir`, and `closedir` instead.

Don’t count on per-program environment variables, or per-program current directories.

Don’t count on specific values of `$!`, neither numeric nor especially the strings values– users may switch their locales causing error messages to be translated into their languages. If you can trust a POSIXish environment, you can portably use the symbols defined by the Errno module, like ENOENT. And don’t trust on the values of `$!` at all except immediately after a failed system call.

52.2.5 Command names versus file pathnames

Don’t assume that the name used to invoke a command or program with `system` or `exec` can also be used to test for the existence of the file that holds the executable code for that command or program. First, many systems have "internal" commands that are built-in to the shell or OS and while these commands can be invoked, there is no corresponding file. Second, some operating systems (e.g., Cygwin, DJGPP, OS/2, and VOS) have required suffixes for executable files; these suffixes are generally permitted on the command name but are not required. Thus, a command like "perl" might exist in a file named "perl", "perl.exe", or "perl.pm", depending on the operating system. The variable "_exe" in the Config module holds the executable suffix, if any. Third, the VMS port carefully sets up $^X and $Config{perlpath} so that no further processing is required. This is just as well, because the matching regular expression used below would then have to deal with a possible trailing version number in the VMS file name.

To convert $^X to a file pathname, taking account of the requirements of the various operating system possibilities, say: use Config; $thisperl = $^X; if ($^O ne ’VMS’) {$thisperl .= $Config{_exe} unless $thisperl =~ m/$Config{_exe}$/i;}

To convert $Config{perlpath} to a file pathname, say: use Config; $thisperl = $Config{perlpath}; if ($^O ne ’VMS’) {$thisperl .= $Config{_exe} unless $thisperl =~ m/$Config{_exe}$/i;}

52.2.6 Networking

Don’t assume that you can reach the public Internet.

Don’t assume that there is only one way to get through firewalls to the public Internet.

Don’t assume that you can reach outside world through any other port than 80, or some web proxy. ftp is blocked by many firewalls.

Don’t assume that you can send email by connecting to the local SMTP port.

Don’t assume that you can reach yourself or any node by the name ’localhost’. The same goes for ’127.0.0.1’. You will have to try both.

Don’t assume that the host has only one network card, or that it can’t bind to many virtual IP addresses.

Don’t assume a particular network device name.

Don’t assume a particular set of ioctl()s will work.

Don’t assume that you can ping hosts and get replies.

Don’t assume that any particular port (service) will respond.

Don’t assume that Sys::Hostname() (or any other API or command) returns either a fully qualified hostname or a non-qualified hostname: it all depends on how the system had been configured. Also remember things like DHCP and NAT– the hostname you get back might not be very useful.

All the above "don’t":s may look daunting, and they are – but the key is to degrade gracefully if one cannot reach the particular network service one wants. Croaking or hanging do not look very professional.

52.2.7 Interprocess Communication (IPC)

In general, don’t directly access the system in code meant to be portable. That means, no `system`, `exec`, `fork`, `pipe`, “, `qx//`, `open` with a |, nor any of the other things that makes being a perl hacker worth being.

Commands that launch external processes are generally supported on most platforms (though many of them do not support any type of forking). The problem with using them arises from what you invoke them on. External tools are often named differently on different platforms, may not be available in the same location, might accept different arguments, can behave differently, and often present their results in a platform-dependent way. Thus, you should seldom depend on them to produce consistent results. (Then again, if you’re calling *netstat -a*, you probably don’t expect it to run on both Unix and CP/M.)

One especially common bit of Perl code is opening a pipe to **sendmail**:

```
    open(MAIL, '|/usr/lib/sendmail -t')
        or die "cannot fork sendmail: $!";
```

This is fine for systems programming when sendmail is known to be available. But it is not fine for many non-Unix systems, and even some Unix systems that may not have sendmail installed. If a portable solution is needed, see the various distributions on CPAN that deal with it. Mail::Mailer and Mail::Send in the MailTools distribution are commonly used, and provide several mailing methods, including mail, sendmail, and direct SMTP (via Net::SMTP) if a mail transfer agent is not available. Mail::Sendmail is a standalone module that provides simple, platform-independent mailing.

The Unix System V IPC (`msg*(), sem*(), shm*()`) is not available even on all Unix platforms.

Do not use either the bare result of `pack("N", 10, 20, 30, 40)` or bare v-strings (such as `v10.20.30.40`) to represent IPv4 addresses: both forms just pack the four bytes into network order. That this would be equal to the C language `in_addr` struct (which is what the socket code internally uses) is not guaranteed. To be portable use the routines of the Socket extension, such as `inet_aton()`, `inet_ntoa()`, and `sockaddr_in()`.

The rule of thumb for portable code is: Do it all in portable Perl, or use a module (that may internally implement it with platform-specific code, but expose a common interface).

52.2.8 External Subroutines (XS)

XS code can usually be made to work with any platform, but dependent libraries, header files, etc., might not be readily available or portable, or the XS code itself might be platform-specific, just as Perl code might be. If the libraries and headers are portable, then it is normally reasonable to make sure the XS code is portable, too.

A different type of portability issue arises when writing XS code: availability of a C compiler on the end-user's system. C brings with it its own portability issues, and writing XS code will expose you to some of those. Writing purely in Perl is an easier way to achieve portability.

52.2.9 Standard Modules

In general, the standard modules work across platforms. Notable exceptions are the CPAN module (which currently makes connections to external programs that may not be available), platform-specific modules (like ExtUtils::MM_VMS), and DBM modules.

There is no one DBM module available on all platforms. SDBM_File and the others are generally available on all Unix and DOSish ports, but not in MacPerl, where only NBDM_File and DB_File are available.

The good news is that at least some DBM module should be available, and AnyDBM_File will use whichever module it can find. Of course, then the code needs to be fairly strict, dropping to the greatest common factor (e.g., not exceeding 1K for each record), so that it will work with any DBM module. See AnyDBM_File for more details.

52.2.10 Time and Date

The system's notion of time of day and calendar date is controlled in widely different ways. Don't assume the timezone is stored in `$ENV{TZ}`, and even if it is, don't assume that you can control the timezone through that variable. Don't assume anything about the three-letter timezone abbreviations (for example that MST would be the Mountain Standard Time, it's been known to stand for Moscow Standard Time). If you need to use timezones, express them in some unambiguous format like the exact number of minutes offset from UTC, or the POSIX timezone format.

Don't assume that the epoch starts at 00:00:00, January 1, 1970, because that is OS- and implementation-specific. It is better to store a date in an unambiguous representation. The ISO 8601 standard defines YYYY-MM-DD as the date format, or YYYY-MM-DDTHH-MM-SS (that's a literal "T" separating the date from the time). Please do use the ISO 8601 instead of making us to guess what date 02/03/04 might be. ISO 8601 even sorts nicely as-is. A text representation (like "1987-12-18") can be easily converted into an OS-specific value using a module like Date::Parse. An array of values, such as those returned by `localtime`, can be converted to an OS-specific representation using Time::Local.

When calculating specific times, such as for tests in time or date modules, it may be appropriate to calculate an offset for the epoch.

```
    require Time::Local;
    $offset = Time::Local::timegm(0, 0, 0, 1, 0, 70);
```

The value for `$offset` in Unix will be `0`, but in Mac OS will be some large number. `$offset` can then be added to a Unix time value to get what should be the proper value on any system.

On Windows (at least), you shouldn't pass a negative value to `gmtime` or `localtime`.

52.2.11 Character sets and character encoding

Assume very little about character sets.

Assume nothing about numerical values (`ord`, `chr`) of characters. Do not use explicit code point ranges (like \xHH-\xHH); use for example symbolic character classes like `[:print:]`.

Do not assume that the alphabetic characters are encoded contiguously (in the numeric sense). There may be gaps.

Do not assume anything about the ordering of the characters. The lowercase letters may come before or after the uppercase letters; the lowercase and uppercase may be interlaced so that both 'a' and 'A' come before 'b'; the accented and other international characters may be interlaced so that ä comes before 'b'.

52.2.12 Internationalisation

If you may assume POSIX (a rather large assumption), you may read more about the POSIX locale system from *perllocale*. The locale system at least attempts to make things a little bit more portable, or at least more convenient and native-friendly for non-English users. The system affects character sets and encoding, and date and time formatting–amongst other things.

If you really want to be international, you should consider Unicode. See *perluniintro* and *perlunicode* for more information.

If you want to use non-ASCII bytes (outside the bytes 0x00..0x7f) in the "source code" of your code, to be portable you have to be explicit about what bytes they are. Someone might for example be using your code under a UTF-8 locale, in which case random native bytes might be illegal ("Malformed UTF-8 ...") This means that for example embedding ISO 8859-1 bytes beyond 0x7f into your strings might cause trouble later. If the bytes are native 8-bit bytes, you can use the `bytes` pragma. If the bytes are in a string (regular expression being a curious string), you can often also use the `\xHH` notation instead of embedding the bytes as-is. If they are in some particular legacy encoding (ether single-byte or something more complicated), you can use the `encoding` pragma. (If you want to write your code in UTF-8, you can use either the `utf8` pragma, or the `encoding` pragma.) The `bytes` and `utf8` pragmata are available since Perl 5.6.0, and the `encoding` pragma since Perl 5.8.0.

52.2.13 System Resources

If your code is destined for systems with severely constrained (or missing!) virtual memory systems then you want to be *especially* mindful of avoiding wasteful constructs such as:

```
    # NOTE: this is no longer "bad" in perl5.005
    for (0..10000000) {}                       # bad
    for (my $x = 0; $x <= 10000000; ++$x) {}   # good

    @lines = <VERY_LARGE_FILE>;                # bad

    while (<FILE>) {$file .= $_}               # sometimes bad
    $file = join('', <FILE>);                  # better
```

The last two constructs may appear unintuitive to most people. The first repeatedly grows a string, whereas the second allocates a large chunk of memory in one go. On some systems, the second is more efficient that the first.

52.2.14 Security

Most multi-user platforms provide basic levels of security, usually implemented at the filesystem level. Some, however, do not– unfortunately. Thus the notion of user id, or "home" directory, or even the state of being logged-in, may be unrecognizable on many platforms. If you write programs that are security-conscious, it is usually best to know what type of system you will be running under so that you can write code explicitly for that platform (or class of platforms).

Don't assume the UNIX filesystem access semantics: the operating system or the filesystem may be using some ACL systems, which are richer languages than the usual rwx. Even if the rwx exist, their semantics might be different.

(From security viewpoint testing for permissions before attempting to do something is silly anyway: if one tries this, there is potential for race conditions– someone or something might change the permissions between the permissions check and the actual operation. Just try the operation.)

Don't assume the UNIX user and group semantics: especially, don't expect the `$<` and `$>` (or the `$(` and `$)`) to work for switching identities (or memberships).

Don't assume set-uid and set-gid semantics. (And even if you do, think twice: set-uid and set-gid are a known can of security worms.)

52.2.15 Style

For those times when it is necessary to have platform-specific code, consider keeping the platform-specific code in one place, making porting to other platforms easier. Use the Config module and the special variable `$^O` to differentiate platforms, as described in §52.4.

Be careful in the tests you supply with your module or programs. Module code may be fully portable, but its tests might not be. This often happens when tests spawn off other processes or call external programs to aid in the testing, or when (as noted above) the tests assume certain things about the filesystem and paths. Be careful not to depend on a specific output style for errors, such as when checking `$!` after a failed system call. Using `$!` for anything else than displaying it as output is doubtful (though see the Errno module for testing reasonably portably for error value). Some platforms expect a certain output format, and Perl on those platforms may have been adjusted accordingly. Most specifically, don't anchor a regex when testing an error value.

52.3 CPAN Testers

Modules uploaded to CPAN are tested by a variety of volunteers on different platforms. These CPAN testers are notified by mail of each new upload, and reply to the list with PASS, FAIL, NA (not applicable to this platform), or UNKNOWN (unknown), along with any relevant notations.

The purpose of the testing is twofold: one, to help developers fix any problems in their code that crop up because of lack of testing on other platforms; two, to provide users with information about whether a given module works on a given platform.

Mailing list: cpan-testers@perl.org

Testing results: http://testers.cpan.org/

52.4 PLATFORMS

As of version 5.002, Perl is built with a `$^O` variable that indicates the operating system it was built on. This was implemented to help speed up code that would otherwise have to `use Config` and use the value of `$Config{osname}`. Of course, to get more detailed information about the system, looking into `%Config` is certainly recommended.

`%Config` cannot always be trusted, however, because it was built at compile time. If perl was built in one place, then transferred elsewhere, some values may be wrong. The values may even have been edited after the fact.

52.4.1 Unix

Perl works on a bewildering variety of Unix and Unix-like platforms (see e.g. most of the files in the *hints/* directory in the source code kit). On most of these systems, the value of `$^O` (hence `$Config{'osname'}`, too) is determined either by lowercasing and stripping punctuation from the first field of the string returned by typing `uname -a` (or a similar command) at the shell prompt or by testing the file system for the presence of uniquely named files such as a kernel or header file. Here, for example, are a few of the more popular Unix flavors:

```
    uname         $^O        $Config{'archname'}
    --------------------------------------------
    AIX           aix        aix
    BSD/OS        bsdos      i386-bsdos
    Darwin        darwin     darwin
    dgux          dgux       AViiON-dgux
    DYNIX/ptx     dynixptx   i386-dynixptx
    FreeBSD       freebsd    freebsd-i386
    Linux         linux      arm-linux
    Linux         linux      i386-linux
    Linux         linux      i586-linux
    Linux         linux      ppc-linux
    HP-UX         hpux       PA-RISC1.1
    IRIX          irix       irix
    Mac OS X      darwin     darwin
    MachTen PPC   machten    powerpc-machten
    NeXT 3        next       next-fat
    NeXT 4        next       OPENSTEP-Mach
    openbsd       openbsd    i386-openbsd
    OSF1          dec_osf    alpha-dec_osf
    reliantunix-n svr4       RM400-svr4
    SCO_SV        sco_sv     i386-sco_sv
    SINIX-N       svr4       RM400-svr4
    sn4609        unicos     CRAY_C90-unicos
    sn6521        unicosmk   t3e-unicosmk
    sn9617        unicos     CRAY_J90-unicos
    SunOS         solaris    sun4-solaris
    SunOS         solaris    i86pc-solaris
    SunOS4        sunos      sun4-sunos
```

Because the value of `$Config{archname}` may depend on the hardware architecture, it can vary more than the value of `$^O`.

52.4.2 DOS and Derivatives

Perl has long been ported to Intel-style microcomputers running under systems like PC-DOS, MS-DOS, OS/2, and most Windows platforms you can bring yourself to mention (except for Windows CE, if you count that). Users familiar with *COMMAND.COM* or *CMD.EXE* style shells should be aware that each of these file specifications may have subtle differences:

```
    $filespec0 = "c:/foo/bar/file.txt";
    $filespec1 = "c:\\foo\\bar\\file.txt";
    $filespec2 = 'c:\foo\bar\file.txt';
    $filespec3 = 'c:\\foo\\bar\\file.txt';
```

System calls accept either `/` or `\` as the path separator. However, many command-line utilities of DOS vintage treat `/` as the option prefix, so may get confused by filenames containing `/`. Aside from calling any external programs, `/` will work just fine, and probably better, as it is more consistent with popular usage, and avoids the problem of remembering what to backwhack and what not to.

The DOS FAT filesystem can accommodate only "8.3" style filenames. Under the "case-insensitive, but case-preserving" HPFS (OS/2) and NTFS (NT) filesystems you may have to be careful about case returned with functions like `readdir` or used with functions like `open` or `opendir`.

DOS also treats several filenames as special, such as AUX, PRN, NUL, CON, COM1, LPT1, LPT2, etc. Unfortunately, sometimes these filenames won't even work if you include an explicit directory prefix. It is best to avoid such filenames, if you want your code to be portable to DOS and its derivatives. It's hard to know what these all are, unfortunately.

Users of these operating systems may also wish to make use of scripts such as *pl2bat.bat* or *pl2cmd* to put wrappers around your scripts.

Newline (`\n`) is translated as `\015\012` by STDIO when reading from and writing to files (see §52.2.1). `binmode(FILEHANDLE)` will keep `\n` translated as `\012` for that filehandle. Since it is a no-op on other systems, `binmode` should be used for cross-platform code that deals with binary data. That's assuming you realize in advance that your data is in binary. General-purpose programs should often assume nothing about their data.

The `$^O` variable and the `$Config{archname}` values for various DOSish perls are as follows:

```
OS            $^O       $Config{archname}   ID    Version
--------------------------------------------------------
MS-DOS        dos        ?
PC-DOS        dos        ?
OS/2          os2        ?
Windows 3.1   ?          ?                  0      3 01
Windows 95    MSWin32    MSWin32-x86        1      4 00
Windows 98    MSWin32    MSWin32-x86        1      4 10
Windows ME    MSWin32    MSWin32-x86        1      ?
Windows NT    MSWin32    MSWin32-x86        2      4 xx
Windows NT    MSWin32    MSWin32-ALPHA      2      4 xx
Windows NT    MSWin32    MSWin32-ppc        2      4 xx
Windows 2000  MSWin32    MSWin32-x86        2      5 xx
Windows XP    MSWin32    MSWin32-x86        2      ?
Windows CE    MSWin32    ?                  3
Cygwin        cygwin     ?
```

The various MSWin32 Perl's can distinguish the OS they are running on via the value of the fifth element of the list returned from Win32::GetOSVersion(). For example:

```
if ($^O eq 'MSWin32') {
    my @os_version_info = Win32::GetOSVersion();
    print +('3.1','95','NT')[$os_version_info[4]],"\n";
}
```

There are also Win32::IsWinNT() and Win32::IsWin95(), try `perldoc Win32`, and as of libwin32 0.19 (not part of the core Perl distribution) Win32::GetOSName(). The very portable POSIX::uname() will work too:

```
c:\> perl -MPOSIX -we "print join '|', uname"
Windows NT|moonru|5.0|Build 2195 (Service Pack 2)|x86
```

52.4.3 Mac OS

Any module requiring XS compilation is right out for most people, because MacPerl is built using non-free (and non-cheap!) compilers. Some XS modules that can work with MacPerl are built and distributed in binary form on CPAN.

Directories are specified as:

```
    volume:folder:file              for absolute pathnames
    volume:folder:                  for absolute pathnames
    :folder:file                    for relative pathnames
    :folder:                        for relative pathnames
    :file                           for relative pathnames
    file                            for relative pathnames
```

Files are stored in the directory in alphabetical order. Filenames are limited to 31 characters, and may include any character except for null and `:`, which is reserved as the path separator.

Instead of `flock`, see `FSpSetFLock` and `FSpRstFLock` in the Mac::Files module, or `chmod(0444, ...)` and `chmod(0666, ...)`.

In the MacPerl application, you can't run a program from the command line; programs that expect `@ARGV` to be populated can be edited with something like the following, which brings up a dialog box asking for the command line arguments.

```
    if (!@ARGV) {
        @ARGV = split /\s+/, MacPerl::Ask('Arguments?');
    }
```

A MacPerl script saved as a "droplet" will populate `@ARGV` with the full pathnames of the files dropped onto the script.

Mac users can run programs under a type of command line interface under MPW (Macintosh Programmer's Workshop, a free development environment from Apple). MacPerl was first introduced as an MPW tool, and MPW can be used like a shell:

```
    perl myscript.plx some arguments
```

ToolServer is another app from Apple that provides access to MPW tools from MPW and the MacPerl app, which allows MacPerl programs to use `system`, backticks, and piped `open`.

"Mac OS" is the proper name for the operating system, but the value in `$^O` is "MacOS". To determine architecture, version, or whether the application or MPW tool version is running, check:

```
    $is_app    = $MacPerl::Version =~ /App/;
    $is_tool   = $MacPerl::Version =~ /MPW/;
    ($version) = $MacPerl::Version =~ /^(\S+)/;
    $is_ppc    = $MacPerl::Architecture eq 'MacPPC';
    $is_68k    = $MacPerl::Architecture eq 'Mac68K';
```

Mac OS X, based on NeXT's OpenStep OS, runs MacPerl natively, under the "Classic" environment. There is no "Carbon" version of MacPerl to run under the primary Mac OS X environment. Mac OS X and its Open Source version, Darwin, both run Unix perl natively.

Also see:

- MacPerl Development, http://dev.macperl.org/ .
- The MacPerl Pages, http://www.macperl.com/ .
- The MacPerl mailing lists, http://lists.perl.org/ .

52.4.4 VMS

Perl on VMS is discussed in *perlvms* in the perl distribution. Perl on VMS can accept either VMS- or Unix-style file specifications as in either of the following:

```
    $ perl -ne "print if /perl_setup/i" SYS$LOGIN:LOGIN.COM
    $ perl -ne "print if /perl_setup/i" /sys$login/login.com
```

but not a mixture of both as in:

```
    $ perl -ne "print if /perl_setup/i" sys$login:/login.com
    Can't open sys$login:/login.com: file specification syntax error
```

Interacting with Perl from the Digital Command Language (DCL) shell often requires a different set of quotation marks than Unix shells do. For example:

```
    $ perl -e "print ""Hello, world.\n"""
    Hello, world.
```

There are several ways to wrap your perl scripts in DCL *.COM* files, if you are so inclined. For example:

```
    $ write sys$output "Hello from DCL!"
    $ if p1 .eqs. ""
    $ then perl -x 'f$environment("PROCEDURE")
    $ else perl -x - 'p1 'p2 'p3 'p4 'p5 'p6 'p7 'p8
    $ deck/dollars="__END__"
    #!/usr/bin/perl

    print "Hello from Perl!\n";

    __END__
    $ endif
```

Do take care with `$ ASSIGN/nolog/user SYS$COMMAND: SYS$INPUT` if your perl-in-DCL script expects to do things like `$read = <STDIN>;`.

Filenames are in the format "name.extension;version". The maximum length for filenames is 39 characters, and the maximum length for extensions is also 39 characters. Version is a number from 1 to 32767. Valid characters are `/[A-Z0-9$_-]/`.

VMS's RMS filesystem is case-insensitive and does not preserve case. `readdir` returns lowercased filenames, but specifying a file for opening remains case-insensitive. Files without extensions have a trailing period on them, so doing a `readdir` with a file named *A.;5* will return *a.* (though that file could be opened with `open(FH, 'A')`).

RMS had an eight level limit on directory depths from any rooted logical (allowing 16 levels overall) prior to VMS 7.2. Hence `PERL_ROOT:[LIB.2.3.4.5.6.7.8]` is a valid directory specification but `PERL_ROOT:[LIB.2.3.4.5.6.7.8.9]` is not. *Makefile.PL* authors might have to take this into account, but at least they can refer to the former as `/PERL_ROOT/lib/2/3/4/5/6/7/8/`.

The VMS::Filespec module, which gets installed as part of the build process on VMS, is a pure Perl module that can easily be installed on non-VMS platforms and can be helpful for conversions to and from RMS native formats.

What `\n` represents depends on the type of file opened. It usually represents `\012` but it could also be `\015`, `\012`, `\015\012`, `\000`, `\040`, or nothing depending on the file organiztion and record format. The VMS::Stdio module provides access to the special fopen() requirements of files with unusual attributes on VMS.

TCP/IP stacks are optional on VMS, so socket routines might not be implemented. UDP sockets may not be supported.

The value of `$^O` on OpenVMS is "VMS". To determine the architecture that you are running on without resorting to loading all of `%Config` you can examine the content of the `@INC` array like so:

```
    if (grep(/VMS_AXP/, @INC)) {
        print "I'm on Alpha!\n";

    } elsif (grep(/VMS_VAX/, @INC)) {
        print "I'm on VAX!\n";

    } else {
        print "I'm not so sure about where $^O is...\n";
    }
```

On VMS, perl determines the UTC offset from the `SYS$TIMEZONE_DIFFERENTIAL` logical name. Although the VMS epoch began at 17-NOV-1858 00:00:00.00, calls to `localtime` are adjusted to count offsets from 01-JAN-1970 00:00:00.00, just like Unix.

Also see:

- *README.vms* (installed as README_vms), *perlvms*
- vmsperl list, majordomo@perl.org

  (Put the words `subscribe vmsperl` in message body.)
- vmsperl on the web, http://www.sidhe.org/vmsperl/index.html

52.4.5 VOS

Perl on VOS is discussed in *README.vos* in the perl distribution (installed as *perlvos*). Perl on VOS can accept either VOS- or Unix-style file specifications as in either of the following:

```
    C<< $ perl -ne "print if /perl_setup/i" >system>notices >>
    C<< $ perl -ne "print if /perl_setup/i" /system/notices >>
```

or even a mixture of both as in:

```
    C<< $ perl -ne "print if /perl_setup/i" >system/notices >>
```

Even though VOS allows the slash character to appear in object names, because the VOS port of Perl interprets it as a pathname delimiting character, VOS files, directories, or links whose names contain a slash character cannot be processed. Such files must be renamed before they can be processed by Perl. Note that VOS limits file names to 32 or fewer characters.

Perl on VOS can be built using two different compilers and two different versions of the POSIX runtime. The recommended method for building full Perl is with the GNU C compiler and the generally-available version of VOS POSIX support. See *README.vos* (installed as *perlvos*) for restrictions that apply when Perl is built using the VOS Standard C compiler or the alpha version of VOS POSIX support.

The value of `$^O` on VOS is "VOS". To determine the architecture that you are running on without resorting to loading all of `%Config` you can examine the content of the @INC array like so:

```
    if ($^O =~ /VOS/) {
        print "I'm on a Stratus box!\n";
    } else {
        print "I'm not on a Stratus box!\n";
        die;
    }

    if (grep(/860/, @INC)) {
        print "This box is a Stratus XA/R!\n";
```

```
} elsif (grep(/7100/, @INC)) {
    print "This box is a Stratus HP 7100 or 8xxx!\n";

} elsif (grep(/8000/, @INC)) {
    print "This box is a Stratus HP 8xxx!\n";

} else {
    print "This box is a Stratus 68K!\n";
}
```

Also see:

- *README.vos* (installed as *perlvos*)
- The VOS mailing list.

  There is no specific mailing list for Perl on VOS. You can post comments to the comp.sys.stratus newsgroup, or subscribe to the general Stratus mailing list. Send a letter with "subscribe Info-Stratus" in the message body to majordomo@list.stratagy.com.
- VOS Perl on the web at http://ftp.stratus.com/pub/vos/posix/posix.html

52.4.6 EBCDIC Platforms

Recent versions of Perl have been ported to platforms such as OS/400 on AS/400 minicomputers as well as OS/390, VM/ESA, and BS2000 for S/390 Mainframes. Such computers use EBCDIC character sets internally (usually Character Code Set ID 0037 for OS/400 and either 1047 or POSIX-BC for S/390 systems). On the mainframe perl currently works under the "Unix system services for OS/390" (formerly known as OpenEdition), VM/ESA OpenEdition, or the BS200 POSIX-BC system (BS2000 is supported in perl 5.6 and greater). See *perlos390* for details. Note that for OS/400 there is also a port of Perl 5.8.1/5.9.0 or later to the PASE which is ASCII-based (as opposed to ILE which is EBCDIC-based), see *perlos400*.

As of R2.5 of USS for OS/390 and Version 2.3 of VM/ESA these Unix sub-systems do not support the `#!` shebang trick for script invocation. Hence, on OS/390 and VM/ESA perl scripts can be executed with a header similar to the following simple script:

```
: # use perl
    eval 'exec /usr/local/bin/perl -S $0 ${1+"$@"}'
        if 0;
#!/usr/local/bin/perl     # just a comment really

print "Hello from perl!\n";
```

OS/390 will support the `#!` shebang trick in release 2.8 and beyond. Calls to `system` and backticks can use POSIX shell syntax on all S/390 systems.

On the AS/400, if PERL5 is in your library list, you may need to wrap your perl scripts in a CL procedure to invoke them like so:

```
BEGIN
  CALL PGM(PERL5/PERL) PARM('/QOpenSys/hello.pl')
ENDPGM
```

This will invoke the perl script *hello.pl* in the root of the QOpenSys file system. On the AS/400 calls to `system` or backticks must use CL syntax.

On these platforms, bear in mind that the EBCDIC character set may have an effect on what happens with some perl functions (such as `chr`, `pack`, `print`, `printf`, `ord`, `sort`, `sprintf`, `unpack`), as well as bit-fiddling with ASCII constants using operators like ^, & and |, not to mention dealing with socket interfaces to ASCII computers (see §52.2.1).

Fortunately, most web servers for the mainframe will correctly translate the `\n` in the following statement to its ASCII equivalent (`\r` is the same under both Unix and OS/390 & VM/ESA):

```
print "Content-type: text/html\r\n\r\n";
```

The values of `$^O` on some of these platforms includes:

```
uname         $^O        $Config{'archname'}
--------------------------------------------
OS/390        os390      os390
OS400         os400      os400
POSIX-BC      posix-bc   BS2000-posix-bc
VM/ESA        vmesa      vmesa
```

Some simple tricks for determining if you are running on an EBCDIC platform could include any of the following (perhaps all):

```
if ("\t" eq "\05")   { print "EBCDIC may be spoken here!\n"; }

if (ord('A') == 193) { print "EBCDIC may be spoken here!\n"; }

if (chr(169) eq 'z') { print "EBCDIC may be spoken here!\n"; }
```

One thing you may not want to rely on is the EBCDIC encoding of punctuation characters since these may differ from code page to code page (and once your module or script is rumoured to work with EBCDIC, folks will want it to work with all EBCDIC character sets).

Also see:

- *

  perlos390, *README.os390*, *perlbs2000*, *README.vmesa*, *perlebcdic*.
- The perl-mvs@perl.org list is for discussion of porting issues as well as general usage issues for all EBCDIC Perls. Send a message body of "subscribe perl-mvs" to majordomo@perl.org.
- AS/400 Perl information at http://as400.rochester.ibm.com/ as well as on CPAN in the *ports/* directory.

52.4.7 Acorn RISC OS

Because Acorns use ASCII with newlines (`\n`) in text files as `\012` like Unix, and because Unix filename emulation is turned on by default, most simple scripts will probably work "out of the box". The native filesystem is modular, and individual filesystems are free to be case-sensitive or insensitive, and are usually case-preserving. Some native filesystems have name length limits, which file and directory names are silently truncated to fit. Scripts should be aware that the standard filesystem currently has a name length limit of **10** characters, with up to 77 items in a directory, but other filesystems may not impose such limitations.

Native filenames are of the form

```
Filesystem#Special_Field::DiskName.$.Directory.Directory.File
```

where

```
Special_Field is not usually present, but may contain . and $ .
Filesystem =~ m|[A-Za-z0-9_]|
DsicName   =~ m|[A-Za-z0-9_/]|
$ represents the root directory
. is the path separator
@ is the current directory (per filesystem but machine global)
^ is the parent directory
Directory and File =~ m|[^\0- "\.\$\%\&:\@\\^\|\177]+|
```

The default filename translation is roughly tr|/.|./|;

Note that "ADFS::HardDisk.$.File" ne 'ADFS::HardDisk.$.File' and that the second stage of $ interpolation in regular expressions will fall foul of the $. if scripts are not careful.

Logical paths specified by system variables containing comma-separated search lists are also allowed; hence System:Modules is a valid filename, and the filesystem will prefix Modules with each section of System$Path until a name is made that points to an object on disk. Writing to a new file System:Modules would be allowed only if System$Path contains a single item list. The filesystem will also expand system variables in filenames if enclosed in angle brackets, so <System$Dir>.Modules would look for the file $ENV{'System$Dir'} . 'Modules'. The obvious implication of this is that **fully qualified filenames can start with** <> and should be protected when open is used for input.

Because . was in use as a directory separator and filenames could not be assumed to be unique after 10 characters, Acorn implemented the C compiler to strip the trailing .c .h .s and .o suffix from filenames specified in source code and store the respective files in subdirectories named after the suffix. Hence files are translated:

```
    foo.h           h.foo
    C:foo.h         C:h.foo         (logical path variable)
    sys/os.h        sys.h.os        (C compiler groks Unix-speak)
    10charname.c    c.10charname
    10charname.o    o.10charname
    11charname_.c   c.11charname    (assuming filesystem truncates at 10)
```

The Unix emulation library's translation of filenames to native assumes that this sort of translation is required, and it allows a user-defined list of known suffixes that it will transpose in this fashion. This may seem transparent, but consider that with these rules foo/bar/baz.h and foo/bar/h/baz both map to foo.bar.h.baz, and that readdir and glob cannot and do not attempt to emulate the reverse mapping. Other .'s in filenames are translated to /.

As implied above, the environment accessed through %ENV is global, and the convention is that program specific environment variables are of the form Program$Name. Each filesystem maintains a current directory, and the current filesystem's current directory is the **global** current directory. Consequently, sociable programs don't change the current directory but rely on full pathnames, and programs (and Makefiles) cannot assume that they can spawn a child process which can change the current directory without affecting its parent (and everyone else for that matter).

Because native operating system filehandles are global and are currently allocated down from 255, with 0 being a reserved value, the Unix emulation library emulates Unix filehandles. Consequently, you can't rely on passing STDIN, STDOUT, or STDERR to your children.

The desire of users to express filenames of the form <Foo$Dir>.Bar on the command line unquoted causes problems, too: " command output capture has to perform a guessing game. It assumes that a string <[^<>]+\$[^<>]> is a reference to an environment variable, whereas anything else involving < or > is redirection, and generally manages to be 99% right. Of course, the problem remains that scripts cannot rely on any Unix tools being available, or that any tools found have Unix-like command line arguments.

Extensions and XS are, in theory, buildable by anyone using free tools. In practice, many don't, as users of the Acorn platform are used to binary distributions. MakeMaker does run, but no available make currently copes with MakeMaker's makefiles; even if and when this should be fixed, the lack of a Unix-like shell will cause problems with makefile rules, especially lines of the form cd sdbm && make all, and anything using quoting.

"RISC OS" is the proper name for the operating system, but the value in $^O is "riscos" (because we don't like shouting).

52.4.8 Other perls

Perl has been ported to many platforms that do not fit into any of the categories listed above. Some, such as AmigaOS, Atari MiNT, BeOS, HP MPE/iX, QNX, Plan 9, and VOS, have been well-integrated into the standard Perl source code kit. You may need to see the *ports/* directory on CPAN for information, and possibly binaries, for the likes of: aos, Atari ST, lynxos, riscos, Novell Netware, Tandem Guardian, *etc.* (Yes, we know that some of these OSes may fall under the Unix category, but we are not a standards body.)

Some approximate operating system names and their $^O values in the "OTHER" category include:

```
    OS            $^O        $Config{'archname'}
    ------------------------------------------
    Amiga DOS     amigaos    m68k-amigos
    BeOS          beos
    MPE/iX        mpeix      PA-RISC1.1
```

See also:

- Amiga, *README.amiga* (installed as *perlamiga*).

- Be OS, *README.beos*
- HP 300 MPE/iX, *README.mpeix* and Mark Bixby's web page http://www.bixby.org/mark/perlix.html
- A free perl5-based PERL.NLM for Novell Netware is available in precompiled binary and source code form from http://www.novell.com/ as well as from CPAN.
- Plan 9, *README.plan9*

52.5 FUNCTION IMPLEMENTATIONS

Listed below are functions that are either completely unimplemented or else have been implemented differently on various platforms. Following each description will be, in parentheses, a list of platforms that the description applies to.

The list may well be incomplete, or even wrong in some places. When in doubt, consult the platform-specific README files in the Perl source distribution, and any other documentation resources accompanying a given port.

Be aware, moreover, that even among Unix-ish systems there are variations.

For many functions, you can also query `%Config`, exported by default from the Config module. For example, to check whether the platform has the `lstat` call, check `$Config{d_lstat}`. See *Config* for a full description of available variables.

52.5.1 Alphabetical Listing of Perl Functions

-X FILEHANDLE

-X EXPR

-X

`-r`, `-w`, and `-x` have a limited meaning only; directories and applications are executable, and there are no uid/gid considerations. `-o` is not supported. (Mac OS)

`-r`, `-w`, `-x`, and `-o` tell whether the file is accessible, which may not reflect UIC-based file protections. (VMS)

`-s` returns the size of the data fork, not the total size of data fork plus resource fork. (Mac OS).

`-s` by name on an open file will return the space reserved on disk, rather than the current extent. `-s` on an open filehandle returns the current size. (RISC OS)

`-R`, `-W`, `-X`, `-O` are indistinguishable from `-r`, `-w`, `-x`, `-o`. (Mac OS, Win32, VMS, RISC OS)

`-b`, `-c`, `-k`, `-g`, `-p`, `-u`, `-A` are not implemented. (Mac OS)

`-g`, `-k`, `-l`, `-p`, `-u`, `-A` are not particularly meaningful. (Win32, VMS, RISC OS)

`-d` is true if passed a device spec without an explicit directory. (VMS)

`-T` and `-B` are implemented, but might misclassify Mac text files with foreign characters; this is the case will all platforms, but may affect Mac OS often. (Mac OS)

`-x` (or `-X`) determine if a file ends in one of the executable suffixes. `-S` is meaningless. (Win32)

`-x` (or `-X`) determine if a file has an executable file type. (RISC OS)

binmode FILEHANDLE

Meaningless. (Mac OS, RISC OS)

Reopens file and restores pointer; if function fails, underlying filehandle may be closed, or pointer may be in a different position. (VMS)

The value returned by `tell` may be affected after the call, and the filehandle may be flushed. (Win32)

chmod LIST

Only limited meaning. Disabling/enabling write permission is mapped to locking/unlocking the file. (Mac OS)

Only good for changing "owner" read-write access, "group", and "other" bits are meaningless. (Win32)

Only good for changing "owner" and "other" read-write access. (RISC OS)

Access permissions are mapped onto VOS access-control list changes. (VOS)

The actual permissions set depend on the value of the `CYGWIN` in the SYSTEM environment settings. (Cygwin)

chown LIST

Not implemented. (Mac OS, Win32, Plan 9, RISC OS, VOS)

Does nothing, but won't fail. (Win32)

chroot FILENAME

chroot

Not implemented. (Mac OS, Win32, VMS, Plan 9, RISC OS, VOS, VM/ESA)

crypt PLAINTEXT,SALT

May not be available if library or source was not provided when building perl. (Win32)

Not implemented. (VOS)

dbmclose HASH

Not implemented. (VMS, Plan 9, VOS)

dbmopen HASH,DBNAME,MODE

Not implemented. (VMS, Plan 9, VOS)

dump LABEL

Not useful. (Mac OS, RISC OS)

Not implemented. (Win32)

Invokes VMS debugger. (VMS)

exec LIST

Not implemented. (Mac OS)

Implemented via Spawn. (VM/ESA)

Does not automatically flush output handles on some platforms. (SunOS, Solaris, HP-UX)

exit EXPR

exit

Emulates UNIX exit() (which considers `exit 1` to indicate an error) by mapping the `1` to SS$_ABORT (`44`). This behavior may be overridden with the pragma `use vmsish 'exit'`. As with the CRTL's exit() function, `exit 0` is also mapped to an exit status of SS$_NORMAL (`1`); this mapping cannot be overridden. Any other argument to exit() is used directly as Perl's exit status. (VMS)

fcntl FILEHANDLE,FUNCTION,SCALAR

Not implemented. (Win32, VMS)

flock FILEHANDLE,OPERATION

Not implemented (Mac OS, VMS, RISC OS, VOS).

Available only on Windows NT (not on Windows 95). (Win32)

fork

Not implemented. (Mac OS, AmigaOS, RISC OS, VOS, VM/ESA, VMS)

Emulated using multiple interpreters. See *perlfork*. (Win32)

Does not automatically flush output handles on some platforms. (SunOS, Solaris, HP-UX)

getlogin

Not implemented. (Mac OS, RISC OS)

getpgrp PID

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS)

getppid

Not implemented. (Mac OS, Win32, RISC OS)

getpriority WHICH,WHO

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS, VM/ESA)

getpwnam NAME

Not implemented. (Mac OS, Win32)

Not useful. (RISC OS)

getgrnam NAME

Not implemented. (Mac OS, Win32, VMS, RISC OS)

getnetbyname NAME

Not implemented. (Mac OS, Win32, Plan 9)

getpwuid UID

Not implemented. (Mac OS, Win32)

Not useful. (RISC OS)

getgrgid GID

Not implemented. (Mac OS, Win32, VMS, RISC OS)

getnetbyaddr ADDR,ADDRTYPE

Not implemented. (Mac OS, Win32, Plan 9)

getprotobynumber NUMBER

Not implemented. (Mac OS)

getservbyport PORT,PROTO

Not implemented. (Mac OS)

getpwent

Not implemented. (Mac OS, Win32, VM/ESA)

getgrent

Not implemented. (Mac OS, Win32, VMS, VM/ESA)

gethostbyname

`gethostbyname('localhost')` does not work everywhere: you may have to use `gethostbyname('127.0.0.1')`. (Mac OS, Irix 5)

gethostent

Not implemented. (Mac OS, Win32)

getnetent

Not implemented. (Mac OS, Win32, Plan 9)

getprotoent

Not implemented. (Mac OS, Win32, Plan 9)

getservent

Not implemented. (Win32, Plan 9)

sethostent STAYOPEN

Not implemented. (Mac OS, Win32, Plan 9, RISC OS)

setnetent STAYOPEN

Not implemented. (Mac OS, Win32, Plan 9, RISC OS)

setprotoent STAYOPEN

Not implemented. (Mac OS, Win32, Plan 9, RISC OS)

setservent STAYOPEN

Not implemented. (Plan 9, Win32, RISC OS)

endpwent

Not implemented. (Mac OS, MPE/iX, VM/ESA, Win32)

endgrent

Not implemented. (Mac OS, MPE/iX, RISC OS, VM/ESA, VMS, Win32)

endhostent

Not implemented. (Mac OS, Win32)

endnetent

Not implemented. (Mac OS, Win32, Plan 9)

endprotoent

Not implemented. (Mac OS, Win32, Plan 9)

endservent

Not implemented. (Plan 9, Win32)

getsockopt SOCKET,LEVEL,OPTNAME

Not implemented. (Plan 9)

glob EXPR

glob

This operator is implemented via the File::Glob extension on most platforms. See *File::Glob* for portability information.

ioctl FILEHANDLE,FUNCTION,SCALAR

Not implemented. (VMS)

Available only for socket handles, and it does what the ioctlsocket() call in the Winsock API does. (Win32)

Available only for socket handles. (RISC OS)

kill SIGNAL, LIST

`kill(0, LIST)` is implemented for the sake of taint checking; use with other signals is unimplemented. (Mac OS)

Not implemented, hence not useful for taint checking. (RISC OS)

`kill()` doesn't have the semantics of `raise()`, i.e. it doesn't send a signal to the identified process like it does on Unix platforms. Instead `kill($sig, $pid)` terminates the process identified by $pid, and makes it exit immediately with exit status $sig. As in Unix, if $sig is 0 and the specified process exists, it returns true without actually terminating it. (Win32)

link OLDFILE,NEWFILE

Not implemented. (Mac OS, MPE/iX, VMS, RISC OS)

Link count not updated because hard links are not quite that hard (They are sort of half-way between hard and soft links). (AmigaOS)

Hard links are implemented on Win32 (Windows NT and Windows 2000) under NTFS only.

lstat FILEHANDLE

lstat EXPR

lstat

Not implemented. (VMS, RISC OS)

Return values (especially for device and inode) may be bogus. (Win32)

msgctl ID,CMD,ARG

msgget KEY,FLAGS

msgsnd ID,MSG,FLAGS

msgrcv ID,VAR,SIZE,TYPE,FLAGS

Not implemented. (Mac OS, Win32, VMS, Plan 9, RISC OS, VOS)

open FILEHANDLE,EXPR

open FILEHANDLE

The | variants are supported only if ToolServer is installed. (Mac OS)

open to |- and -| are unsupported. (Mac OS, Win32, RISC OS)

Opening a process does not automatically flush output handles on some platforms. (SunOS, Solaris, HP-UX)

pipe READHANDLE,WRITEHANDLE

Very limited functionality. (MiNT)

readlink EXPR

readlink

Not implemented. (Win32, VMS, RISC OS)

select RBITS,WBITS,EBITS,TIMEOUT

Only implemented on sockets. (Win32, VMS)

Only reliable on sockets. (RISC OS)

Note that the `select FILEHANDLE` form is generally portable.

semctl ID,SEMNUM,CMD,ARG

semget KEY,NSEMS,FLAGS

semop KEY,OPSTRING

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS)

setgrent

Not implemented. (Mac OS, MPE/iX, VMS, Win32, RISC OS)

setpgrp PID,PGRP

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS)

setpriority WHICH,WHO,PRIORITY

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS)

setpwent

Not implemented. (Mac OS, MPE/iX, Win32, RISC OS)

setsockopt SOCKET,LEVEL,OPTNAME,OPTVAL

Not implemented. (Plan 9)

shmctl ID,CMD,ARG

shmget KEY,SIZE,FLAGS

shmread ID,VAR,POS,SIZE

shmwrite ID,STRING,POS,SIZE

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS)

sockatmark SOCKET

A relatively recent addition to socket functions, may not be implemented even in UNIX platforms.

socketpair SOCKET1,SOCKET2,DOMAIN,TYPE,PROTOCOL

Not implemented. (Win32, VMS, RISC OS, VOS, VM/ESA)

stat FILEHANDLE

stat EXPR

stat

Platforms that do not have rdev, blksize, or blocks will return these as ”, so numeric comparison or manipulation of these fields may cause ’not numeric’ warnings.

mtime and atime are the same thing, and ctime is creation time instead of inode change time. (Mac OS).

ctime not supported on UFS (Mac OS X).

ctime is creation time instead of inode change time (Win32).

device and inode are not meaningful. (Win32)

device and inode are not necessarily reliable. (VMS)

mtime, atime and ctime all return the last modification time. Device and inode are not necessarily reliable. (RISC OS)

dev, rdev, blksize, and blocks are not available. inode is not meaningful and will differ between stat calls on the same file. (os2)

some versions of cygwin when doing a stat("foo") and if not finding it may then attempt to stat("foo.exe") (Cygwin)

symlink OLDFILE,NEWFILE

Not implemented. (Win32, VMS, RISC OS)

syscall LIST

Not implemented. (Mac OS, Win32, VMS, RISC OS, VOS, VM/ESA)

sysopen FILEHANDLE,FILENAME,MODE,PERMS

The traditional "0", "1", and "2" MODEs are implemented with different numeric values on some systems. The flags exported by `Fcntl` (O_RDONLY, O_WRONLY, O_RDWR) should work everywhere though. (Mac OS, OS/390, VM/ESA)

system LIST

In general, do not assume the UNIX/POSIX semantics that you can shift `$?` right by eight to get the exit value, or that `$? & 127` would give you the number of the signal that terminated the program, or that `$? & 128` would test true if the program was terminated by a coredump. Instead, use the POSIX W*() interfaces: for example, use WIFEXITED($?) and WEXITVALUE($?) to test for a normal exit and the exit value, WIFSIGNALED($?) and WTERMSIG($?) for a signal exit and the signal. Core dumping is not a portable concept, so there's no portable way to test for that.

Only implemented if ToolServer is installed. (Mac OS)

As an optimization, may not call the command shell specified in `$ENV{PERL5SHELL}`. `system(1, @args)` spawns an external process and immediately returns its process designator, without waiting for it to terminate. Return value may be used subsequently in `wait` or `waitpid`. Failure to spawn() a subprocess is indicated by setting $? to "255 << 8". `$?` is set in a way compatible with Unix (i.e. the exitstatus of the subprocess is obtained by "$? >> 8", as described in the documentation). (Win32)

There is no shell to process metacharacters, and the native standard is to pass a command line terminated by "\n" "\r" or "\0" to the spawned program. Redirection such as `> foo` is performed (if at all) by the run time library of the spawned program. `system` *list* will call the Unix emulation library's `exec` emulation, which attempts to provide emulation of the stdin, stdout, stderr in force in the parent, providing the child program uses a compatible version of the emulation library. *scalar* will call the native command line direct and no such emulation of a child Unix program will exists. Mileage **will** vary. (RISC OS)

Far from being POSIX compliant. Because there may be no underlying /bin/sh tries to work around the problem by forking and execing the first token in its argument string. Handles basic redirection ("<" or ">") on its own behalf. (MiNT)

Does not automatically flush output handles on some platforms. (SunOS, Solaris, HP-UX)

The return value is POSIX-like (shifted up by 8 bits), which only allows room for a made-up value derived from the severity bits of the native 32-bit condition code (unless overridden by `use vmsish 'status'`). For more details see `$?` in *perlvms*. (VMS)

times

Only the first entry returned is nonzero. (Mac OS)

"cumulative" times will be bogus. On anything other than Windows NT or Windows 2000, "system" time will be bogus, and "user" time is actually the time returned by the clock() function in the C runtime library. (Win32)

Not useful. (RISC OS)

truncate FILEHANDLE,LENGTH

truncate EXPR,LENGTH

Not implemented. (Older versions of VMS)

Truncation to zero-length only. (VOS)

If a FILEHANDLE is supplied, it must be writable and opened in append mode (i.e., use `open(FH, '>>filename')` or `sysopen(FH,...,O_APPEND|O_RDWR)`. If a filename is supplied, it should not be held open elsewhere. (Win32)

umask EXPR

umask

Returns undef where unavailable, as of version 5.005.

`umask` works but the correct permissions are set only when the file is finally closed. (AmigaOS)

utime LIST

Only the modification time is updated. (BeOS, Mac OS, VMS, RISC OS)

May not behave as expected. Behavior depends on the C runtime library's implementation of utime(), and the filesystem being used. The FAT filesystem typically does not support an "access time" field, and it may limit timestamps to a granularity of two seconds. (Win32)

wait

waitpid PID,FLAGS

Not implemented. (Mac OS, VOS)

Can only be applied to process handles returned for processes spawned using `system(1, ...)` or pseudo processes created with `fork()`. (Win32)

Not useful. (RISC OS)

52.6 CHANGES

v1.48, 02 February 2001

Various updates from perl5-porters over the past year, supported platforms update from Jarkko Hietaniemi.

v1.47, 22 March 2000

Various cleanups from Tom Christiansen, including migration of long platform listings from *perl*.

v1.46, 12 February 2000

Updates for VOS and MPE/iX. (Peter Prymmer) Other small changes.

v1.45, 20 December 1999

Small changes from 5.005_63 distribution, more changes to EBCDIC info.

v1.44, 19 July 1999

A bunch of updates from Peter Prymmer for `$^O` values, endianness, File::Spec, VMS, BS2000, OS/400.

v1.43, 24 May 1999

Added a lot of cleaning up from Tom Christiansen.

v1.42, 22 May 1999

Added notes about tests, sprintf/printf, and epoch offsets.

v1.41, 19 May 1999

Lots more little changes to formatting and content.

Added a bunch of `$^O` and related values for various platforms; fixed mail and web addresses, and added and changed miscellaneous notes. (Peter Prymmer)

v1.40, 11 April 1999

Miscellaneous changes.

v1.39, 11 February 1999

Changes from Jarkko and EMX URL fixes Michael Schwern. Additional note about newlines added.

v1.38, 31 December 1998

More changes from Jarkko.

v1.37, 19 December 1998

More minor changes. Merge two separate version 1.35 documents.

v1.36, 9 September 1998

Updated for Stratus VOS. Also known as version 1.35.

v1.35, 13 August 1998

Integrate more minor changes, plus addition of new sections under §52.2: §52.2.2, §52.2.11, §52.2.12.

v1.33, 06 August 1998

Integrate more minor changes.

v1.32, 05 August 1998

Integrate more minor changes.

v1.30, 03 August 1998

Major update for RISC OS, other minor changes.

v1.23, 10 July 1998

First public release with perl5.005.

52.7 Supported Platforms

As of September 2003 (the Perl release 5.8.1), the following platforms are able to build Perl from the standard source code distribution available at http://www.cpan.org/src/index.html

```
AIX
BeOS
BSD/OS          (BSDi)
Cygwin
DG/UX
DOS DJGPP       1)
DYNIX/ptx
EPOC R5
FreeBSD
HI-UXMPP        (Hitachi) (5.8.0 worked but we didn't know it)
HP-UX
IRIX
Linux
LynxOS
Mac OS Classic
Mac OS X        (Darwin)
MPE/iX
NetBSD
NetWare
NonStop-UX
ReliantUNIX     (formerly SINIX)
OpenBSD
OpenVMS         (formerly VMS)
Open UNIX       (Unixware) (since Perl 5.8.1/5.9.0)
OS/2
OS/400          (using the PASE) (since Perl 5.8.1/5.9.0)
PowerUX
POSIX-BC        (formerly BS2000)
QNX
```

```
        Solaris
        SunOS 4
        SUPER-UX        (NEC)
        SVR4
        Tru64 UNIX      (formerly DEC OSF/1, Digital UNIX)
        UNICOS
        UNICOS/mk
        UTS
        VOS
        Win95/98/ME/2K/XP 2)
        WinCE
        z/OS            (formerly OS/390)
        VM/ESA

        1) in DOS mode either the DOS or OS/2 ports can be used
        2) compilers: Borland, MinGW (GCC), VC6
```

The following platforms worked with the previous releases (5.6 and 5.7), but we did not manage either to fix or to test these in time for the 5.8.1 release. There is a very good chance that many of these will work fine with the 5.8.1.

```
        DomainOS
        Hurd
        MachTen
        PowerMAX
        SCO SV
        Unixware
        Windows 3.1
```

Known to be broken for 5.8.0 and 5.8.1 (but 5.6.1 and 5.7.2 can be used):

```
        AmigaOS
```

The following platforms have been known to build Perl from source in the past (5.005_03 and earlier), but we haven't been able to verify their status for the current release, either because the hardware/software platforms are rare or because we don't have an active champion on these platforms–or both. They used to work, though, so go ahead and try compiling them, and let perlbug@perl.org of any trouble.

```
        3b1
        A/UX
        ConvexOS
        CX/UX
        DC/OSx
        DDE SMES
        DOS EMX
        Dynix
        EP/IX
        ESIX
        FPS
        GENIX
        Greenhills
        ISC
        MachTen 68k
        MiNT
        MPC
        NEWS-OS
        NextSTEP
        OpenSTEP
        Opus
        Plan 9
        RISC/os
        SCO ODT/OSR
        Stellar
        SVR2
        TI1500
        TitanOS
        Ultrix
        Unisys Dynix
```

The following platforms have their own source code distributions and binaries available via http://www.cpan.org/ports/

```
                                Perl release

        OS/400 (ILE)            5.005_02
        Tandem Guardian         5.004
```

The following platforms have only binaries available via http://www.cpan.org/ports/index.html :

```
                                Perl release

        Acorn RISCOS            5.005_02
        AOS                     5.002
        LynxOS                  5.004_02
```

Although we do suggest that you always build your own Perl from the source code, both for maximal configurability and for security, in case you are in a hurry you can check http://www.cpan.org/ports/index.html for binary distributions.

Chapter 53

perllocale

Perl locale handling (internationalization and localization)

53.1 DESCRIPTION

Perl supports language-specific notions of data such as "is this a letter", "what is the uppercase equivalent of this letter", and "which of these letters comes first". These are important issues, especially for languages other than English–but also for English: it would be naïve to imagine that `A-Za-z` defines all the "letters" needed to write in English. Perl is also aware that some character other than '.' may be preferred as a decimal point, and that output date representations may be language-specific. The process of making an application take account of its users' preferences in such matters is called **internationalization** (often abbreviated as **i18n**); telling such an application about a particular set of preferences is known as **localization** (**l10n**).

Perl can understand language-specific data via the standardized (ISO C, XPG4, POSIX 1.c) method called "the locale system". The locale system is controlled per application using one pragma, one function call, and several environment variables.

NOTE: This feature is new in Perl 5.004, and does not apply unless an application specifically requests it–see Backward compatibility. The one exception is that write() now **always** uses the current locale - see §53.7.

53.2 PREPARING TO USE LOCALES

If Perl applications are to understand and present your data correctly according a locale of your choice, **all** of the following must be true:

- **Your operating system must support the locale system**. If it does, you should find that the setlocale() function is a documented part of its C library.
- **Definitions for locales that you use must be installed**. You, or your system administrator, must make sure that this is the case. The available locales, the location in which they are kept, and the manner in which they are installed all vary from system to system. Some systems provide only a few, hard-wired locales and do not allow more to be added. Others allow you to add "canned" locales provided by the system supplier. Still others allow you or the system administrator to define and add arbitrary locales. (You may have to ask your supplier to provide canned locales that are not delivered with your operating system.) Read your system documentation for further illumination.
- **Perl must believe that the locale system is supported**. If it does, `perl -V:d_setlocale` will say that the value for `d_setlocale` is `define`.

If you want a Perl application to process and present your data according to a particular locale, the application code should include the `use locale` pragma (see The use locale pragma) where appropriate, and **at least one** of the following must be true:

- **The locale-determining environment variables (see §53.6) must be correctly set up** at the time the application is started, either by yourself or by whoever set up your system account.
- **The application must set its own locale** using the method described in The setlocale function.

53.3 USING LOCALES

53.3.1 The use locale pragma

By default, Perl ignores the current locale. The `use locale` pragma tells Perl to use the current locale for some operations:

- **The comparison operators** (`lt`, `le`, `cmp`, `ge`, and `gt`) and the POSIX string collation functions strcoll() and strxfrm() use `LC_COLLATE`. sort() is also affected if used without an explicit comparison function, because it uses `cmp` by default.

  Note: `eq` and `ne` are unaffected by locale: they always perform a char-by-char comparison of their scalar operands. What's more, if `cmp` finds that its operands are equal according to the collation sequence specified by the current locale, it goes on to perform a char-by-char comparison, and only returns *0* (equal) if the operands are char-for-char identical. If you really want to know whether two strings–which `eq` and `cmp` may consider different–are equal as far as collation in the locale is concerned, see the discussion in Category LC_COLLATE: Collation.
- **Regular expressions and case-modification functions** (uc(), lc(), ucfirst(), and lcfirst()) use `LC_CTYPE`
- **The formatting functions** (printf(), sprintf() and write()) use `LC_NUMERIC`
- **The POSIX date formatting function** (strftime()) uses `LC_TIME`.

`LC_COLLATE`, `LC_CTYPE`, and so on, are discussed further in LOCALE CATEGORIES.

The default behavior is restored with the `no locale` pragma, or upon reaching the end of block enclosing `use locale`.

The string result of any operation that uses locale information is tainted, as it is possible for a locale to be untrustworthy. See §53.5.

53.3.2 The setlocale function

You can switch locales as often as you wish at run time with the POSIX::setlocale() function:

```
# This functionality not usable prior to Perl 5.004
require 5.004;

# Import locale-handling tool set from POSIX module.
# This example uses: setlocale -- the function call
#                    LC_CTYPE -- explained below
use POSIX qw(locale_h);

# query and save the old locale
$old_locale = setlocale(LC_CTYPE);

setlocale(LC_CTYPE, "fr_CA.ISO8859-1");
# LC_CTYPE now in locale "French, Canada, codeset ISO 8859-1"

setlocale(LC_CTYPE, "");
# LC_CTYPE now reset to default defined by LC_ALL/LC_CTYPE/LANG
# environment variables.  See below for documentation.
```

```
        # restore the old locale
        setlocale(LC_CTYPE, $old_locale);
```

The first argument of setlocale() gives the **category**, the second the **locale**. The category tells in what aspect of data processing you want to apply locale-specific rules. Category names are discussed in LOCALE CATEGORIES and §53.6. The locale is the name of a collection of customization information corresponding to a particular combination of language, country or territory, and codeset. Read on for hints on the naming of locales: not all systems name locales as in the example.

If no second argument is provided and the category is something else than LC_ALL, the function returns a string naming the current locale for the category. You can use this value as the second argument in a subsequent call to setlocale().

If no second argument is provided and the category is LC_ALL, the result is implementation-dependent. It may be a string of concatenated locales names (separator also implementation-dependent) or a single locale name. Please consult your *setlocale*(3) for details.

If a second argument is given and it corresponds to a valid locale, the locale for the category is set to that value, and the function returns the now-current locale value. You can then use this in yet another call to setlocale(). (In some implementations, the return value may sometimes differ from the value you gave as the second argument–think of it as an alias for the value you gave.)

As the example shows, if the second argument is an empty string, the category's locale is returned to the default specified by the corresponding environment variables. Generally, this results in a return to the default that was in force when Perl started up: changes to the environment made by the application after startup may or may not be noticed, depending on your system's C library.

If the second argument does not correspond to a valid locale, the locale for the category is not changed, and the function returns *undef*.

For further information about the categories, consult *setlocale*(3).

53.3.3 Finding locales

For locales available in your system, consult also *setlocale*(3) to see whether it leads to the list of available locales (search for the *SEE ALSO* section). If that fails, try the following command lines:

```
        locale -a

        nlsinfo

        ls /usr/lib/nls/loc

        ls /usr/lib/locale

        ls /usr/lib/nls

        ls /usr/share/locale
```

and see whether they list something resembling these

```
        en_US.ISO8859-1     de_DE.ISO8859-1     ru_RU.ISO8859-5
        en_US.iso88591      de_DE.iso88591      ru_RU.iso88595
        en_US               de_DE               ru_RU
        en                  de                  ru
        english             german              russian
        english.iso88591    german.iso88591     russian.iso88595
        english.roman8                          russian.koi8r
```

Sadly, even though the calling interface for setlocale() has been standardized, names of locales and the directories where the configuration resides have not been. The basic form of the name is *language_territory***.***codeset*, but the latter parts after *language* are not always present. The *language* and *country* are usually from the standards **ISO 3166** and **ISO 639**, the two-letter abbreviations for the countries and the languages of the world, respectively. The *codeset* part often mentions some **ISO 8859** character set, the Latin codesets. For example, `ISO 8859-1` is the so-called "Western European codeset" that can be used to encode most Western European languages adequately. Again, there are several ways to write even the name of that one standard. Lamentably.

Two special locales are worth particular mention: "C" and "POSIX". Currently these are effectively the same locale: the difference is mainly that the first one is defined by the C standard, the second by the POSIX standard. They define the **default locale** in which every program starts in the absence of locale information in its environment. (The *default* default locale, if you will.) Its language is (American) English and its character codeset ASCII.

NOTE: Not all systems have the "POSIX" locale (not all systems are POSIX-conformant), so use "C" when you need explicitly to specify this default locale.

53.3.4 LOCALE PROBLEMS

You may encounter the following warning message at Perl startup:

```
perl: warning: Setting locale failed.
perl: warning: Please check that your locale settings:
        LC_ALL = "En_US",
        LANG = (unset)
    are supported and installed on your system.
perl: warning: Falling back to the standard locale ("C").
```

This means that your locale settings had LC_ALL set to "En_US" and LANG exists but has no value. Perl tried to believe you but could not. Instead, Perl gave up and fell back to the "C" locale, the default locale that is supposed to work no matter what. This usually means your locale settings were wrong, they mention locales your system has never heard of, or the locale installation in your system has problems (for example, some system files are broken or missing). There are quick and temporary fixes to these problems, as well as more thorough and lasting fixes.

53.3.5 Temporarily fixing locale problems

The two quickest fixes are either to render Perl silent about any locale inconsistencies or to run Perl under the default locale "C".

Perl's moaning about locale problems can be silenced by setting the environment variable PERL_BADLANG to a zero value, for example "0". This method really just sweeps the problem under the carpet: you tell Perl to shut up even when Perl sees that something is wrong. Do not be surprised if later something locale-dependent misbehaves.

Perl can be run under the "C" locale by setting the environment variable LC_ALL to "C". This method is perhaps a bit more civilized than the PERL_BADLANG approach, but setting LC_ALL (or other locale variables) may affect other programs as well, not just Perl. In particular, external programs run from within Perl will see these changes. If you make the new settings permanent (read on), all programs you run see the changes. See *ENVIRONMENT* for the full list of relevant environment variables and USING LOCALES for their effects in Perl. Effects in other programs are easily deducible. For example, the variable LC_COLLATE may well affect your **sort** program (or whatever the program that arranges 'records' alphabetically in your system is called).

You can test out changing these variables temporarily, and if the new settings seem to help, put those settings into your shell startup files. Consult your local documentation for the exact details. For in Bourne-like shells (**sh**, **ksh**, **bash**, **zsh**):

```
LC_ALL=en_US.ISO8859-1
export LC_ALL
```

This assumes that we saw the locale "en_US.ISO8859-1" using the commands discussed above. We decided to try that instead of the above faulty locale "En_US"–and in Cshish shells (**csh**, **tcsh**)

```
        setenv LC_ALL en_US.ISO8859-1
```

or if you have the "env" application you can do in any shell

```
        env LC_ALL=en_US.ISO8859-1 perl ...
```

If you do not know what shell you have, consult your local helpdesk or the equivalent.

53.3.6 Permanently fixing locale problems

The slower but superior fixes are when you may be able to yourself fix the misconfiguration of your own environment variables. The mis(sing)configuration of the whole system's locales usually requires the help of your friendly system administrator.

First, see earlier in this document about Finding locales. That tells how to find which locales are really supported–and more importantly, installed–on your system. In our example error message, environment variables affecting the locale are listed in the order of decreasing importance (and unset variables do not matter). Therefore, having LC_ALL set to "En_US" must have been the bad choice, as shown by the error message. First try fixing locale settings listed first.

Second, if using the listed commands you see something **exactly** (prefix matches do not count and case usually counts) like "En_US" without the quotes, then you should be okay because you are using a locale name that should be installed and available in your system. In this case, see Permanently fixing your system's locale configuration.

53.3.7 Permanently fixing your system's locale configuration

This is when you see something like:

```
        perl: warning: Please check that your locale settings:
                LC_ALL = "En_US",
                LANG = (unset)
            are supported and installed on your system.
```

but then cannot see that "En_US" listed by the above-mentioned commands. You may see things like "en_US.ISO8859-1", but that isn't the same. In this case, try running under a locale that you can list and which somehow matches what you tried. The rules for matching locale names are a bit vague because standardization is weak in this area. See again the Finding locales about general rules.

53.3.8 Fixing system locale configuration

Contact a system administrator (preferably your own) and report the exact error message you get, and ask them to read this same documentation you are now reading. They should be able to check whether there is something wrong with the locale configuration of the system. The Finding locales section is unfortunately a bit vague about the exact commands and places because these things are not that standardized.

53.3.9 The localeconv function

The POSIX::localeconv() function allows you to get particulars of the locale-dependent numeric formatting information specified by the current `LC_NUMERIC` and `LC_MONETARY` locales. (If you just want the name of the current locale for a particular category, use POSIX::setlocale() with a single parameter–see The setlocale function.)

```
        use POSIX qw(locale_h);

        # Get a reference to a hash of locale-dependent info
        $locale_values = localeconv();
        # Output sorted list of the values
        for (sort keys %$locale_values) {
            printf "%-20s = %s\n", $_, $locale_values->{$_}
        }
```

localeconv() takes no arguments, and returns **a reference to** a hash. The keys of this hash are variable names for formatting, such as `decimal_point` and `thousands_sep`. The values are the corresponding, er, values. See localeconv in *POSIX* for a longer example listing the categories an implementation might be expected to provide; some provide more and others fewer. You don't need an explicit `use locale`, because localeconv() always observes the current locale.

Here's a simple-minded example program that rewrites its command-line parameters as integers correctly formatted in the current locale:

```
        # See comments in previous example
        require 5.004;
        use POSIX qw(locale_h);

        # Get some of locale's numeric formatting parameters
        my ($thousands_sep, $grouping) =
             @{localeconv()}{'thousands_sep', 'grouping'};

        # Apply defaults if values are missing
        $thousands_sep = ',' unless $thousands_sep;

        # grouping and mon_grouping are packed lists
        # of small integers (characters) telling the
        # grouping (thousand_seps and mon_thousand_seps
        # being the group dividers) of numbers and
        # monetary quantities.  The integers' meanings:
        # 255 means no more grouping, 0 means repeat
        # the previous grouping, 1-254 means use that
        # as the current grouping.  Grouping goes from
        # right to left (low to high digits).  In the
        # below we cheat slightly by never using anything
        # else than the first grouping (whatever that is).
        if ($grouping) {
            @grouping = unpack("C*", $grouping);
        } else {
            @grouping = (3);
        }

        # Format command line params for current locale
        for (@ARGV) {
            $_ = int;    # Chop non-integer part
            1 while
            s/(\d)(\d{$grouping[0]}($|$thousands_sep))/$1$thousands_sep$2/;
            print "$_";
        }
        print "\n";
```

53.3.10 I18N::Langinfo

Another interface for querying locale-dependent information is the I18N::Langinfo::langinfo() function, available at least in UNIX-like systems and VMS.

The following example will import the langinfo() function itself and three constants to be used as arguments to langinfo(): a constant for the abbreviated first day of the week (the numbering starts from Sunday = 1) and two more constants for the affirmative and negative answers for a yes/no question in the current locale.

```
    use I18N::Langinfo qw(langinfo ABDAY_1 YESSTR NOSTR);

    my ($abday_1, $yesstr, $nostr) = map { langinfo } qw(ABDAY_1 YESSTR NOSTR);

    print "$abday_1? [$yesstr/$nostr] ";
```

In other words, in the "C" (or English) locale the above will probably print something like:

```
    Sun? [yes/no]
```

See *I18N::Langinfo* for more information.

53.4 LOCALE CATEGORIES

The following subsections describe basic locale categories. Beyond these, some combination categories allow manipulation of more than one basic category at a time. See §53.6 for a discussion of these.

53.4.1 Category LC_COLLATE: Collation

In the scope of `use locale`, Perl looks to the `LC_COLLATE` environment variable to determine the application's notions on collation (ordering) of characters. For example, 'b' follows 'a' in Latin alphabets, but where do 'á' and 'å' belong? And while 'color' follows 'chocolate' in English, what about in Spanish?

The following collations all make sense and you may meet any of them if you "use locale".

```
        A B C D E a b c d e
        A a B b C c D d E e
        a A b B c C d D e E
        a b c d e A B C D E
```

Here is a code snippet to tell what "word" characters are in the current locale, in that locale's order:

```
        use locale;
        print +(sort grep /\w/, map { chr } 0..255), "\n";
```

Compare this with the characters that you see and their order if you state explicitly that the locale should be ignored:

```
        no locale;
        print +(sort grep /\w/, map { chr } 0..255), "\n";
```

This machine-native collation (which is what you get unless `use locale` has appeared earlier in the same block) must be used for sorting raw binary data, whereas the locale-dependent collation of the first example is useful for natural text.

As noted in USING LOCALES, `cmp` compares according to the current collation locale when `use locale` is in effect, but falls back to a char-by-char comparison for strings that the locale says are equal. You can use POSIX::strcoll() if you don't want this fall-back:

```
        use POSIX qw(strcoll);
        $equal_in_locale =
            !strcoll("space and case ignored", "SpaceAndCaseIgnored");
```

$equal_in_locale will be true if the collation locale specifies a dictionary-like ordering that ignores space characters completely and which folds case.

If you have a single string that you want to check for "equality in locale" against several others, you might think you could gain a little efficiency by using POSIX::strxfrm() in conjunction with `eq`:

```
use POSIX qw(strxfrm);
$xfrm_string = strxfrm("Mixed-case string");
print "locale collation ignores spaces\n"
    if $xfrm_string eq strxfrm("Mixed-casestring");
print "locale collation ignores hyphens\n"
    if $xfrm_string eq strxfrm("Mixedcase string");
print "locale collation ignores case\n"
    if $xfrm_string eq strxfrm("mixed-case string");
```

strxfrm() takes a string and maps it into a transformed string for use in char-by-char comparisons against other transformed strings during collation. "Under the hood", locale-affected Perl comparison operators call strxfrm() for both operands, then do a char-by-char comparison of the transformed strings. By calling strxfrm() explicitly and using a non locale-affected comparison, the example attempts to save a couple of transformations. But in fact, it doesn't save anything: Perl magic (see Magic Variables in *perlguts*) creates the transformed version of a string the first time it's needed in a comparison, then keeps this version around in case it's needed again. An example rewritten the easy way with `cmp` runs just about as fast. It also copes with null characters embedded in strings; if you call strxfrm() directly, it treats the first null it finds as a terminator. don't expect the transformed strings it produces to be portable across systems–or even from one revision of your operating system to the next. In short, don't call strxfrm() directly: let Perl do it for you.

Note: `use locale` isn't shown in some of these examples because it isn't needed: strcoll() and strxfrm() exist only to generate locale-dependent results, and so always obey the current `LC_COLLATE` locale.

53.4.2 Category LC_CTYPE: Character Types

In the scope of `use locale`, Perl obeys the `LC_CTYPE` locale setting. This controls the application's notion of which characters are alphabetic. This affects Perl's `\w` regular expression metanotation, which stands for alphanumeric characters–that is, alphabetic, numeric, and including other special characters such as the underscore or hyphen. (Consult *perlre* for more information about regular expressions.) Thanks to `LC_CTYPE`, depending on your locale setting, characters like 'æ', 'ð', 'ß', and 'ø' may be understood as `\w` characters.

The `LC_CTYPE` locale also provides the map used in transliterating characters between lower and uppercase. This affects the case-mapping functions–lc(), lcfirst, uc(), and ucfirst(); case-mapping interpolation with `\l`, `\L`, `\u`, or `\U` in double-quoted strings and `s///` substitutions; and case-independent regular expression pattern matching using the `i` modifier.

Finally, `LC_CTYPE` affects the POSIX character-class test functions–isalpha(), islower(), and so on. For example, if you move from the "C" locale to a 7-bit Scandinavian one, you may find–possibly to your surprise–that "|" moves from the ispunct() class to isalpha().

Note: A broken or malicious `LC_CTYPE` locale definition may result in clearly ineligible characters being considered to be alphanumeric by your application. For strict matching of (mundane) letters and digits–for example, in command strings–locale-aware applications should use `\w` inside a `no locale` block. See §53.5.

53.4.3 Category LC_NUMERIC: Numeric Formatting

In the scope of `use locale`, Perl obeys the `LC_NUMERIC` locale information, which controls an application's idea of how numbers should be formatted for human readability by the printf(), sprintf(), and write() functions. String-to-numeric conversion by the POSIX::strtod() function is also affected. In most implementations the only effect is to change the character used for the decimal point–perhaps from '.' to ','. These functions aren't aware of such niceties as thousands separation and so on. (See The localeconv function if you care about these things.)

Output produced by print() is also affected by the current locale: it depends on whether `use locale` or `no locale` is in effect, and corresponds to what you'd get from printf() in the "C" locale. The same is true for Perl's internal conversions between numeric and string formats:

```
use POSIX qw(strtod);
use locale;

$n = 5/2;   # Assign numeric 2.5 to $n
```

```
        $a = " $n"; # Locale-dependent conversion to string

        print "half five is $n\n";       # Locale-dependent output

        printf "half five is %g\n", $n;  # Locale-dependent output

        print "DECIMAL POINT IS COMMA\n"
            if $n == (strtod("2,5"))[0]; # Locale-dependent conversion
```

See also *I18N::Langinfo* and `RADIXCHAR`.

53.4.4 Category LC_MONETARY: Formatting of monetary amounts

The C standard defines the `LC_MONETARY` category, but no function that is affected by its contents. (Those with experience of standards committees will recognize that the working group decided to punt on the issue.) Consequently, Perl takes no notice of it. If you really want to use `LC_MONETARY`, you can query its contents–see The localeconv function–and use the information that it returns in your application's own formatting of currency amounts. However, you may well find that the information, voluminous and complex though it may be, still does not quite meet your requirements: currency formatting is a hard nut to crack.

See also *I18N::Langinfo* and `CRNCYSTR`.

53.4.5 LC_TIME

Output produced by POSIX::strftime(), which builds a formatted human-readable date/time string, is affected by the current `LC_TIME` locale. Thus, in a French locale, the output produced by the `%B` format element (full month name) for the first month of the year would be "janvier". Here's how to get a list of long month names in the current locale:

```
        use POSIX qw(strftime);
        for (0..11) {
            $long_month_name[$_] =
                strftime("%B", 0, 0, 0, 1, $_, 96);
        }
```

Note: `use locale` isn't needed in this example: as a function that exists only to generate locale-dependent results, strftime() always obeys the current `LC_TIME` locale.

See also *I18N::Langinfo* and `ABDAY_1..ABDAY_7`, `DAY_1..DAY_7`, `ABMON_1..ABMON_12`, and `ABMON_1..ABMON_12`.

53.4.6 Other categories

The remaining locale category, `LC_MESSAGES` (possibly supplemented by others in particular implementations) is not currently used by Perl–except possibly to affect the behavior of library functions called by extensions outside the standard Perl distribution and by the operating system and its utilities. Note especially that the string value of `$!` and the error messages given by external utilities may be changed by `LC_MESSAGES`. If you want to have portable error codes, use `%!`. See *Errno*.

53.5 SECURITY

Although the main discussion of Perl security issues can be found in *perlsec*, a discussion of Perl's locale handling would be incomplete if it did not draw your attention to locale-dependent security issues. Locales–particularly on systems that allow unprivileged users to build their own locales–are untrustworthy. A malicious (or just plain broken) locale can make a locale-aware application give unexpected results. Here are a few possibilities:

- Regular expression checks for safe file names or mail addresses using `\w` may be spoofed by an `LC_CTYPE` locale that claims that characters such as ">" and "|" are alphanumeric.
- String interpolation with case-mapping, as in, say, `$dest = "C:\U$name.$ext"`, may produce dangerous results if a bogus LC_CTYPE case-mapping table is in effect.
- A sneaky `LC_COLLATE` locale could result in the names of students with "D" grades appearing ahead of those with "A"s.
- An application that takes the trouble to use information in `LC_MONETARY` may format debits as if they were credits and vice versa if that locale has been subverted. Or it might make payments in US dollars instead of Hong Kong dollars.
- The date and day names in dates formatted by strftime() could be manipulated to advantage by a malicious user able to subvert the `LC_DATE` locale. ("Look–it says I wasn't in the building on Sunday.")

Such dangers are not peculiar to the locale system: any aspect of an application's environment which may be modified maliciously presents similar challenges. Similarly, they are not specific to Perl: any programming language that allows you to write programs that take account of their environment exposes you to these issues.

Perl cannot protect you from all possibilities shown in the examples–there is no substitute for your own vigilance–but, when `use locale` is in effect, Perl uses the tainting mechanism (see *perlsec*) to mark string results that become locale-dependent, and which may be untrustworthy in consequence. Here is a summary of the tainting behavior of operators and functions that may be affected by the locale:

- **Comparison operators** (`lt`, `le`, `ge`, `gt` and `cmp`):

  Scalar true/false (or less/equal/greater) result is never tainted.
- **Case-mapping interpolation** (with `\l`, `\L`, `\u` or `\U`)

  Result string containing interpolated material is tainted if `use locale` is in effect.
- **Matching operator** (`m//`):

  Scalar true/false result never tainted.

  Subpatterns, either delivered as a list-context result or as $1 etc. are tainted if `use locale` is in effect, and the subpattern regular expression contains `\w` (to match an alphanumeric character), `\W` (non-alphanumeric character), `\s` (white-space character), or `\S` (non white-space character). The matched-pattern variable, $&, $‘ (pre-match), $’ (post-match), and $+ (last match) are also tainted if `use locale` is in effect and the regular expression contains `\w`, `\W`, `\s`, or `\S`.
- **Substitution operator** (`s///`):

  Has the same behavior as the match operator. Also, the left operand of `=~` becomes tainted when `use locale` in effect if modified as a result of a substitution based on a regular expression match involving `\w`, `\W`, `\s`, or `\S`; or of case-mapping with `\l`, `\L`,`\u` or `\U`.
- **Output formatting functions** (printf() and write()):

  Results are never tainted because otherwise even output from print, for example `print(1/7)`, should be tainted if `use locale` is in effect.
- **Case-mapping functions** (lc(), lcfirst(), uc(), ucfirst()):

  Results are tainted if `use locale` is in effect.
- **POSIX locale-dependent functions** (localeconv(), strcoll(), strftime(), strxfrm()):

  Results are never tainted.
- **POSIX character class tests** (isalnum(), isalpha(), isdigit(), isgraph(), islower(), isprint(), ispunct(), isspace(), isupper(), isxdigit()):

  True/false results are never tainted.

Three examples illustrate locale-dependent tainting. The first program, which ignores its locale, won't run: a value taken directly from the command line may not be used to name an output file when taint checks are enabled.

```
#/usr/local/bin/perl -T
# Run with taint checking

# Command line sanity check omitted...
$tainted_output_file = shift;

open(F, ">$tainted_output_file")
    or warn "Open of $untainted_output_file failed: $!\n";
```

The program can be made to run by "laundering" the tainted value through a regular expression: the second example–which still ignores locale information–runs, creating the file named on its command line if it can.

```
#/usr/local/bin/perl -T

$tainted_output_file = shift;
$tainted_output_file =~ m%[\w/]+%;
$untainted_output_file = $&;

open(F, ">$untainted_output_file")
    or warn "Open of $untainted_output_file failed: $!\n";
```

Compare this with a similar but locale-aware program:

```
#/usr/local/bin/perl -T

$tainted_output_file = shift;
use locale;
$tainted_output_file =~ m%[\w/]+%;
$localized_output_file = $&;

open(F, ">$localized_output_file")
    or warn "Open of $localized_output_file failed: $!\n";
```

This third program fails to run because $& is tainted: it is the result of a match involving `\w` while `use locale` is in effect.

53.6 ENVIRONMENT

PERL_BADLANG

A string that can suppress Perl's warning about failed locale settings at startup. Failure can occur if the locale support in the operating system is lacking (broken) in some way–or if you mistyped the name of a locale when you set up your environment. If this environment variable is absent, or has a value that does not evaluate to integer zero–that is, "0" or ""– Perl will complain about locale setting failures.

NOTE: PERL_BADLANG only gives you a way to hide the warning message. The message tells about some problem in your system's locale support, and you should investigate what the problem is.

The following environment variables are not specific to Perl: They are part of the standardized (ISO C, XPG4, POSIX 1.c) setlocale() method for controlling an application's opinion on data.

LC_ALL

LC_ALL is the "override-all" locale environment variable. If set, it overrides all the rest of the locale environment variables.

LANGUAGE

NOTE: LANGUAGE is a GNU extension, it affects you only if you are using the GNU libc. This is the case if you are using e.g. Linux. If you are using "commercial" UNIXes you are most probably *not* using GNU libc and you can ignore LANGUAGE.

However, in the case you are using LANGUAGE: it affects the language of informational, warning, and error messages output by commands (in other words, it's like LC_MESSAGES) but it has higher priority than LC_ALL. Moreover, it's not a single value but instead a "path" (":"-separated list) of *languages* (not locales). See the GNU gettext library documentation for more information.

LC_CTYPE

In the absence of LC_ALL, LC_CTYPE chooses the character type locale. In the absence of both LC_ALL and LC_CTYPE, LANG chooses the character type locale.

LC_COLLATE

In the absence of LC_ALL, LC_COLLATE chooses the collation (sorting) locale. In the absence of both LC_ALL and LC_COLLATE, LANG chooses the collation locale.

LC_MONETARY

In the absence of LC_ALL, LC_MONETARY chooses the monetary formatting locale. In the absence of both LC_ALL and LC_MONETARY, LANG chooses the monetary formatting locale.

LC_NUMERIC

In the absence of LC_ALL, LC_NUMERIC chooses the numeric format locale. In the absence of both LC_ALL and LC_NUMERIC, LANG chooses the numeric format.

LC_TIME

In the absence of LC_ALL, LC_TIME chooses the date and time formatting locale. In the absence of both LC_ALL and LC_TIME, LANG chooses the date and time formatting locale.

LANG

LANG is the "catch-all" locale environment variable. If it is set, it is used as the last resort after the overall LC_ALL and the category-specific LC_....

53.7 NOTES

53.7.1 Backward compatibility

Versions of Perl prior to 5.004 **mostly** ignored locale information, generally behaving as if something similar to the "C" locale were always in force, even if the program environment suggested otherwise (see The setlocale function). By default, Perl still behaves this way for backward compatibility. If you want a Perl application to pay attention to locale information, you **must** use the use locale pragma (see The use locale pragma) to instruct it to do so.

Versions of Perl from 5.002 to 5.003 did use the LC_CTYPE information if available; that is, \w did understand what were the letters according to the locale environment variables. The problem was that the user had no control over the feature: if the C library supported locales, Perl used them.

53.7.2 I18N:Collate obsolete

In versions of Perl prior to 5.004, per-locale collation was possible using the I18N::Collate library module. This module is now mildly obsolete and should be avoided in new applications. The LC_COLLATE functionality is now integrated into the Perl core language: One can use locale-specific scalar data completely normally with use locale, so there is no longer any need to juggle with the scalar references of I18N::Collate.

53.7.3 Sort speed and memory use impacts

Comparing and sorting by locale is usually slower than the default sorting; slow-downs of two to four times have been observed. It will also consume more memory: once a Perl scalar variable has participated in any string comparison or sorting operation obeying the locale collation rules, it will take 3-15 times more memory than before. (The exact multiplier depends on the string's contents, the operating system and the locale.) These downsides are dictated more by the operating system's implementation of the locale system than by Perl.

53.7.4 write() and LC_NUMERIC

Formats are the only part of Perl that unconditionally use information from a program's locale; if a program's environment specifies an LC_NUMERIC locale, it is always used to specify the decimal point character in formatted output. Formatted output cannot be controlled by `use locale` because the pragma is tied to the block structure of the program, and, for historical reasons, formats exist outside that block structure.

53.7.5 Freely available locale definitions

There is a large collection of locale definitions at ftp://dkuug.dk/i18n/WG15-collection . You should be aware that it is unsupported, and is not claimed to be fit for any purpose. If your system allows installation of arbitrary locales, you may find the definitions useful as they are, or as a basis for the development of your own locales.

53.7.6 I18n and l10n

"Internationalization" is often abbreviated as **i18n** because its first and last letters are separated by eighteen others. (You may guess why the internalin ... internaliti ... i18n tends to get abbreviated.) In the same way, "localization" is often abbreviated to **l10n**.

53.7.7 An imperfect standard

Internationalization, as defined in the C and POSIX standards, can be criticized as incomplete, ungainly, and having too large a granularity. (Locales apply to a whole process, when it would arguably be more useful to have them apply to a single thread, window group, or whatever.) They also have a tendency, like standards groups, to divide the world into nations, when we all know that the world can equally well be divided into bankers, bikers, gamers, and so on. But, for now, it's the only standard we've got. This may be construed as a bug.

53.8 Unicode and UTF-8

The support of Unicode is new starting from Perl version 5.6, and more fully implemented in the version 5.8. See *perluniintro* and *perlunicode* for more details.

Usually locale settings and Unicode do not affect each other, but there are exceptions, see Locales in *perlunicode* for examples.

53.9 BUGS

53.9.1 Broken systems

In certain systems, the operating system's locale support is broken and cannot be fixed or used by Perl. Such deficiencies can and will result in mysterious hangs and/or Perl core dumps when the `use locale` is in effect. When confronted with such a system, please report in excruciating detail to <*perlbug@perl.org*>, and complain to your vendor: bug fixes may exist for these problems in your operating system. Sometimes such bug fixes are called an operating system upgrade.

Chapter 54

perluniintro

Perl Unicode introduction

54.1 DESCRIPTION

This document gives a general idea of Unicode and how to use Unicode in Perl.

54.1.1 Unicode

Unicode is a character set standard which plans to codify all of the writing systems of the world, plus many other symbols.

Unicode and ISO/IEC 10646 are coordinated standards that provide code points for characters in almost all modern character set standards, covering more than 30 writing systems and hundreds of languages, including all commercially-important modern languages. All characters in the largest Chinese, Japanese, and Korean dictionaries are also encoded. The standards will eventually cover almost all characters in more than 250 writing systems and thousands of languages. Unicode 1.0 was released in October 1991, and 4.0 in April 2003.

A Unicode *character* is an abstract entity. It is not bound to any particular integer width, especially not to the C language `char`. Unicode is language-neutral and display-neutral: it does not encode the language of the text and it does not define fonts or other graphical layout details. Unicode operates on characters and on text built from those characters.

Unicode defines characters like `LATIN CAPITAL LETTER A` or `GREEK SMALL LETTER ALPHA` and unique numbers for the characters, in this case 0x0041 and 0x03B1, respectively. These unique numbers are called *code points*.

The Unicode standard prefers using hexadecimal notation for the code points. If numbers like `0x0041` are unfamiliar to you, take a peek at a later section, §54.1.14. The Unicode standard uses the notation `U+0041 LATIN CAPITAL LETTER A`, to give the hexadecimal code point and the normative name of the character.

Unicode also defines various *properties* for the characters, like "uppercase" or "lowercase", "decimal digit", or "punctuation"; these properties are independent of the names of the characters. Furthermore, various operations on the characters like uppercasing, lowercasing, and collating (sorting) are defined.

A Unicode character consists either of a single code point, or a *base character* (like `LATIN CAPITAL LETTER A`), followed by one or more *modifiers* (like `COMBINING ACUTE ACCENT`). This sequence of base character and modifiers is called a *combining character sequence*.

Whether to call these combining character sequences "characters" depends on your point of view. If you are a programmer, you probably would tend towards seeing each element in the sequences as one unit, or "character". The whole sequence could be seen as one "character", however, from the user's point of view, since that's probably what it looks like in the context of the user's language.

With this "whole sequence" view of characters, the total number of characters is open-ended. But in the programmer's "one unit is one character" point of view, the concept of "characters" is more deterministic. In this document, we take that second point of view: one "character" is one Unicode code point, be it a base character or a combining character.

For some combinations, there are *precomposed* characters. `LATIN CAPITAL LETTER A WITH ACUTE`, for example, is defined as a single code point. These precomposed characters are, however, only available for some combinations, and are mainly meant to support round-trip conversions between Unicode and legacy standards (like the ISO 8859). In the general case, the composing method is more extensible. To support conversion between different compositions of the characters, various *normalization forms* to standardize representations are also defined.

Because of backward compatibility with legacy encodings, the "a unique number for every character" idea breaks down a bit: instead, there is "at least one number for every character". The same character could be represented differently in several legacy encodings. The converse is also not true: some code points do not have an assigned character. Firstly, there are unallocated code points within otherwise used blocks. Secondly, there are special Unicode control characters that do not represent true characters.

A common myth about Unicode is that it would be "16-bit", that is, Unicode is only represented as `0x10000` (or 65536) characters from `0x0000` to `0xFFFF`. **This is untrue.** Since Unicode 2.0 (July 1996), Unicode has been defined all the way up to 21 bits (`0x10FFFF`), and since Unicode 3.1 (March 2001), characters have been defined beyond `0xFFFF`. The first `0x10000` characters are called the *Plane 0*, or the *Basic Multilingual Plane* (BMP). With Unicode 3.1, 17 (yes, seventeen) planes in all were defined–but they are nowhere near full of defined characters, yet.

Another myth is that the 256-character blocks have something to do with languages–that each block would define the characters used by a language or a set of languages. **This is also untrue.** The division into blocks exists, but it is almost completely accidental–an artifact of how the characters have been and still are allocated. Instead, there is a concept called *scripts*, which is more useful: there is `Latin` script, `Greek` script, and so on. Scripts usually span varied parts of several blocks. For further information see *Unicode::UCD*.

The Unicode code points are just abstract numbers. To input and output these abstract numbers, the numbers must be *encoded* or *serialised* somehow. Unicode defines several *character encoding forms*, of which *UTF-8* is perhaps the most popular. UTF-8 is a variable length encoding that encodes Unicode characters as 1 to 6 bytes (only 4 with the currently defined characters). Other encodings include UTF-16 and UTF-32 and their big- and little-endian variants (UTF-8 is byte-order independent) The ISO/IEC 10646 defines the UCS-2 and UCS-4 encoding forms.

For more information about encodings–for instance, to learn what *surrogates* and *byte order marks* (BOMs) are–see *perlunicode*.

54.1.2 Perl's Unicode Support

Starting from Perl 5.6.0, Perl has had the capacity to handle Unicode natively. Perl 5.8.0, however, is the first recommended release for serious Unicode work. The maintenance release 5.6.1 fixed many of the problems of the initial Unicode implementation, but for example regular expressions still do not work with Unicode in 5.6.1.

Starting from Perl 5.8.0, the use of `use utf8` is no longer necessary. In earlier releases the `utf8` pragma was used to declare that operations in the current block or file would be Unicode-aware. This model was found to be wrong, or at least clumsy: the "Unicodeness" is now carried with the data, instead of being attached to the operations. Only one case remains where an explicit `use utf8` is needed: if your Perl script itself is encoded in UTF-8, you can use UTF-8 in your identifier names, and in string and regular expression literals, by saying `use utf8`. This is not the default because scripts with legacy 8-bit data in them would break. See *utf8*.

54.1.3 Perl's Unicode Model

Perl supports both pre-5.6 strings of eight-bit native bytes, and strings of Unicode characters. The principle is that Perl tries to keep its data as eight-bit bytes for as long as possible, but as soon as Unicodeness cannot be avoided, the data is transparently upgraded to Unicode.

Internally, Perl currently uses either whatever the native eight-bit character set of the platform (for example Latin-1) is, defaulting to UTF-8, to encode Unicode strings. Specifically, if all code points in the string are `0xFF` or less, Perl uses the native eight-bit character set. Otherwise, it uses UTF-8.

A user of Perl does not normally need to know nor care how Perl happens to encode its internal strings, but it becomes relevant when outputting Unicode strings to a stream without a PerlIO layer – one with the "default" encoding. In such a case, the raw bytes used internally (the native character set or UTF-8, as appropriate for each string) will be used, and a "Wide character" warning will be issued if those strings contain a character beyond 0x00FF.

For example,

```
    perl -e 'print "\x{DF}\n", "\x{0100}\x{DF}\n"'
```

produces a fairly useless mixture of native bytes and UTF-8, as well as a warning:

```
    Wide character in print at ...
```

To output UTF-8, use the `:utf8` output layer. Prepending

```
    binmode(STDOUT, ":utf8");
```

to this sample program ensures that the output is completely UTF-8, and removes the program's warning.

You can enable automatic UTF-8-ification of your standard file handles, default `open()` layer, and `@ARGV` by using either the `-C` command line switch or the `PERL_UNICODE` environment variable, see *perlrun* for the documentation of the `-C` switch.

Note that this means that Perl expects other software to work, too: if Perl has been led to believe that STDIN should be UTF-8, but then STDIN coming in from another command is not UTF-8, Perl will complain about the malformed UTF-8.

All features that combine Unicode and I/O also require using the new PerlIO feature. Almost all Perl 5.8 platforms do use PerlIO, though: you can see whether yours is by running "perl -V" and looking for `useperlio=define`.

54.1.4 Unicode and EBCDIC

Perl 5.8.0 also supports Unicode on EBCDIC platforms. There, Unicode support is somewhat more complex to implement since additional conversions are needed at every step. Some problems remain, see *perlebcdic* for details.

In any case, the Unicode support on EBCDIC platforms is better than in the 5.6 series, which didn't work much at all for EBCDIC platform. On EBCDIC platforms, the internal Unicode encoding form is UTF-EBCDIC instead of UTF-8. The difference is that as UTF-8 is "ASCII-safe" in that ASCII characters encode to UTF-8 as-is, while UTF-EBCDIC is "EBCDIC-safe".

54.1.5 Creating Unicode

To create Unicode characters in literals for code points above `0xFF`, use the `\x{...}` notation in double-quoted strings:

```
    my $smiley = "\x{263a}";
```

Similarly, it can be used in regular expression literals

```
    $smiley =~ /\x{263a}/;
```

At run-time you can use `chr()`:

```
    my $hebrew_alef = chr(0x05d0);
```

See §54.1.15 for how to find all these numeric codes.

Naturally, `ord()` will do the reverse: it turns a character into a code point.

Note that `\x..` (no `{}` and only two hexadecimal digits), `\x{...}`, and `chr(...)` for arguments less than `0x100` (decimal 256) generate an eight-bit character for backward compatibility with older Perls. For arguments of `0x100` or more, Unicode characters are always produced. If you want to force the production of Unicode characters regardless of the numeric value, use `pack("U", ...)` instead of `\x..`, `\x{...}`, or `chr()`.

You can also use the `charnames` pragma to invoke characters by name in double-quoted strings:

```
    use charnames ':full';
    my $arabic_alef = "\N{ARABIC LETTER ALEF}";
```

And, as mentioned above, you can also `pack()` numbers into Unicode characters:

```
   my $georgian_an  = pack("U", 0x10a0);
```

Note that both `\x{...}` and `\N{...}` are compile-time string constants: you cannot use variables in them. if you want similar run-time functionality, use `chr()` and `charnames::vianame()`.

If you want to force the result to Unicode characters, use the special `"U0"` prefix. It consumes no arguments but forces the result to be in Unicode characters, instead of bytes.

```
   my $chars = pack("U0C*", 0x80, 0x42);
```

Likewise, you can force the result to be bytes by using the special `"C0"` prefix.

54.1.6 Handling Unicode

Handling Unicode is for the most part transparent: just use the strings as usual. Functions like `index()`, `length()`, and `substr()` will work on the Unicode characters; regular expressions will work on the Unicode characters (see *perlunicode* and *perlretut*).

Note that Perl considers combining character sequences to be separate characters, so for example

```
    use charnames ':full';
    print length("\N{LATIN CAPITAL LETTER A}\N{COMBINING ACUTE ACCENT}"), "\n";
```

will print 2, not 1. The only exception is that regular expressions have `\X` for matching a combining character sequence.

Life is not quite so transparent, however, when working with legacy encodings, I/O, and certain special cases:

54.1.7 Legacy Encodings

When you combine legacy data and Unicode the legacy data needs to be upgraded to Unicode. Normally ISO 8859-1 (or EBCDIC, if applicable) is assumed. You can override this assumption by using the `encoding` pragma, for example

```
    use encoding 'latin2'; # ISO 8859-2
```

in which case literals (string or regular expressions), `chr()`, and `ord()` in your whole script are assumed to produce Unicode characters from ISO 8859-2 code points. Note that the matching for encoding names is forgiving: instead of `latin2` you could have said `Latin 2`, or `iso8859-2`, or other variations. With just

```
    use encoding;
```

the environment variable `PERL_ENCODING` will be consulted. If that variable isn't set, the encoding pragma will fail.

The `Encode` module knows about many encodings and has interfaces for doing conversions between those encodings:

```
    use Encode 'decode';
    $data = decode("iso-8859-3", $data); # convert from legacy to utf-8
```

54.1.8 Unicode I/O

Normally, writing out Unicode data

```
    print FH $some_string_with_unicode, "\n";
```

produces raw bytes that Perl happens to use to internally encode the Unicode string. Perl's internal encoding depends on the system as well as what characters happen to be in the string at the time. If any of the characters are at code points `0x100` or above, you will get a warning. To ensure that the output is explicitly rendered in the encoding you desire–and to avoid the warning–open the stream with the desired encoding. Some examples:

```
    open FH, ">:utf8", "file";

    open FH, ">:encoding(ucs2)",      "file";
    open FH, ">:encoding(UTF-8)",     "file";
    open FH, ">:encoding(shift_jis)", "file";
```

and on already open streams, use `binmode()`:

```
    binmode(STDOUT, ":utf8");

    binmode(STDOUT, ":encoding(ucs2)");
    binmode(STDOUT, ":encoding(UTF-8)");
    binmode(STDOUT, ":encoding(shift_jis)");
```

The matching of encoding names is loose: case does not matter, and many encodings have several aliases. Note that the `:utf8` layer must always be specified exactly like that; it is *not* subject to the loose matching of encoding names.

See *PerlIO* for the `:utf8` layer, *PerlIO::encoding* and *Encode::PerlIO* for the `:encoding()` layer, and *Encode::Supported* for many encodings supported by the `Encode` module.

Reading in a file that you know happens to be encoded in one of the Unicode or legacy encodings does not magically turn the data into Unicode in Perl's eyes. To do that, specify the appropriate layer when opening files

```
    open(my $fh,'<:utf8', 'anything');
    my $line_of_unicode = <$fh>;

    open(my $fh,'<:encoding(Big5)', 'anything');
    my $line_of_unicode = <$fh>;
```

The I/O layers can also be specified more flexibly with the `open` pragma. See *open*, or look at the following example.

```
    use open ':utf8'; # input and output default layer will be UTF-8
    open X, ">file";
    print X chr(0x100), "\n";
    close X;
    open Y, "<file";
    printf "%#x\n", ord(<Y>); # this should print 0x100
    close Y;
```

With the `open` pragma you can use the `:locale` layer

```
    BEGIN { $ENV{LC_ALL} = $ENV{LANG} = 'ru_RU.KOI8-R' }
    # the :locale will probe the locale environment variables like LC_ALL
    use open OUT => ':locale'; # russki parusski
    open(O, ">koi8");
    print O chr(0x430); # Unicode CYRILLIC SMALL LETTER A = KOI8-R 0xc1
    close O;
    open(I, "<koi8");
    printf "%#x\n", ord(<I>), "\n"; # this should print 0xc1
    close I;
```

or you can also use the `':encoding(...)'` layer

```
    open(my $epic,'<:encoding(iso-8859-7)','iliad.greek');
    my $line_of_unicode = <$epic>;
```

These methods install a transparent filter on the I/O stream that converts data from the specified encoding when it is read in from the stream. The result is always Unicode.

The *open* pragma affects all the `open()` calls after the pragma by setting default layers. If you want to affect only certain streams, use explicit layers directly in the `open()` call.

You can switch encodings on an already opened stream by using `binmode()`; see binmode in *perlfunc*.

The `:locale` does not currently (as of Perl 5.8.0) work with `open()` and `binmode()`, only with the `open` pragma. The `:utf8` and `:encoding(...)` methods do work with all of `open()`, `binmode()`, and the `open` pragma.

Similarly, you may use these I/O layers on output streams to automatically convert Unicode to the specified encoding when it is written to the stream. For example, the following snippet copies the contents of the file "text.jis" (encoded as ISO-2022-JP, aka JIS) to the file "text.utf8", encoded as UTF-8:

```
    open(my $nihongo, '<:encoding(iso-2022-jp)', 'text.jis');
    open(my $unicode, '>:utf8',                  'text.utf8');
    while (<$nihongo>) { print $unicode $_ }
```

The naming of encodings, both by the `open()` and by the `open` pragma, is similar to the `encoding` pragma in that it allows for flexible names: `koi8-r` and `KOI8R` will both be understood.

Common encodings recognized by ISO, MIME, IANA, and various other standardisation organisations are recognised; for a more detailed list see *Encode::Supported*.

`read()` reads characters and returns the number of characters. `seek()` and `tell()` operate on byte counts, as do `sysread()` and `sysseek()`.

Notice that because of the default behaviour of not doing any conversion upon input if there is no default layer, it is easy to mistakenly write code that keeps on expanding a file by repeatedly encoding the data:

```
    # BAD CODE WARNING
    open F, "file";
    local $/; ## read in the whole file of 8-bit characters
    $t = <F>;
    close F;
    open F, ">:utf8", "file";
    print F $t; ## convert to UTF-8 on output
    close F;
```

If you run this code twice, the contents of the *file* will be twice UTF-8 encoded. A `use open ':utf8'` would have avoided the bug, or explicitly opening also the *file* for input as UTF-8.

NOTE: the `:utf8` and `:encoding` features work only if your Perl has been built with the new PerlIO feature (which is the default on most systems).

54.1.9 Displaying Unicode As Text

Sometimes you might want to display Perl scalars containing Unicode as simple ASCII (or EBCDIC) text. The following subroutine converts its argument so that Unicode characters with code points greater than 255 are displayed as `\x{...}`, control characters (like `\n`) are displayed as `\x..`, and the rest of the characters as themselves:

```
sub nice_string {
    join("",
      map { $_ > 255 ?                  # if wide character...
            sprintf("\\x{%04X}", $_) :  # \x{...}
            chr($_) =~ /[[:cntrl:]]/ ?  # else if control character ...
            sprintf("\\x%02X", $_) :    # \x..
            quotemeta(chr($_))          # else quoted or as themselves
      } unpack("U*", $_[0]));           # unpack Unicode characters
}
```

For example,

```
nice_string("foo\x{100}bar\n")
```

returns the string

```
'foo\x{0100}bar\x0A'
```

which is ready to be printed.

54.1.10 Special Cases

- Bit Complement Operator ~ And vec()

  The bit complement operator ~ may produce surprising results if used on strings containing characters with ordinal values above 255. In such a case, the results are consistent with the internal encoding of the characters, but not with much else. So don't do that. Similarly for `vec()`: you will be operating on the internally-encoded bit patterns of the Unicode characters, not on the code point values, which is very probably not what you want.

- Peeking At Perl's Internal Encoding

  Normal users of Perl should never care how Perl encodes any particular Unicode string (because the normal ways to get at the contents of a string with Unicode–via input and output–should always be via explicitly-defined I/O layers). But if you must, there are two ways of looking behind the scenes.

  One way of peeking inside the internal encoding of Unicode characters is to use `unpack("C*", ...` to get the bytes or `unpack("H*", ...)` to display the bytes:

  ```
  # this prints  c4 80  for the UTF-8 bytes 0xc4 0x80
  print join(" ", unpack("H*", pack("U", 0x100))), "\n";
  ```

  Yet another way would be to use the Devel::Peek module:

  ```
  perl -MDevel::Peek -e 'Dump(chr(0x100))'
  ```

  That shows the `UTF8` flag in FLAGS and both the UTF-8 bytes and Unicode characters in `PV`. See also later in this document the discussion about the `utf8::is_utf8()` function.

54.1.11 Advanced Topics

- String Equivalence

  The question of string equivalence turns somewhat complicated in Unicode: what do you mean by "equal"?

  (Is `LATIN CAPITAL LETTER A WITH ACUTE` equal to `LATIN CAPITAL LETTER A`?)

  The short answer is that by default Perl compares equivalence (`eq`, `ne`) based only on code points of the characters. In the above case, the answer is no (because 0x00C1 != 0x0041). But sometimes, any CAPITAL LETTER As should be considered equal, or even As of any case.

  The long answer is that you need to consider character normalization and casing issues: see *Unicode::Normalize*, Unicode Technical Reports #15 and #21, *Unicode Normalization Forms* and *Case Mappings*, http://www.unicode.org/unicode/reports/tr15/ and http://www.unicode.org/unicode/reports/tr21/

  As of Perl 5.8.0, the "Full" case-folding of *Case Mappings/SpecialCasing* is implemented.

- String Collation

  People like to see their strings nicely sorted–or as Unicode parlance goes, collated. But again, what do you mean by collate?

  (Does `LATIN CAPITAL LETTER A WITH ACUTE` come before or after `LATIN CAPITAL LETTER A WITH GRAVE`?)

  The short answer is that by default, Perl compares strings (`lt`, `le`, `cmp`, `ge`, `gt`) based only on the code points of the characters. In the above case, the answer is "after", since `0x00C1` > `0x00C0`.

  The long answer is that "it depends", and a good answer cannot be given without knowing (at the very least) the language context. See *Unicode::Collate*, and *Unicode Collation Algorithm* http://www.unicode.org/unicode/reports/tr10/

54.1.12 Miscellaneous

- Character Ranges and Classes

  Character ranges in regular expression character classes (`/[a-z]/`) and in the `tr///` (also known as `y///`) operator are not magically Unicode-aware. What this means that `[A-Za-z]` will not magically start to mean "all alphabetic letters"; not that it does mean that even for 8-bit characters, you should be using `/[[:alpha:]]/` in that case.

  For specifying character classes like that in regular expressions, you can use the various Unicode properties–`\pL`, or perhaps `\p{Alphabetic}`, in this particular case. You can use Unicode code points as the end points of character ranges, but there is no magic associated with specifying a certain range. For further information–there are dozens of Unicode character classes–see *perlunicode*.

- String-To-Number Conversions

  Unicode does define several other decimal–and numeric–characters besides the familiar 0 to 9, such as the Arabic and Indic digits. Perl does not support string-to-number conversion for digits other than ASCII 0 to 9 (and ASCII a to f for hexadecimal).

54.1.13 Questions With Answers

- Will My Old Scripts Break?

  Very probably not. Unless you are generating Unicode characters somehow, old behaviour should be preserved. About the only behaviour that has changed and which could start generating Unicode is the old behaviour of `chr()` where supplying an argument more than 255 produced a character modulo 255. `chr(300)`, for example, was equal to `chr(45)` or "-" (in ASCII), now it is LATIN CAPITAL LETTER I WITH BREVE.

- How Do I Make My Scripts Work With Unicode?

  Very little work should be needed since nothing changes until you generate Unicode data. The most important thing is getting input as Unicode; for that, see the earlier I/O discussion.

- How Do I Know Whether My String Is In Unicode?

  You shouldn't care. No, you really shouldn't. No, really. If you have to care–beyond the cases described above–it means that we didn't get the transparency of Unicode quite right.

  Okay, if you insist:

  ```
  print utf8::is_utf8($string) ? 1 : 0, "\n";
  ```

  But note that this doesn't mean that any of the characters in the string are necessary UTF-8 encoded, or that any of the characters have code points greater than 0xFF (255) or even 0x80 (128), or that the string has any characters at all. All the `is_utf8()` does is to return the value of the internal "utf8ness" flag attached to the `$string`. If the flag is off, the bytes in the scalar are interpreted as a single byte encoding. If the flag is on, the bytes in the scalar are interpreted as the (multi-byte, variable-length) UTF-8 encoded code points of the characters. Bytes added to an

UTF-8 encoded string are automatically upgraded to UTF-8. If mixed non-UTF-8 and UTF-8 scalars are merged (double-quoted interpolation, explicit concatenation, and printf/sprintf parameter substitution), the result will be UTF-8 encoded as if copies of the byte strings were upgraded to UTF-8: for example,

```
$a = "ab\x80c";
$b = "\x{100}";
print "$a = $b\n";
```

the output string will be UTF-8-encoded `ab\x80c = \x{100}\n`, but `$a` will stay byte-encoded.

Sometimes you might really need to know the byte length of a string instead of the character length. For that use either the `Encode::encode_utf8()` function or the `bytes` pragma and its only defined function `length()`:

```
my $unicode = chr(0x100);
print length($unicode), "\n"; # will print 1
require Encode;
print length(Encode::encode_utf8($unicode)), "\n"; # will print 2
use bytes;
print length($unicode), "\n"; # will also print 2
                              # (the 0xC4 0x80 of the UTF-8)
```

- How Do I Detect Data That's Not Valid In a Particular Encoding?

  Use the `Encode` package to try converting it. For example,

```
use Encode 'decode_utf8';
if (decode_utf8($string_of_bytes_that_I_think_is_utf8)) {
    # valid
} else {
    # invalid
}
```

  For UTF-8 only, you can use:

```
use warnings;
@chars = unpack("U0U*", $string_of_bytes_that_I_think_is_utf8);
```

  If invalid, a `Malformed UTF-8 character (byte 0x##) in unpack` warning is produced. The "U0" means "expect strictly UTF-8 encoded Unicode". Without that the `unpack("U*", ...)` would accept also data like `chr(0xFF)`, similarly to the `pack` as we saw earlier.

- How Do I Convert Binary Data Into a Particular Encoding, Or Vice Versa?

  This probably isn't as useful as you might think. Normally, you shouldn't need to.

  In one sense, what you are asking doesn't make much sense: encodings are for characters, and binary data are not "characters", so converting "data" into some encoding isn't meaningful unless you know in what character set and encoding the binary data is in, in which case it's not just binary data, now is it?

  If you have a raw sequence of bytes that you know should be interpreted via a particular encoding, you can use `Encode`:

```
use Encode 'from_to';
from_to($data, "iso-8859-1", "utf-8"); # from latin-1 to utf-8
```

  The call to `from_to()` changes the bytes in `$data`, but nothing material about the nature of the string has changed as far as Perl is concerned. Both before and after the call, the string `$data` contains just a bunch of 8-bit bytes. As far as Perl is concerned, the encoding of the string remains as "system-native 8-bit bytes".

  You might relate this to a fictional 'Translate' module:

```
use Translate;
my $phrase = "Yes";
Translate::from_to($phrase, 'english', 'deutsch');
## phrase now contains "Ja"
```

The contents of the string changes, but not the nature of the string. Perl doesn't know any more after the call than before that the contents of the string indicates the affirmative.

Back to converting data. If you have (or want) data in your system's native 8-bit encoding (e.g. Latin-1, EBCDIC, etc.), you can use pack/unpack to convert to/from Unicode.

```
$native_string  = pack("C*", unpack("U*", $Unicode_string));
$Unicode_string = pack("U*", unpack("C*", $native_string));
```

If you have a sequence of bytes you **know** is valid UTF-8, but Perl doesn't know it yet, you can make Perl a believer, too:

```
use Encode 'decode_utf8';
$Unicode = decode_utf8($bytes);
```

You can convert well-formed UTF-8 to a sequence of bytes, but if you just want to convert random binary data into UTF-8, you can't. **Any random collection of bytes isn't well-formed UTF-8**. You can use `unpack("C*", $string)` for the former, and you can create well-formed Unicode data by `pack("U*", 0xff, ...)`.

- How Do I Display Unicode? How Do I Input Unicode?

  See http://www.alanwood.net/unicode/ and http://www.cl.cam.ac.uk/˜mgk25/unicode.html

- How Does Unicode Work With Traditional Locales?

  In Perl, not very well. Avoid using locales through the `locale` pragma. Use only one or the other. But see *perlrun* for the description of the `-C` switch and its environment counterpart, `$ENV{PERL_UNICODE}` to see how to enable various Unicode features, for example by using locale settings.

54.1.14 Hexadecimal Notation

The Unicode standard prefers using hexadecimal notation because that more clearly shows the division of Unicode into blocks of 256 characters. Hexadecimal is also simply shorter than decimal. You can use decimal notation, too, but learning to use hexadecimal just makes life easier with the Unicode standard. The `U+HHHH` notation uses hexadecimal, for example.

The `0x` prefix means a hexadecimal number, the digits are 0-9 *and* a-f (or A-F, case doesn't matter). Each hexadecimal digit represents four bits, or half a byte. `print 0x..., "\n"` will show a hexadecimal number in decimal, and `printf "%x\n", $decimal` will show a decimal number in hexadecimal. If you have just the "hex digits" of a hexadecimal number, you can use the `hex()` function.

```
print 0x0009, "\n";    # 9
print 0x000a, "\n";    # 10
print 0x000f, "\n";    # 15
print 0x0010, "\n";    # 16
print 0x0011, "\n";    # 17
print 0x0100, "\n";    # 256

print 0x0041, "\n";    # 65

printf "%x\n",  65;    # 41
printf "%#x\n", 65;    # 0x41

print hex("41"), "\n"; # 65
```

  http://www.cl.cam.ac.uk/~mgk25/unicode.html
  ```

- Legacy Character Sets

  ```
  http://www.czyborra.com/
  http://www.eki.ee/letter/
  ```

- The Unicode support files live within the Perl installation in the directory

  ```
  $Config{installprivlib}/unicore
  ```

  in Perl 5.8.0 or newer, and

  ```
  $Config{installprivlib}/unicode
  ```

  in the Perl 5.6 series. (The renaming to *lib/unicore* was done to avoid naming conflicts with lib/Unicode in case-insensitive filesystems.) The main Unicode data file is *UnicodeData.txt* (or *Unicode.301* in Perl 5.6.1.) You can find the `$Config{installprivlib}` by

  ```
  perl "-V:installprivlib"
  ```

  You can explore various information from the Unicode data files using the `Unicode::UCD` module.

54.2 UNICODE IN OLDER PERLS

If you cannot upgrade your Perl to 5.8.0 or later, you can still do some Unicode processing by using the modules `Unicode::String`, `Unicode::Map8`, and `Unicode::Map`, available from CPAN. If you have the GNU recode installed, you can also use the Perl front-end `Convert::Recode` for character conversions.

The following are fast conversions from ISO 8859-1 (Latin-1) bytes to UTF-8 bytes and back, the code works even with older Perl 5 versions.

```
# ISO 8859-1 to UTF-8
s/([\x80-\xFF])/chr(0xC0|ord($1)>>6).chr(0x80|ord($1)&0x3F)/eg;

# UTF-8 to ISO 8859-1
s/([\xC2\xC3])([\x80-\xBF])/chr(ord($1)<<6&0xC0|ord($2)&0x3F)/eg;
```

Chapter 55

perlunicode

Unicode support in Perl

55.1 DESCRIPTION

55.1.1 Important Caveats

Unicode support is an extensive requirement. While Perl does not implement the Unicode standard or the accompanying technical reports from cover to cover, Perl does support many Unicode features.

Input and Output Layers

Perl knows when a filehandle uses Perl's internal Unicode encodings (UTF-8, or UTF-EBCDIC if in EBCDIC) if the filehandle is opened with the ":utf8" layer. Other encodings can be converted to Perl's encoding on input or from Perl's encoding on output by use of the ":encoding(...)" layer. See *open*.

To indicate that Perl source itself is using a particular encoding, see *encoding*.

Regular Expressions

The regular expression compiler produces polymorphic opcodes. That is, the pattern adapts to the data and automatically switches to the Unicode character scheme when presented with Unicode data–or instead uses a traditional byte scheme when presented with byte data.

`use utf8` still needed to enable UTF-8/UTF-EBCDIC in scripts

As a compatibility measure, the `use utf8` pragma must be explicitly included to enable recognition of UTF-8 in the Perl scripts themselves (in string or regular expression literals, or in identifier names) on ASCII-based machines or to recognize UTF-EBCDIC on EBCDIC-based machines. **These are the only times when an explicit `use utf8` is needed.** See *utf8*.

You can also use the `encoding` pragma to change the default encoding of the data in your script; see *encoding*.

BOM-marked scripts and UTF-16 scripts autodetected

If a Perl script begins marked with the Unicode BOM (UTF-16LE, UTF16-BE, or UTF-8), or if the script looks like non-BOM-marked UTF-16 of either endianness, Perl will correctly read in the script as Unicode. (BOMless UTF-8 cannot be effectively recognized or differentiated from ISO 8859-1 or other eight-bit encodings.)

`use encoding` needed to upgrade non-Latin-1 byte strings

By default, there is a fundamental asymmetry in Perl's unicode model: implicit upgrading from byte strings to Unicode strings assumes that they were encoded in *ISO 8859-1 (Latin-1)*, but Unicode strings are downgraded with UTF-8 encoding. This happens because the first 256 codepoints in Unicode happens to agree with Latin-1.

If you wish to interpret byte strings as UTF-8 instead, use the `encoding` pragma:

```
use encoding 'utf8';
```

See §55.1.2 for more details.

55.1.2 Byte and Character Semantics

Beginning with version 5.6, Perl uses logically-wide characters to represent strings internally.

In future, Perl-level operations will be expected to work with characters rather than bytes.

However, as an interim compatibility measure, Perl aims to provide a safe migration path from byte semantics to character semantics for programs. For operations where Perl can unambiguously decide that the input data are characters, Perl switches to character semantics. For operations where this determination cannot be made without additional information from the user, Perl decides in favor of compatibility and chooses to use byte semantics.

This behavior preserves compatibility with earlier versions of Perl, which allowed byte semantics in Perl operations only if none of the program's inputs were marked as being as source of Unicode character data. Such data may come from filehandles, from calls to external programs, from information provided by the system (such as %ENV), or from literals and constants in the source text.

The `bytes` pragma will always, regardless of platform, force byte semantics in a particular lexical scope. See *bytes*.

The `utf8` pragma is primarily a compatibility device that enables recognition of UTF-(8|EBCDIC) in literals encountered by the parser. Note that this pragma is only required while Perl defaults to byte semantics; when character semantics become the default, this pragma may become a no-op. See *utf8*.

Unless explicitly stated, Perl operators use character semantics for Unicode data and byte semantics for non-Unicode data. The decision to use character semantics is made transparently. If input data comes from a Unicode source–for example, if a character encoding layer is added to a filehandle or a literal Unicode string constant appears in a program–character semantics apply. Otherwise, byte semantics are in effect. The `bytes` pragma should be used to force byte semantics on Unicode data.

If strings operating under byte semantics and strings with Unicode character data are concatenated, the new string will be created by decoding the byte strings as *ISO 8859-1 (Latin-1)*, even if the old Unicode string used EBCDIC. This translation is done without regard to the system's native 8-bit encoding. To change this for systems with non-Latin-1 and non-EBCDIC native encodings, use the `encoding` pragma. See *encoding*.

Under character semantics, many operations that formerly operated on bytes now operate on characters. A character in Perl is logically just a number ranging from 0 to 2**31 or so. Larger characters may encode into longer sequences of bytes internally, but this internal detail is mostly hidden for Perl code. See *perluniintro* for more.

55.1.3 Effects of Character Semantics

Character semantics have the following effects:

- Strings–including hash keys–and regular expression patterns may contain characters that have an ordinal value larger than 255.

  If you use a Unicode editor to edit your program, Unicode characters may occur directly within the literal strings in one of the various Unicode encodings (UTF-8, UTF-EBCDIC, UCS-2, etc.), but will be recognized as such and converted to Perl's internal representation only if the appropriate *encoding* is specified.

  Unicode characters can also be added to a string by using the `\x{...}` notation. The Unicode code for the desired character, in hexadecimal, should be placed in the braces. For instance, a smiley face is `\x{263A}`. This encoding scheme only works for characters with a code of 0x100 or above.

  Additionally, if you

  ```
  use charnames ':full';
  ```

  you can use the `\N{...}` notation and put the official Unicode character name within the braces, such as `\N{WHITE SMILING FACE}`.

- If an appropriate *encoding* is specified, identifiers within the Perl script may contain Unicode alphanumeric characters, including ideographs. Perl does not currently attempt to canonicalize variable names.

- Regular expressions match characters instead of bytes. "." matches a character instead of a byte. The `\C` pattern is provided to force a match a single byte–a `char` in C, hence `\C`.

- Character classes in regular expressions match characters instead of bytes and match against the character properties specified in the Unicode properties database. `\w` can be used to match a Japanese ideograph, for instance.

  (However, and as a limitation of the current implementation, using `\w` or `\W` *inside* a `[...]` character class will still match with byte semantics.)

- Named Unicode properties, scripts, and block ranges may be used like character classes via the `\p{}` "matches property" construct and the `\P{}` negation, "doesn't match property".

  For instance, `\p{Lu}` matches any character with the Unicode "Lu" (Letter, uppercase) property, while `\p{M}` matches any character with an "M" (mark–accents and such) property. Brackets are not required for single letter properties, so `\p{M}` is equivalent to `\pM`. Many predefined properties are available, such as `\p{Mirrored}` and `\p{Tibetan}`.

  The official Unicode script and block names have spaces and dashes as separators, but for convenience you can use dashes, spaces, or underbars, and case is unimportant. It is recommended, however, that for consistency you use the following naming: the official Unicode script, property, or block name (see below for the additional rules that apply to block names) with whitespace and dashes removed, and the words "uppercase-first-lowercase-rest". `Latin-1 Supplement` thus becomes `Latin1Supplement`.

  You can also use negation in both `\p{}` and `\P{}` by introducing a caret (^) between the first brace and the property name: `\p{^Tamil}` is equal to `\P{Tamil}`.

  NOTE: the properties, scripts, and blocks listed here are as of Unicode 3.2.0, March 2002, or Perl 5.8.0, July 2002. Unicode 4.0.0 came out in April 2003, and Perl 5.8.1 in September 2003.

  Here are the basic Unicode General Category properties, followed by their long form. You can use either; `\p{Lu}` and `\p{UppercaseLetter}`, for instance, are identical.

```
    Short       Long

    L           Letter
    LC          CasedLetter
    Lu          UppercaseLetter
    Ll          LowercaseLetter
    Lt          TitlecaseLetter
    Lm          ModifierLetter
    Lo          OtherLetter

    M           Mark
    Mn          NonspacingMark
    Mc          SpacingMark
    Me          EnclosingMark

    N           Number
    Nd          DecimalNumber
    Nl          LetterNumber
    No          OtherNumber

    P           Punctuation
    Pc          ConnectorPunctuation
    Pd          DashPunctuation
    Ps          OpenPunctuation
    Pe          ClosePunctuation
    Pi          InitialPunctuation
                (may behave like Ps or Pe depending on usage)
    Pf          FinalPunctuation
                (may behave like Ps or Pe depending on usage)
    Po          OtherPunctuation
```

S	Symbol
Sm	MathSymbol
Sc	CurrencySymbol
Sk	ModifierSymbol
So	OtherSymbol
Z	Separator
Zs	SpaceSeparator
Zl	LineSeparator
Zp	ParagraphSeparator
C	Other
Cc	Control
Cf	Format
Cs	Surrogate (not usable)
Co	PrivateUse
Cn	Unassigned

Single-letter properties match all characters in any of the two-letter sub-properties starting with the same letter. `LC` and `L&` are special cases, which are aliases for the set of `Ll`, `Lu`, and `Lt`.

Because Perl hides the need for the user to understand the internal representation of Unicode characters, there is no need to implement the somewhat messy concept of surrogates. `Cs` is therefore not supported.

Because scripts differ in their directionality–Hebrew is written right to left, for example–Unicode supplies these properties in the BidiClass class:

Property	Meaning
L	Left-to-Right
LRE	Left-to-Right Embedding
LRO	Left-to-Right Override
R	Right-to-Left
AL	Right-to-Left Arabic
RLE	Right-to-Left Embedding
RLO	Right-to-Left Override
PDF	Pop Directional Format
EN	European Number
ES	European Number Separator
ET	European Number Terminator
AN	Arabic Number
CS	Common Number Separator
NSM	Non-Spacing Mark
BN	Boundary Neutral
B	Paragraph Separator
S	Segment Separator
WS	Whitespace
ON	Other Neutrals

For example, `\p{BidiClass:R}` matches characters that are normally written right to left.

55.1.4 Scripts

The script names which can be used by `\p{...}` and `\P{...}`, such as in `\p{Latin}` or `\p{Cyrillic}`, are as follows:

```
    Arabic
    Armenian
    Bengali
    Bopomofo
    Buhid
    CanadianAboriginal
    Cherokee
    Cyrillic
    Deseret
    Devanagari
    Ethiopic
    Georgian
    Gothic
    Greek
    Gujarati
    Gurmukhi
    Han
    Hangul
    Hanunoo
    Hebrew
    Hiragana
    Inherited
    Kannada
    Katakana
    Khmer
    Lao
    Latin
    Malayalam
    Mongolian
    Myanmar
    Ogham
    OldItalic
    Oriya
    Runic
    Sinhala
    Syriac
    Tagalog
    Tagbanwa
    Tamil
    Telugu
    Thaana
    Thai
    Tibetan
    Yi
```

Extended property classes can supplement the basic properties, defined by the *PropList* Unicode database:

```
    ASCIIHexDigit
    BidiControl
    Dash
    Deprecated
    Diacritic
    Extender
    GraphemeLink
    HexDigit
    Hyphen
    Ideographic
    IDSBinaryOperator
    IDSTrinaryOperator
    JoinControl
    LogicalOrderException
    NoncharacterCodePoint
    OtherAlphabetic
    OtherDefaultIgnorableCodePoint
    OtherGraphemeExtend
    OtherLowercase
    OtherMath
    OtherUppercase
    QuotationMark
    Radical
    SoftDotted
    TerminalPunctuation
    UnifiedIdeograph
    WhiteSpace
```

and there are further derived properties:

```
    Alphabetic      Lu + Ll + Lt + Lm + Lo + OtherAlphabetic
    Lowercase       Ll + OtherLowercase
    Uppercase       Lu + OtherUppercase
    Math            Sm + OtherMath

    ID_Start        Lu + Ll + Lt + Lm + Lo + Nl
    ID_Continue     ID_Start + Mn + Mc + Nd + Pc

    Any             Any character
    Assigned        Any non-Cn character (i.e. synonym for \P{Cn})
    Unassigned      Synonym for \p{Cn}
    Common          Any character (or unassigned code point)
                    not explicitly assigned to a script
```

For backward compatibility (with Perl 5.6), all properties mentioned so far may have `Is` prepended to their name, so `\P{IsLu}`, for example, is equal to `\P{Lu}`.

55.1.5 Blocks

In addition to **scripts**, Unicode also defines **blocks** of characters. The difference between scripts and blocks is that the concept of scripts is closer to natural languages, while the concept of blocks is more of an artificial grouping based on groups of 256 Unicode characters. For example, the `Latin` script contains letters from many blocks but does not contain all the characters from those blocks. It does not, for example, contain digits, because digits are shared across many scripts. Digits and similar groups, like punctuation, are in a category called `Common`.

For more about scripts, see the UTR #24:

```
   http://www.unicode.org/unicode/reports/tr24/
```

For more about blocks, see:

```
   http://www.unicode.org/Public/UNIDATA/Blocks.txt
```

Block names are given with the `In` prefix. For example, the Katakana block is referenced via `\p{InKatakana}`. The `In` prefix may be omitted if there is no naming conflict with a script or any other property, but it is recommended that `In` always be used for block tests to avoid confusion.

These block names are supported:

- The special pattern `\X` matches any extended Unicode sequence–"a combining character sequence" in Standardese–where the first character is a base character and subsequent characters are mark characters that apply to the base character. `\X` is equivalent to `(?:\PM\pM*)`.
- The `tr///` operator translates characters instead of bytes. Note that the `tr///CU` functionality has been removed. For similar functionality see pack('U0', ...) and pack('C0', ...).
- Case translation operators use the Unicode case translation tables when character input is provided. Note that `uc()`, or `\U` in interpolated strings, translates to uppercase, while `ucfirst`, or `\u` in interpolated strings, translates to titlecase in languages that make the distinction.
- Most operators that deal with positions or lengths in a string will automatically switch to using character positions, including `chop()`, `chomp()`, `substr()`, `pos()`, `index()`, `rindex()`, `sprintf()`, `write()`, and `length()`. Operators that specifically do not switch include `vec()`, `pack()`, and `unpack()`. Operators that really don't care include operators that treats strings as a bucket of bits such as `sort()`, and operators dealing with filenames.
- The `pack()`/`unpack()` letters `c` and `C` do *not* change, since they are often used for byte-oriented formats. Again, think `char` in the C language.

  There is a new `U` specifier that converts between Unicode characters and code points.
- The `chr()` and `ord()` functions work on characters, similar to `pack("U")` and `unpack("U")`, *not* `pack("C")` and `unpack("C")`. `pack("C")` and `unpack("C")` are methods for emulating byte-oriented `chr()` and `ord()` on Unicode strings. While these methods reveal the internal encoding of Unicode strings, that is not something one normally needs to care about at all.
- The bit string operators, `& | ^ ~`, can operate on character data. However, for backward compatibility, such as when using bit string operations when characters are all less than 256 in ordinal value, one should not use `~` (the bit complement) with characters of both values less than 256 and values greater than 256. Most importantly, DeMorgan's laws (`~($x|$y) eq ~$x&~$y` and `~($x&$y) eq ~$x|~$y`) will not hold. The reason for this mathematical *faux pas* is that the complement cannot return **both** the 8-bit (byte-wide) bit complement **and** the full character-wide bit complement.
- lc(), uc(), lcfirst(), and ucfirst() work for the following cases:
  - the case mapping is from a single Unicode character to another single Unicode character, or
  - the case mapping is from a single Unicode character to more than one Unicode character.

  Things to do with locales (Lithuanian, Turkish, Azeri) do **not** work since Perl does not understand the concept of Unicode locales.

  See the Unicode Technical Report #21, Case Mappings, for more details.
- And finally, `scalar reverse()` reverses by character rather than by byte.

55.1.6 User-Defined Character Properties

You can define your own character properties by defining subroutines whose names begin with "In" or "Is". The subroutines can be defined in any package. The user-defined properties can be used in the regular expression `\p` and `\P` constructs; if you are using a user-defined property from a package other than the one you are in, you must specify its package in the `\p` or `\P` construct.

```
# assuming property IsForeign defined in Lang::
package main;  # property package name required
if ($txt =~ /\p{Lang::IsForeign}+/) { ... }
```

```
    package Lang;  # property package name not required
    if ($txt =~ /\p{IsForeign}+/) { ... }
```

Note that the effect is compile-time and immutable once defined.

The subroutines must return a specially-formatted string, with one or more newline-separated lines. Each line must be one of the following:

- Two hexadecimal numbers separated by horizontal whitespace (space or tabular characters) denoting a range of Unicode code points to include.
- Something to include, prefixed by "+": a built-in character property (prefixed by "utf8::") or a user-defined character property, to represent all the characters in that property; two hexadecimal code points for a range; or a single hexadecimal code point.
- Something to exclude, prefixed by "-": an existing character property (prefixed by "utf8::") or a user-defined character property, to represent all the characters in that property; two hexadecimal code points for a range; or a single hexadecimal code point.
- Something to negate, prefixed "!": an existing character property (prefixed by "utf8::") or a user-defined character property, to represent all the characters in that property; two hexadecimal code points for a range; or a single hexadecimal code point.
- Something to intersect with, prefixed by "&": an existing character property (prefixed by "utf8::") or a user-defined character property, for all the characters except the characters in the property; two hexadecimal code points for a range; or a single hexadecimal code point.

For example, to define a property that covers both the Japanese syllabaries (hiragana and katakana), you can define

```
    sub InKana {
        return <<END;
    3040\t309F
    30A0\t30FF
    END
    }
```

Imagine that the here-doc end marker is at the beginning of the line. Now you can use `\p{InKana}` and `\P{InKana}`.

You could also have used the existing block property names:

```
    sub InKana {
        return <<'END';
    +utf8::InHiragana
    +utf8::InKatakana
    END
    }
```

Suppose you wanted to match only the allocated characters, not the raw block ranges: in other words, you want to remove the non-characters:

```
    sub InKana {
        return <<'END';
    +utf8::InHiragana
    +utf8::InKatakana
    -utf8::IsCn
    END
    }
```

The negation is useful for defining (surprise!) negated classes.

```
    sub InNotKana {
        return <<'END';
    !utf8::InHiragana
    -utf8::InKatakana
    +utf8::IsCn
    END
    }
```

Intersection is useful for getting the common characters matched by two (or more) classes.

```
    sub InFooAndBar {
        return <<'END';
    +main::Foo
    &main::Bar
    END
    }
```

It's important to remember not to use "&" for the first set – that would be intersecting with nothing (resulting in an empty set).

You can also define your own mappings to be used in the lc(), lcfirst(), uc(), and ucfirst() (or their string-inlined versions). The principle is the same: define subroutines in the `main` package with names like `ToLower` (for lc() and lcfirst()), `ToTitle` (for the first character in ucfirst()), and `ToUpper` (for uc(), and the rest of the characters in ucfirst()).

The string returned by the subroutines needs now to be three hexadecimal numbers separated by tabulators: start of the source range, end of the source range, and start of the destination range. For example:

```
    sub ToUpper {
        return <<END;
    0061\t0063\t0041
    END
    }
```

defines an uc() mapping that causes only the characters "a", "b", and "c" to be mapped to "A", "B", "C", all other characters will remain unchanged.

If there is no source range to speak of, that is, the mapping is from a single character to another single character, leave the end of the source range empty, but the two tabulator characters are still needed. For example:

```
    sub ToLower {
        return <<END;
    0041\t\t0061
    END
    }
```

defines a lc() mapping that causes only "A" to be mapped to "a", all other characters will remain unchanged.

(For serious hackers only) If you want to introspect the default mappings, you can find the data in the directory `$Config{privlib}`*/unicore/To/*. The mapping data is returned as the here-document, and the `utf8::ToSpecFoo` are special exception mappings derived from <$Config{privlib}>*/unicore/SpecialCasing.txt*. The `Digit` and `Fold` mappings that one can see in the directory are not directly user-accessible, one can use either the `Unicode::UCD` module, or just match case-insensitively (that's when the `Fold` mapping is used).

A final note on the user-defined property tests and mappings: they will be used only if the scalar has been marked as having Unicode characters. Old byte-style strings will not be affected.

55.1.7 Character Encodings for Input and Output

See *Encode*.

55.1.8 Unicode Regular Expression Support Level

The following list of Unicode support for regular expressions describes all the features currently supported. The references to "Level N" and the section numbers refer to the Unicode Technical Report 18, "Unicode Regular Expression Guidelines", version 6 (Unicode 3.2.0, Perl 5.8.0).

- Level 1 - Basic Unicode Support

```
        2.1 Hex Notation                        - done          [1]
            Named Notation                      - done          [2]
        2.2 Categories                          - done          [3][4]
        2.3 Subtraction                         - MISSING       [5][6]
        2.4 Simple Word Boundaries              - done          [7]
        2.5 Simple Loose Matches                - done          [8]
        2.6 End of Line                         - MISSING       [9][10]

        [ 1] \x{...}
        [ 2] \N{...}
        [ 3] . \p{...} \P{...}
        [ 4] support for scripts (see UTR#24 Script Names), blocks,
             binary properties, enumerated non-binary properties, and
             numeric properties (as listed in UTR#18 Other Properties)
        [ 5] have negation
        [ 6] can use regular expression look-ahead [a]
             or user-defined character properties [b] to emulate subtraction
        [ 7] include Letters in word characters
        [ 8] note that Perl does Full case-folding in matching, not Simple:
             for example U+1F88 is equivalent with U+1F00 U+03B9,
             not with 1F80.  This difference matters for certain Greek
             capital letters with certain modifiers: the Full case-folding
             decomposes the letter, while the Simple case-folding would map
             it to a single character.
        [ 9] see UTR #13 Unicode Newline Guidelines
        [10] should do ^ and $ also on \x{85}, \x{2028} and \x{2029}
             (should also affect <>, $., and script line numbers)
             (the \x{85}, \x{2028} and \x{2029} do match \s)
```

[a] You can mimic class subtraction using lookahead. For example, what UTR #18 might write as

```
    [{Greek}-[{UNASSIGNED}]]
```

in Perl can be written as:

```
    (?!\p{Unassigned})\p{InGreekAndCoptic}
    (?=\p{Assigned})\p{InGreekAndCoptic}
```

But in this particular example, you probably really want

```
    \p{GreekAndCoptic}
```

which will match assigned characters known to be part of the Greek script.

Also see the Unicode::Regex::Set module, it does implement the full UTR #18 grouping, intersection, union, and removal (subtraction) syntax.

[b] See §55.1.6.

- Level 2 - Extended Unicode Support

```
3.1 Surrogates                          - MISSING       [11]
3.2 Canonical Equivalents               - MISSING       [12][13]
3.3 Locale-Independent Graphemes        - MISSING       [14]
3.4 Locale-Independent Words            - MISSING       [15]
3.5 Locale-Independent Loose Matches    - MISSING       [16]

[11] Surrogates are solely a UTF-16 concept and Perl's internal
     representation is UTF-8.  The Encode module does UTF-16, though.
[12] see UTR#15 Unicode Normalization
[13] have Unicode::Normalize but not integrated to regexes
[14] have \X but at this level . should equal that
[15] need three classes, not just \w and \W
[16] see UTR#21 Case Mappings
```

- Level 3 - Locale-Sensitive Support

```
4.1 Locale-Dependent Categories         - MISSING
4.2 Locale-Dependent Graphemes          - MISSING       [16][17]
4.3 Locale-Dependent Words              - MISSING
4.4 Locale-Dependent Loose Matches      - MISSING
4.5 Locale-Dependent Ranges             - MISSING

[16] see UTR#10 Unicode Collation Algorithms
[17] have Unicode::Collate but not integrated to regexes
```

55.1.9 Unicode Encodings

Unicode characters are assigned to *code points*, which are abstract numbers. To use these numbers, various encodings are needed.

- UTF-8

  UTF-8 is a variable-length (1 to 6 bytes, current character allocations require 4 bytes), byte-order independent encoding. For ASCII (and we really do mean 7-bit ASCII, not another 8-bit encoding), UTF-8 is transparent.

  The following table is from Unicode 3.2.

```
 Code Points            1st Byte  2nd Byte  3rd Byte  4th Byte

   U+0000..U+007F       00..7F
   U+0080..U+07FF       C2..DF    80..BF
   U+0800..U+0FFF       E0        A0..BF    80..BF
   U+1000..U+CFFF       E1..EC    80..BF    80..BF
   U+D000..U+D7FF       ED        80..9F    80..BF
   U+D800..U+DFFF       ******* ill-formed *******
   U+E000..U+FFFF       EE..EF    80..BF    80..BF
  U+10000..U+3FFFF      F0        90..BF    80..BF    80..BF
  U+40000..U+FFFFF      F1..F3    80..BF    80..BF    80..BF
 U+100000..U+10FFFF     F4        80..8F    80..BF    80..BF
```

Note the `A0..BF` in `U+0800..U+0FFF`, the `80..9F` in `U+D000...U+D7FF`, the `90..BF` in `U+10000..U+3FFFF`, and the `80...8F` in `U+100000..U+10FFFF`. The "gaps" are caused by legal UTF-8 avoiding non-shortest encodings: it is technically possible to UTF-8-encode a single code point in different ways, but that is explicitly forbidden, and the shortest possible encoding should always be used. So that's what Perl does.

Another way to look at it is via bits:

```
 Code Points                    1st Byte   2nd Byte  3rd Byte  4th Byte

                    0aaaaaaa     0aaaaaaa
            00000bbbbbaaaaaa     110bbbbb  10aaaaaa
            ccccbbbbbbaaaaaa     1110cccc  10bbbbbb  10aaaaaa
  00000dddccccccbbbbbbaaaaaa     11110ddd  10cccccc  10bbbbbb  10aaaaaa
```

As you can see, the continuation bytes all begin with `10`, and the leading bits of the start byte tell how many bytes the are in the encoded character.

- UTF-EBCDIC

  Like UTF-8 but EBCDIC-safe, in the way that UTF-8 is ASCII-safe.

- UTF-16, UTF-16BE, UTF-16LE, Surrogates, and BOMs (Byte Order Marks)

  The followings items are mostly for reference and general Unicode knowledge, Perl doesn't use these constructs internally.

  UTF-16 is a 2 or 4 byte encoding. The Unicode code points `U+0000..U+FFFF` are stored in a single 16-bit unit, and the code points `U+10000..U+10FFFF` in two 16-bit units. The latter case is using *surrogates*, the first 16-bit unit being the *high surrogate*, and the second being the *low surrogate*.

  Surrogates are code points set aside to encode the `U+10000..U+10FFFF` range of Unicode code points in pairs of 16-bit units. The *high surrogates* are the range `U+D800..U+DBFF`, and the *low surrogates* are the range `U+DC00..U+DFFF`. The surrogate encoding is

```
        $hi = ($uni - 0x10000) / 0x400 + 0xD800;
        $lo = ($uni - 0x10000) % 0x400 + 0xDC00;
```

  and the decoding is

```
        $uni = 0x10000 + ($hi - 0xD800) * 0x400 + ($lo - 0xDC00);
```

  If you try to generate surrogates (for example by using chr()), you will get a warning if warnings are turned on, because those code points are not valid for a Unicode character.

  Because of the 16-bitness, UTF-16 is byte-order dependent. UTF-16 itself can be used for in-memory computations, but if storage or transfer is required either UTF-16BE (big-endian) or UTF-16LE (little-endian) encodings must be chosen.

  This introduces another problem: what if you just know that your data is UTF-16, but you don't know which endianness? Byte Order Marks, or BOMs, are a solution to this. A special character has been reserved in Unicode to function as a byte order marker: the character with the code point `U+FEFF` is the BOM.

  The trick is that if you read a BOM, you will know the byte order, since if it was written on a big-endian platform, you will read the bytes `0xFE 0xFF`, but if it was written on a little-endian platform, you will read the bytes `0xFF 0xFE`. (And if the originating platform was writing in UTF-8, you will read the bytes `0xEF 0xBB 0xBF`.)

  The way this trick works is that the character with the code point `U+FFFE` is guaranteed not to be a valid Unicode character, so the sequence of bytes `0xFF 0xFE` is unambiguously "BOM, represented in little-endian format" and cannot be `U+FFFE`, represented in big-endian format".

- UTF-32, UTF-32BE, UTF-32LE

  The UTF-32 family is pretty much like the UTF-16 family, expect that the units are 32-bit, and therefore the surrogate scheme is not needed. The BOM signatures will be `0x00 0x00 0xFE 0xFF` for BE and `0xFF 0xFE 0x00 0x00` for LE.

- UCS-2, UCS-4

  Encodings defined by the ISO 10646 standard. UCS-2 is a 16-bit encoding. Unlike UTF-16, UCS-2 is not extensible beyond `U+FFFF`, because it does not use surrogates. UCS-4 is a 32-bit encoding, functionally identical to UTF-32.

- UTF-7

  A seven-bit safe (non-eight-bit) encoding, which is useful if the transport or storage is not eight-bit safe. Defined by RFC 2152.

55.1.10 Security Implications of Unicode

- Malformed UTF-8

  Unfortunately, the specification of UTF-8 leaves some room for interpretation of how many bytes of encoded output one should generate from one input Unicode character. Strictly speaking, the shortest possible sequence of UTF-8 bytes should be generated, because otherwise there is potential for an input buffer overflow at the receiving end of a UTF-8 connection. Perl always generates the shortest length UTF-8, and with warnings on Perl will warn about non-shortest length UTF-8 along with other malformations, such as the surrogates, which are not real Unicode code points.

- Regular expressions behave slightly differently between byte data and character (Unicode) data. For example, the "word character" character class `\w` will work differently depending on if data is eight-bit bytes or Unicode.

  In the first case, the set of `\w` characters is either small–the default set of alphabetic characters, digits, and the "_"–or, if you are using a locale (see *perllocale*), the `\w` might contain a few more letters according to your language and country.

  In the second case, the `\w` set of characters is much, much larger. Most importantly, even in the set of the first 256 characters, it will probably match different characters: unlike most locales, which are specific to a language and country pair, Unicode classifies all the characters that are letters *somewhere* as `\w`. For example, your locale might not think that LATIN SMALL LETTER ETH is a letter (unless you happen to speak Icelandic), but Unicode does.

  As discussed elsewhere, Perl has one foot (two hooves?) planted in each of two worlds: the old world of bytes and the new world of characters, upgrading from bytes to characters when necessary. If your legacy code does not explicitly use Unicode, no automatic switch-over to characters should happen. Characters shouldn't get downgraded to bytes, either. It is possible to accidentally mix bytes and characters, however (see *perluniintro*), in which case `\w` in regular expressions might start behaving differently. Review your code. Use warnings and the `strict` pragma.

55.1.11 Unicode in Perl on EBCDIC

The way Unicode is handled on EBCDIC platforms is still experimental. On such platforms, references to UTF-8 encoding in this document and elsewhere should be read as meaning the UTF-EBCDIC specified in Unicode Technical Report 16, unless ASCII vs. EBCDIC issues are specifically discussed. There is no `utfebcdic` pragma or ":utfebcdic" layer; rather, "utf8" and ":utf8" are reused to mean the platform's "natural" 8-bit encoding of Unicode. See *perlebcdic* for more discussion of the issues.

55.1.12 Locales

Usually locale settings and Unicode do not affect each other, but there are a couple of exceptions:

- You can enable automatic UTF-8-ification of your standard file handles, default `open()` layer, and `@ARGV` by using either the `-C` command line switch or the `PERL_UNICODE` environment variable, see *perlrun* for the documentation of the `-C` switch.

- Perl tries really hard to work both with Unicode and the old byte-oriented world. Most often this is nice, but sometimes Perl's straddling of the proverbial fence causes problems.

55.1.13 When Unicode Does Not Happen

While Perl does have extensive ways to input and output in Unicode, and few other 'entry points' like the @ARGV which can be interpreted as Unicode (UTF-8), there still are many places where Unicode (in some encoding or another) could be given as arguments or received as results, or both, but it is not.

The following are such interfaces. For all of these interfaces Perl currently (as of 5.8.3) simply assumes byte strings both as arguments and results, or UTF-8 strings if the `encoding` pragma has been used.

One reason why Perl does not attempt to resolve the role of Unicode in this cases is that the answers are highly dependent on the operating system and the file system(s). For example, whether filenames can be in Unicode, and in exactly what kind of encoding, is not exactly a portable concept. Similarly for the qx and system: how well will the 'command line interface' (and which of them?) handle Unicode?

- chmod, chmod, chown, chroot, exec, link, lstat, mkdir, rename, rmdir, stat, symlink, truncate, unlink, utime, -X
- %ENV
- glob (aka the <*>)
- open, opendir, sysopen
- qx (aka the backtick operator), system
- readdir, readlink

55.1.14 Forcing Unicode in Perl (Or Unforcing Unicode in Perl)

Sometimes (see §55.1.13) there are situations where you simply need to force Perl to believe that a byte string is UTF-8, or vice versa. The low-level calls utf8::upgrade($bytestring) and utf8::downgrade($utf8string) are the answers.

Do not use them without careful thought, though: Perl may easily get very confused, angry, or even crash, if you suddenly change the 'nature' of scalar like that. Especially careful you have to be if you use the utf8::upgrade(): any random byte string is not valid UTF-8.

55.1.15 Using Unicode in XS

If you want to handle Perl Unicode in XS extensions, you may find the following C APIs useful. See also Unicode Support in *perlguts* for an explanation about Unicode at the XS level, and *perlapi* for the API details.

- `DO_UTF8(sv)` returns true if the `UTF8` flag is on and the bytes pragma is not in effect. `SvUTF8(sv)` returns true is the `UTF8` flag is on; the bytes pragma is ignored. The `UTF8` flag being on does **not** mean that there are any characters of code points greater than 255 (or 127) in the scalar or that there are even any characters in the scalar. What the `UTF8` flag means is that the sequence of octets in the representation of the scalar is the sequence of UTF-8 encoded code points of the characters of a string. The `UTF8` flag being off means that each octet in this representation encodes a single character with code point 0..255 within the string. Perl's Unicode model is not to use UTF-8 until it is absolutely necessary.
- `uvuni_to_utf8(buf, chr)` writes a Unicode character code point into a buffer encoding the code point as UTF-8, and returns a pointer pointing after the UTF-8 bytes.
- `utf8_to_uvuni(buf, lenp)` reads UTF-8 encoded bytes from a buffer and returns the Unicode character code point and, optionally, the length of the UTF-8 byte sequence.
- `utf8_length(start, end)` returns the length of the UTF-8 encoded buffer in characters. `sv_len_utf8(sv)` returns the length of the UTF-8 encoded scalar.

- `sv_utf8_upgrade(sv)` converts the string of the scalar to its UTF-8 encoded form. `sv_utf8_downgrade(sv)` does the opposite, if possible. `sv_utf8_encode(sv)` is like sv_utf8_upgrade except that it does not set the `UTF8` flag. `sv_utf8_decode()` does the opposite of `sv_utf8_encode()`. Note that none of these are to be used as general-purpose encoding or decoding interfaces: `use Encode` for that. `sv_utf8_upgrade()` is affected by the encoding pragma but `sv_utf8_downgrade()` is not (since the encoding pragma is designed to be a one-way street).
- `is_utf8_char(s)` returns true if the pointer points to a valid UTF-8 character.
- `is_utf8_string(buf, len)` returns true if `len` bytes of the buffer are valid UTF-8.
- `UTF8SKIP(buf)` will return the number of bytes in the UTF-8 encoded character in the buffer. `UNISKIP(chr)` will return the number of bytes required to UTF-8-encode the Unicode character code point. `UTF8SKIP()` is useful for example for iterating over the characters of a UTF-8 encoded buffer; `UNISKIP()` is useful, for example, in computing the size required for a UTF-8 encoded buffer.
- `utf8_distance(a, b)` will tell the distance in characters between the two pointers pointing to the same UTF-8 encoded buffer.
- `utf8_hop(s, off)` will return a pointer to an UTF-8 encoded buffer that is `off` (positive or negative) Unicode characters displaced from the UTF-8 buffer `s`. Be careful not to overstep the buffer: `utf8_hop()` will merrily run off the end or the beginning of the buffer if told to do so.
- `pv_uni_display(dsv, spv, len, pvlim, flags)` and `sv_uni_display(dsv, ssv, pvlim, flags)` are useful for debugging the output of Unicode strings and scalars. By default they are useful only for debugging–they display **all** characters as hexadecimal code points–but with the flags `UNI_DISPLAY_ISPRINT`, `UNI_DISPLAY_BACKSLASH`, and `UNI_DISPLAY_QQ` you can make the output more readable.
- `ibcmp_utf8(s1, pe1, u1, l1, u1, s2, pe2, l2, u2)` can be used to compare two strings case-insensitively in Unicode. For case-sensitive comparisons you can just use `memEQ()` and `memNE()` as usual.

For more information, see *perlapi*, and *utf8.c* and *utf8.h* in the Perl source code distribution.

55.2 BUGS

55.2.1 Interaction with Locales

Use of locales with Unicode data may lead to odd results. Currently, Perl attempts to attach 8-bit locale info to characters in the range 0..255, but this technique is demonstrably incorrect for locales that use characters above that range when mapped into Unicode. Perl's Unicode support will also tend to run slower. Use of locales with Unicode is discouraged.

55.2.2 Interaction with Extensions

When Perl exchanges data with an extension, the extension should be able to understand the UTF-8 flag and act accordingly. If the extension doesn't know about the flag, it's likely that the extension will return incorrectly-flagged data.

So if you're working with Unicode data, consult the documentation of every module you're using if there are any issues with Unicode data exchange. If the documentation does not talk about Unicode at all, suspect the worst and probably look at the source to learn how the module is implemented. Modules written completely in Perl shouldn't cause problems. Modules that directly or indirectly access code written in other programming languages are at risk.

For affected functions, the simple strategy to avoid data corruption is to always make the encoding of the exchanged data explicit. Choose an encoding that you know the extension can handle. Convert arguments passed to the extensions to that encoding and convert results back from that encoding. Write wrapper functions that do the conversions for you, so you can later change the functions when the extension catches up.

To provide an example, let's say the popular Foo::Bar::escape_html function doesn't deal with Unicode data yet. The wrapper function would convert the argument to raw UTF-8 and convert the result back to Perl's internal representation like so:

```
sub my_escape_html ($) {
  my($what) = shift;
  return unless defined $what;
  Encode::decode_utf8(Foo::Bar::escape_html(Encode::encode_utf8($what)));
}
```

Sometimes, when the extension does not convert data but just stores and retrieves them, you will be in a position to use the otherwise dangerous Encode::_utf8_on() function. Let's say the popular `Foo::Bar` extension, written in C, provides a `param` method that lets you store and retrieve data according to these prototypes:

```
$self->param($name, $value);            # set a scalar
$value = $self->param($name);           # retrieve a scalar
```

If it does not yet provide support for any encoding, one could write a derived class with such a `param` method:

```
sub param {
  my($self,$name,$value) = @_;
  utf8::upgrade($name);     # make sure it is UTF-8 encoded
  if (defined $value)
    utf8::upgrade($value);  # make sure it is UTF-8 encoded
    return $self->SUPER::param($name,$value);
  } else {
    my $ret = $self->SUPER::param($name);
    Encode::_utf8_on($ret); # we know, it is UTF-8 encoded
    return $ret;
  }
}
```

Some extensions provide filters on data entry/exit points, such as DB_File::filter_store_key and family. Look out for such filters in the documentation of your extensions, they can make the transition to Unicode data much easier.

55.2.3 Speed

Some functions are slower when working on UTF-8 encoded strings than on byte encoded strings. All functions that need to hop over characters such as length(), substr() or index(), or matching regular expressions can work **much** faster when the underlying data are byte-encoded.

In Perl 5.8.0 the slowness was often quite spectacular; in Perl 5.8.1 a caching scheme was introduced which will hopefully make the slowness somewhat less spectacular, at least for some operations. In general, operations with UTF-8 encoded strings are still slower. As an example, the Unicode properties (character classes) like `\p{Nd}` are known to be quite a bit slower (5-20 times) than their simpler counterparts like `\d` (then again, there 268 Unicode characters matching `Nd` compared with the 10 ASCII characters matching `d`).

55.2.4 Porting code from perl-5.6.X

Perl 5.8 has a different Unicode model from 5.6. In 5.6 the programmer was required to use the `utf8` pragma to declare that a given scope expected to deal with Unicode data and had to make sure that only Unicode data were reaching that scope. If you have code that is working with 5.6, you will need some of the following adjustments to your code. The examples are written such that the code will continue to work under 5.6, so you should be safe to try them out.

- A filehandle that should read or write UTF-8

  ```
  if ($] > 5.007) {
    binmode $fh, ":utf8";
  }
  ```

- A scalar that is going to be passed to some extension

  Be it Compress::Zlib, Apache::Request or any extension that has no mention of Unicode in the manpage, you need to make sure that the UTF-8 flag is stripped off. Note that at the time of this writing (October 2002) the mentioned modules are not UTF-8-aware. Please check the documentation to verify if this is still true.

  ```
  if ($] > 5.007) {
    require Encode;
    $val = Encode::encode_utf8($val); # make octets
  }
  ```

- A scalar we got back from an extension

  If you believe the scalar comes back as UTF-8, you will most likely want the UTF-8 flag restored:

  ```
  if ($] > 5.007) {
    require Encode;
    $val = Encode::decode_utf8($val);
  }
  ```

- Same thing, if you are really sure it is UTF-8

  ```
  if ($] > 5.007) {
    require Encode;
    Encode::_utf8_on($val);
  }
  ```

- A wrapper for fetchrow_array and fetchrow_hashref

  When the database contains only UTF-8, a wrapper function or method is a convenient way to replace all your fetchrow_array and fetchrow_hashref calls. A wrapper function will also make it easier to adapt to future enhancements in your database driver. Note that at the time of this writing (October 2002), the DBI has no standardized way to deal with UTF-8 data. Please check the documentation to verify if that is still true.

  ```
  sub fetchrow {
    my($self, $sth, $what) = @_; # $what is one of fetchrow_{array,hashref}
    if ($] < 5.007) {
      return $sth->$what;
    } else {
      require Encode;
      if (wantarray) {
        my @arr = $sth->$what;
        for (@arr) {
          defined && /[^\000-\177]/ && Encode::_utf8_on($_);
        }
        return @arr;
      } else {
        my $ret = $sth->$what;
        if (ref $ret) {
          for my $k (keys %$ret) {
            defined && /[^\000-\177]/ && Encode::_utf8_on($_) for $ret->{$k};
          }
          return $ret;
        } else {
          defined && /[^\000-\177]/ && Encode::_utf8_on($_) for $ret;
          return $ret;
        }
      }
    }
  }
  ```

- A large scalar that you know can only contain ASCII

  Scalars that contain only ASCII and are marked as UTF-8 are sometimes a drag to your program. If you recognize such a situation, just remove the UTF-8 flag:

  ```
  utf8::downgrade($val) if $] > 5.007;
  ```

Perl security

56.1 DESCRIPTION

Perl is designed to make it easy to program securely even when running with extra privileges, like setuid or setgid programs. Unlike most command line shells, which are based on multiple substitution passes on each line of the script, Perl uses a more conventional evaluation scheme with fewer hidden snags. Additionally, because the language has more builtin functionality, it can rely less upon external (and possibly untrustworthy) programs to accomplish its purposes.

Perl automatically enables a set of special security checks, called *taint mode*, when it detects its program running with differing real and effective user or group IDs. The setuid bit in Unix permissions is mode 04000, the setgid bit mode 02000; either or both may be set. You can also enable taint mode explicitly by using the **-T** command line flag. This flag is *strongly* suggested for server programs and any program run on behalf of someone else, such as a CGI script. Once taint mode is on, it's on for the remainder of your script.

While in this mode, Perl takes special precautions called *taint checks* to prevent both obvious and subtle traps. Some of these checks are reasonably simple, such as verifying that path directories aren't writable by others; careful programmers have always used checks like these. Other checks, however, are best supported by the language itself, and it is these checks especially that contribute to making a set-id Perl program more secure than the corresponding C program.

You may not use data derived from outside your program to affect something else outside your program–at least, not by accident. All command line arguments, environment variables, locale information (see *perllocale*), results of certain system calls (readdir(), readlink(), the variable of shmread(), the messages returned by msgrcv(), the password, gcos and shell fields returned by the getpwxxx() calls), and all file input are marked as "tainted". Tainted data may not be used directly or indirectly in any command that invokes a sub-shell, nor in any command that modifies files, directories, or processes, **with the following exceptions**:

- Arguments to `print` and `syswrite` are **not** checked for taintedness.
- Symbolic methods

  ```
  $obj->$method(@args);
  ```

  and symbolic sub references

  ```
  &{$foo}(@args);
  $foo->(@args);
  ```

  are not checked for taintedness. This requires extra carefulness unless you want external data to affect your control flow. Unless you carefully limit what these symbolic values are, people are able to call functions **outside** your Perl code, such as POSIX::system, in which case they are able to run arbitrary external code.

For efficiency reasons, Perl takes a conservative view of whether data is tainted. If an expression contains tainted data, any subexpression may be considered tainted, even if the value of the subexpression is not itself affected by the tainted data.

Because taintedness is associated with each scalar value, some elements of an array or hash can be tainted and others not. The keys of a hash are never tainted.

For example:

```
    $arg = shift;               # $arg is tainted
    $hid = $arg, 'bar';         # $hid is also tainted
    $line = <>;                 # Tainted
    $line = <STDIN>;            # Also tainted
    open FOO, "/home/me/bar" or die $!;
    $line = <FOO>;              # Still tainted
    $path = $ENV{'PATH'};       # Tainted, but see below
    $data = 'abc';              # Not tainted

    system "echo $arg";         # Insecure
    system "/bin/echo", $arg;   # Considered insecure
                                # (Perl doesn't know about /bin/echo)
    system "echo $hid";         # Insecure
    system "echo $data";        # Insecure until PATH set

    $path = $ENV{'PATH'};       # $path now tainted

    $ENV{'PATH'} = '/bin:/usr/bin';
    delete @ENV{'IFS', 'CDPATH', 'ENV', 'BASH_ENV'};

    $path = $ENV{'PATH'};       # $path now NOT tainted
    system "echo $data";        # Is secure now!

    open(FOO, "< $arg");        # OK - read-only file
    open(FOO, "> $arg");        # Not OK - trying to write

    open(FOO,"echo $arg|");     # Not OK
    open(FOO,"-|")
        or exec 'echo', $arg;   # Also not OK

    $shout = `echo $arg`;       # Insecure, $shout now tainted

    unlink $data, $arg;         # Insecure
    umask $arg;                 # Insecure

    exec "echo $arg";           # Insecure
    exec "echo", $arg;          # Insecure
    exec "sh", '-c', $arg;      # Very insecure!

    @files = <*.c>;             # insecure (uses readdir() or similar)
    @files = glob('*.c');       # insecure (uses readdir() or similar)

    # In Perl releases older than 5.6.0 the <*.c> and glob('*.c') would
    # have used an external program to do the filename expansion; but in
    # either case the result is tainted since the list of filenames comes
    # from outside of the program.

    $bad = ($arg, 23);          # $bad will be tainted
    $arg, `true`;               # Insecure (although it isn't really)
```

If you try to do something insecure, you will get a fatal error saying something like "Insecure dependency" or "Insecure $ENV{PATH}".

56.1.1 Laundering and Detecting Tainted Data

To test whether a variable contains tainted data, and whose use would thus trigger an "Insecure dependency" message, you can use the tainted() function of the Scalar::Util module, available in your nearby CPAN mirror, and included in Perl starting from the release 5.8.0. Or you may be able to use the following `is_tainted()` function.

```
sub is_tainted {
    return ! eval { eval("#" . substr(join("", @_), 0, 0)); 1 };
}
```

This function makes use of the fact that the presence of tainted data anywhere within an expression renders the entire expression tainted. It would be inefficient for every operator to test every argument for taintedness. Instead, the slightly more efficient and conservative approach is used that if any tainted value has been accessed within the same expression, the whole expression is considered tainted.

But testing for taintedness gets you only so far. Sometimes you have just to clear your data's taintedness. Values may be untainted by using them as keys in a hash; otherwise the only way to bypass the tainting mechanism is by referencing subpatterns from a regular expression match. Perl presumes that if you reference a substring using $1, $2, etc., that you knew what you were doing when you wrote the pattern. That means using a bit of thought–don't just blindly untaint anything, or you defeat the entire mechanism. It's better to verify that the variable has only good characters (for certain values of "good") rather than checking whether it has any bad characters. That's because it's far too easy to miss bad characters that you never thought of.

Here's a test to make sure that the data contains nothing but "word" characters (alphabetics, numerics, and underscores), a hyphen, an at sign, or a dot.

```
if ($data =~ /^([-\@\w.]+)$/) {
    $data = $1;                     # $data now untainted
} else {
    die "Bad data in '$data'";      # log this somewhere
}
```

This is fairly secure because `/\w+/` doesn't normally match shell metacharacters, nor are dot, dash, or at going to mean something special to the shell. Use of `/.+/` would have been insecure in theory because it lets everything through, but Perl doesn't check for that. The lesson is that when untainting, you must be exceedingly careful with your patterns. Laundering data using regular expression is the *only* mechanism for untainting dirty data, unless you use the strategy detailed below to fork a child of lesser privilege.

The example does not untaint $data if `use locale` is in effect, because the characters matched by `\w` are determined by the locale. Perl considers that locale definitions are untrustworthy because they contain data from outside the program. If you are writing a locale-aware program, and want to launder data with a regular expression containing `\w`, put `no locale` ahead of the expression in the same block. See SECURITY in *perllocale* for further discussion and examples.

56.1.2 Switches On the "#!" Line

When you make a script executable, in order to make it usable as a command, the system will pass switches to perl from the script's #! line. Perl checks that any command line switches given to a setuid (or setgid) script actually match the ones set on the #! line. Some Unix and Unix-like environments impose a one-switch limit on the #! line, so you may need to use something like `-wU` instead of `-w -U` under such systems. (This issue should arise only in Unix or Unix-like environments that support #! and setuid or setgid scripts.)

56.1.3 Taint mode and @INC

When the taint mode (`-T`) is in effect, the "." directory is removed from `@INC`, and the environment variables `PERL5LIB` and `PERLLIB` are ignored by Perl. You can still adjust `@INC` from outside the program by using the `-I` command line option as explained in *perlrun*. The two environment variables are ignored because they are obscured, and a user running a program could be unaware that they are set, whereas the `-I` option is clearly visible and therefore permitted.

Another way to modify `@INC` without modifying the program, is to use the `lib` pragma, e.g.:

```
perl -Mlib=/foo program
```

The benefit of using `-Mlib=/foo` over `-I/foo`, is that the former will automagically remove any duplicated directories, while the later will not.

56.1.4 Cleaning Up Your Path

For "Insecure `$ENV{PATH}`" messages, you need to set `$ENV{'PATH'}` to a known value, and each directory in the path must be non-writable by others than its owner and group. You may be surprised to get this message even if the pathname to your executable is fully qualified. This is *not* generated because you didn't supply a full path to the program; instead, it's generated because you never set your PATH environment variable, or you didn't set it to something that was safe. Because Perl can't guarantee that the executable in question isn't itself going to turn around and execute some other program that is dependent on your PATH, it makes sure you set the PATH.

The PATH isn't the only environment variable which can cause problems. Because some shells may use the variables IFS, CDPATH, ENV, and BASH_ENV, Perl checks that those are either empty or untainted when starting subprocesses. You may wish to add something like this to your setid and taint-checking scripts.

```
    delete @ENV{qw(IFS CDPATH ENV BASH_ENV)};   # Make %ENV safer
```

It's also possible to get into trouble with other operations that don't care whether they use tainted values. Make judicious use of the file tests in dealing with any user-supplied filenames. When possible, do opens and such **after** properly dropping any special user (or group!) privileges. Perl doesn't prevent you from opening tainted filenames for reading, so be careful what you print out. The tainting mechanism is intended to prevent stupid mistakes, not to remove the need for thought.

Perl does not call the shell to expand wild cards when you pass **system** and **exec** explicit parameter lists instead of strings with possible shell wildcards in them. Unfortunately, the **open**, **glob**, and backtick functions provide no such alternate calling convention, so more subterfuge will be required.

Perl provides a reasonably safe way to open a file or pipe from a setuid or setgid program: just create a child process with reduced privilege who does the dirty work for you. First, fork a child using the special **open** syntax that connects the parent and child by a pipe. Now the child resets its ID set and any other per-process attributes, like environment variables, umasks, current working directories, back to the originals or known safe values. Then the child process, which no longer has any special permissions, does the **open** or other system call. Finally, the child passes the data it managed to access back to the parent. Because the file or pipe was opened in the child while running under less privilege than the parent, it's not apt to be tricked into doing something it shouldn't.

Here's a way to do backticks reasonably safely. Notice how the **exec** is not called with a string that the shell could expand. This is by far the best way to call something that might be subjected to shell escapes: just never call the shell at all.

```
        use English '-no_match_vars';
        die "Can't fork: $!" unless defined($pid = open(KID, "-|"));
        if ($pid) {           # parent
            while (<KID>) {
                # do something
            }
            close KID;
        } else {
            my @temp     = ($EUID, $EGID);
            my $orig_uid = $UID;
            my $orig_gid = $GID;
            $EUID = $UID;
            $EGID = $GID;
            # Drop privileges
            $UID  = $orig_uid;
            $GID  = $orig_gid;
            # Make sure privs are really gone
            ($EUID, $EGID) = @temp;
            die "Can't drop privileges"
                unless $UID == $EUID  && $GID eq $EGID;
            $ENV{PATH} = "/bin:/usr/bin"; # Minimal PATH.
            # Consider sanitizing the environment even more.
            exec 'myprog', 'arg1', 'arg2'
                or die "can't exec myprog: $!";
        }
```

A similar strategy would work for wildcard expansion via `glob`, although you can use `readdir` instead.

Taint checking is most useful when although you trust yourself not to have written a program to give away the farm, you don't necessarily trust those who end up using it not to try to trick it into doing something bad. This is the kind of security checking that's useful for set-id programs and programs launched on someone else's behalf, like CGI programs.

This is quite different, however, from not even trusting the writer of the code not to try to do something evil. That's the kind of trust needed when someone hands you a program you've never seen before and says, "Here, run this." For that kind of safety, check out the Safe module, included standard in the Perl distribution. This module allows the programmer to set up special compartments in which all system operations are trapped and namespace access is carefully controlled.

56.1.5 Security Bugs

Beyond the obvious problems that stem from giving special privileges to systems as flexible as scripts, on many versions of Unix, set-id scripts are inherently insecure right from the start. The problem is a race condition in the kernel. Between the time the kernel opens the file to see which interpreter to run and when the (now-set-id) interpreter turns around and reopens the file to interpret it, the file in question may have changed, especially if you have symbolic links on your system.

Fortunately, sometimes this kernel "feature" can be disabled. Unfortunately, there are two ways to disable it. The system can simply outlaw scripts with any set-id bit set, which doesn't help much. Alternately, it can simply ignore the set-id bits on scripts. If the latter is true, Perl can emulate the setuid and setgid mechanism when it notices the otherwise useless setuid/gid bits on Perl scripts. It does this via a special executable called **suidperl** that is automatically invoked for you if it's needed.

However, if the kernel set-id script feature isn't disabled, Perl will complain loudly that your set-id script is insecure. You'll need to either disable the kernel set-id script feature, or put a C wrapper around the script. A C wrapper is just a compiled program that does nothing except call your Perl program. Compiled programs are not subject to the kernel bug that plagues set-id scripts. Here's a simple wrapper, written in C:

```
    #define REAL_PATH "/path/to/script"
    main(ac, av)
        char **av;
    {
        execv(REAL_PATH, av);
    }
```

Compile this wrapper into a binary executable and then make *it* rather than your script setuid or setgid.

In recent years, vendors have begun to supply systems free of this inherent security bug. On such systems, when the kernel passes the name of the set-id script to open to the interpreter, rather than using a pathname subject to meddling, it instead passes */dev/fd/3*. This is a special file already opened on the script, so that there can be no race condition for evil scripts to exploit. On these systems, Perl should be compiled with `-DSETUID_SCRIPTS_ARE_SECURE_NOW`. The **Configure** program that builds Perl tries to figure this out for itself, so you should never have to specify this yourself. Most modern releases of SysVr4 and BSD 4.4 use this approach to avoid the kernel race condition.

Prior to release 5.6.1 of Perl, bugs in the code of **suidperl** could introduce a security hole.

56.1.6 Protecting Your Programs

There are a number of ways to hide the source to your Perl programs, with varying levels of "security".

First of all, however, you *can't* take away read permission, because the source code has to be readable in order to be compiled and interpreted. (That doesn't mean that a CGI script's source is readable by people on the web, though.) So you have to leave the permissions at the socially friendly 0755 level. This lets people on your local system only see your source.

Some people mistakenly regard this as a security problem. If your program does insecure things, and relies on people not knowing how to exploit those insecurities, it is not secure. It is often possible for someone to determine the insecure things and exploit them without viewing the source. Security through obscurity, the name for hiding your bugs instead of fixing them, is little security indeed.

You can try using encryption via source filters (Filter::* from CPAN, or Filter::Util::Call and Filter::Simple since Perl 5.8). But crackers might be able to decrypt it. You can try using the byte code compiler and interpreter described below, but crackers might be able to de-compile it. You can try using the native-code compiler described below, but crackers might be able to disassemble it. These pose varying degrees of difficulty to people wanting to get at your code, but none can definitively conceal it (this is true of every language, not just Perl).

If you're concerned about people profiting from your code, then the bottom line is that nothing but a restrictive licence will give you legal security. License your software and pepper it with threatening statements like "This is unpublished proprietary software of XYZ Corp. Your access to it does not give you permission to use it blah blah blah." You should see a lawyer to be sure your licence's wording will stand up in court.

56.1.7 Unicode

Unicode is a new and complex technology and one may easily overlook certain security pitfalls. See *perluniintro* for an overview and *perlunicode* for details, and Security Implications of Unicode in *perlunicode* for security implications in particular.

56.1.8 Algorithmic Complexity Attacks

Certain internal algorithms used in the implementation of Perl can be attacked by choosing the input carefully to consume large amounts of either time or space or both. This can lead into the so-called *Denial of Service* (DoS) attacks.

- Hash Function - the algorithm used to "order" hash elements has been changed several times during the development of Perl, mainly to be reasonably fast. In Perl 5.8.1 also the security aspect was taken into account.

  In Perls before 5.8.1 one could rather easily generate data that as hash keys would cause Perl to consume large amounts of time because internal structure of hashes would badly degenerate. In Perl 5.8.1 the hash function is randomly perturbed by a pseudorandom seed which makes generating such naughty hash keys harder. See PERL_HASH_SEED in *perlrun* for more information.

  The random perturbation is done by default but if one wants for some reason emulate the old behaviour one can set the environment variable PERL_HASH_SEED to zero (or any other integer). One possible reason for wanting to emulate the old behaviour is that in the new behaviour consecutive runs of Perl will order hash keys differently, which may confuse some applications (like Data::Dumper: the outputs of two different runs are no more identical).

  Perl has never guaranteed any ordering of the hash keys, and the ordering has already changed several times during the lifetime of Perl 5. Also, the ordering of hash keys has always been, and continues to be, affected by the insertion order.

  Also note that while the order of the hash elements might be randomised, this "pseudoordering" should **not** be used for applications like shuffling a list randomly (use List::Util::shuffle() for that, see *List::Util*, a standard core module since Perl 5.8.0; or the CPAN module Algorithm::Numerical::Shuffle), or for generating permutations (use e.g. the CPAN modules Algorithm::Permute or Algorithm::FastPermute), or for any cryptographic applications.

- Regular expressions - Perl's regular expression engine is so called NFA (Non-Finite Automaton), which among other things means that it can rather easily consume large amounts of both time and space if the regular expression may match in several ways. Careful crafting of the regular expressions can help but quite often there really isn't much one can do (the book "Mastering Regular Expressions" is required reading, see *perlfaq2*). Running out of space manifests itself by Perl running out of memory.

- Sorting - the quicksort algorithm used in Perls before 5.8.0 to implement the sort() function is very easy to trick into misbehaving so that it consumes a lot of time. Nothing more is required than resorting a list already sorted. Starting from Perl 5.8.0 a different sorting algorithm, mergesort, is used. Mergesort is insensitive to its input data, so it cannot be similarly fooled.

See http://www.cs.rice.edu/˜scrosby/hash/ for more information, and any computer science text book on the algorithmic complexity.

Chapter 57

perlmod

Perl modules (packages and symbol tables)

57.1 DESCRIPTION

57.1.1 Packages

Perl provides a mechanism for alternative namespaces to protect packages from stomping on each other's variables. In fact, there's really no such thing as a global variable in Perl. The package statement declares the compilation unit as being in the given namespace. The scope of the package declaration is from the declaration itself through the end of the enclosing block, `eval`, or file, whichever comes first (the same scope as the my() and local() operators). Unqualified dynamic identifiers will be in this namespace, except for those few identifiers that if unqualified, default to the main package instead of the current one as described below. A package statement affects only dynamic variables–including those you've used local() on–but *not* lexical variables created with my(). Typically it would be the first declaration in a file included by the `do`, `require`, or `use` operators. You can switch into a package in more than one place; it merely influences which symbol table is used by the compiler for the rest of that block. You can refer to variables and filehandles in other packages by prefixing the identifier with the package name and a double colon: `$Package::Variable`. If the package name is null, the `main` package is assumed. That is, `$::sail` is equivalent to `$main::sail`.

The old package delimiter was a single quote, but double colon is now the preferred delimiter, in part because it's more readable to humans, and in part because it's more readable to **emacs** macros. It also makes C++ programmers feel like they know what's going on–as opposed to using the single quote as separator, which was there to make Ada programmers feel like they knew what was going on. Because the old-fashioned syntax is still supported for backwards compatibility, if you try to use a string like `"This is $owner's house"`, you'll be accessing `$owner::s`; that is, the $s variable in package `owner`, which is probably not what you meant. Use braces to disambiguate, as in `"This is ${owner}'s house"`.

Packages may themselves contain package separators, as in `$OUTER::INNER::var`. This implies nothing about the order of name lookups, however. There are no relative packages: all symbols are either local to the current package, or must be fully qualified from the outer package name down. For instance, there is nowhere within package `OUTER` that `$INNER::var` refers to `$OUTER::INNER::var`. `INNER` refers to a totally separate global package.

Only identifiers starting with letters (or underscore) are stored in a package's symbol table. All other symbols are kept in package `main`, including all punctuation variables, like $_. In addition, when unqualified, the identifiers STDIN, STDOUT, STDERR, ARGV, ARGVOUT, ENV, INC, and SIG are forced to be in package `main`, even when used for other purposes than their built-in ones. If you have a package called `m`, `s`, or `y`, then you can't use the qualified form of an identifier because it would be instead interpreted as a pattern match, a substitution, or a transliteration.

Variables beginning with underscore used to be forced into package main, but we decided it was more useful for package writers to be able to use leading underscore to indicate private variables and method names. However, variables and functions named with a single `_`, such as $_ and `sub _`, are still forced into the package `main`. See also Technical Note on the Syntax of Variable Names in *perlvar*.

evaled strings are compiled in the package in which the eval() was compiled. (Assignments to $SIG{}, however, assume the signal handler specified is in the main package. Qualify the signal handler name if you wish to have a signal handler in a package.) For an example, examine *perldb.pl* in the Perl library. It initially switches to the DB package so that the debugger doesn't interfere with variables in the program you are trying to debug. At various points, however, it temporarily switches back to the main package to evaluate various expressions in the context of the main package (or wherever you came from). See *perldebug*.

The special symbol __PACKAGE__ contains the current package, but cannot (easily) be used to construct variable names.

See *perlsub* for other scoping issues related to my() and local(), and *perlref* regarding closures.

57.1.2 Symbol Tables

The symbol table for a package happens to be stored in the hash of that name with two colons appended. The main symbol table's name is thus %main::, or %:: for short. Likewise the symbol table for the nested package mentioned earlier is named %OUTER::INNER::.

The value in each entry of the hash is what you are referring to when you use the *name typeglob notation. In fact, the following have the same effect, though the first is more efficient because it does the symbol table lookups at compile time:

```
    local *main::foo    = *main::bar;
    local $main::{foo}  = $main::{bar};
```

(Be sure to note the **vast** difference between the second line above and local $main::foo = $main::bar. The former is accessing the hash %main::, which is the symbol table of package main. The latter is simply assigning scalar $bar in package main to scalar $foo of the same package.)

You can use this to print out all the variables in a package, for instance. The standard but antiquated *dumpvar.pl* library and the CPAN module Devel::Symdump make use of this.

Assignment to a typeglob performs an aliasing operation, i.e.,

```
    *dick = *richard;
```

causes variables, subroutines, formats, and file and directory handles accessible via the identifier richard also to be accessible via the identifier dick. If you want to alias only a particular variable or subroutine, assign a reference instead:

```
    *dick = \$richard;
```

Which makes $richard and $dick the same variable, but leaves @richard and @dick as separate arrays. Tricky, eh?

There is one subtle difference between the following statements:

```
    *foo = *bar;
    *foo = \$bar;
```

*foo = *bar makes the typeglobs themselves synonymous while *foo = \$bar makes the SCALAR portions of two distinct typeglobs refer to the same scalar value. This means that the following code:

```
    $bar = 1;
    *foo = \$bar;       # Make $foo an alias for $bar

    {
        local $bar = 2; # Restrict changes to block
        print $foo;     # Prints '1'!
    }
```

Would print '1', because `$foo` holds a reference to the *original* `$bar` – the one that was stuffed away by `local()` and which will be restored when the block ends. Because variables are accessed through the typeglob, you can use `*foo = *bar` to create an alias which can be localized. (But be aware that this means you can't have a separate `@foo` and `@bar`, etc.)

What makes all of this important is that the Exporter module uses glob aliasing as the import/export mechanism. Whether or not you can properly localize a variable that has been exported from a module depends on how it was exported:

```
    @EXPORT = qw($FOO); # Usual form, can't be localized
    @EXPORT = qw(*FOO); # Can be localized
```

You can work around the first case by using the fully qualified name (`$Package::FOO`) where you need a local value, or by overriding it by saying `*FOO = *Package::FOO` in your script.

The `*x = \$y` mechanism may be used to pass and return cheap references into or from subroutines if you don't want to copy the whole thing. It only works when assigning to dynamic variables, not lexicals.

```
    %some_hash = ();                    # can't be my()
    *some_hash = fn( \%another_hash );
    sub fn {
        local *hashsym = shift;
        # now use %hashsym normally, and you
        # will affect the caller's %another_hash
        my %nhash = (); # do what you want
        return \%nhash;
    }
```

On return, the reference will overwrite the hash slot in the symbol table specified by the *some_hash typeglob. This is a somewhat tricky way of passing around references cheaply when you don't want to have to remember to dereference variables explicitly.

Another use of symbol tables is for making "constant" scalars.

```
    *PI = \3.14159265358979;
```

Now you cannot alter `$PI`, which is probably a good thing all in all. This isn't the same as a constant subroutine, which is subject to optimization at compile-time. A constant subroutine is one prototyped to take no arguments and to return a constant expression. See *perlsub* for details on these. The `use constant` pragma is a convenient shorthand for these.

You can say `*foo{PACKAGE}` and `*foo{NAME}` to find out what name and package the *foo symbol table entry comes from. This may be useful in a subroutine that gets passed typeglobs as arguments:

```
    sub identify_typeglob {
        my $glob = shift;
        print 'You gave me ', *{$glob}{PACKAGE}, '::', *{$glob}{NAME}, "\n";
    }
    identify_typeglob *foo;
    identify_typeglob *bar::baz;
```

This prints

```
    You gave me main::foo
    You gave me bar::baz
```

The `*foo{THING}` notation can also be used to obtain references to the individual elements of *foo. See *perlref*.

Subroutine definitions (and declarations, for that matter) need not necessarily be situated in the package whose symbol table they occupy. You can define a subroutine outside its package by explicitly qualifying the name of the subroutine:

```
    package main;
    sub Some_package::foo { ... }   # &foo defined in Some_package
```

This is just a shorthand for a typeglob assignment at compile time:

```
    BEGIN { *Some_package::foo = sub { ... } }
```

and is *not* the same as writing:

```
    {
        package Some_package;
        sub foo { ... }
    }
```

In the first two versions, the body of the subroutine is lexically in the main package, *not* in Some_package. So something like this:

```
    package main;

    $Some_package::name = "fred";
    $main::name = "barney";

    sub Some_package::foo {
        print "in ", __PACKAGE__, ": \$name is '$name'\n";
    }

    Some_package::foo();
```

prints:

```
    in main: $name is 'barney'
```

rather than:

```
    in Some_package: $name is 'fred'
```

This also has implications for the use of the SUPER:: qualifier (see *perlobj*).

57.1.3 BEGIN, CHECK, INIT and END

Four specially named code blocks are executed at the beginning and at the end of a running Perl program. These are the `BEGIN`, `CHECK`, `INIT`, and `END` blocks.

These code blocks can be prefixed with `sub` to give the appearance of a subroutine (although this is not considered good style). One should note that these code blocks don't really exist as named subroutines (despite their appearance). The thing that gives this away is the fact that you can have **more than one** of these code blocks in a program, and they will get **all** executed at the appropriate moment. So you can't execute any of these code blocks by name.

A `BEGIN` code block is executed as soon as possible, that is, the moment it is completely defined, even before the rest of the containing file (or string) is parsed. You may have multiple `BEGIN` blocks within a file (or eval'ed string) – they will execute in order of definition. Because a `BEGIN` code block executes immediately, it can pull in definitions of subroutines and such from other files in time to be visible to the rest of the compile and run time. Once a `BEGIN` has run, it is immediately undefined and any code it used is returned to Perl's memory pool.

It should be noted that `BEGIN` code blocks **are** executed inside string `eval()`'s. The `CHECK` and `INIT` code blocks are **not** executed inside a string eval, which e.g. can be a problem in a mod_perl environment.

An END code block is executed as late as possible, that is, after perl has finished running the program and just before the interpreter is being exited, even if it is exiting as a result of a die() function. (But not if it's polymorphing into another program via exec, or being blown out of the water by a signal–you have to trap that yourself (if you can).) You may have multiple END blocks within a file–they will execute in reverse order of definition; that is: last in, first out (LIFO). END blocks are not executed when you run perl with the -c switch, or if compilation fails.

Note that END code blocks are **not** executed at the end of a string eval(): if any END code blocks are created in a string eval(), they will be executed just as any other END code block of that package in LIFO order just before the interpreter is being exited.

Inside an END code block, $? contains the value that the program is going to pass to exit(). You can modify $? to change the exit value of the program. Beware of changing $? by accident (e.g. by running something via system).

CHECK and INIT code blocks are useful to catch the transition between the compilation phase and the execution phase of the main program.

CHECK code blocks are run just after the **initial** Perl compile phase ends and before the run time begins, in LIFO order. CHECK code blocks are used in the Perl compiler suite to save the compiled state of the program.

INIT blocks are run just before the Perl runtime begins execution, in "first in, first out" (FIFO) order. For example, the code generators documented in *perlcc* make use of INIT blocks to initialize and resolve pointers to XSUBs.

When you use the **-n** and **-p** switches to Perl, BEGIN and END work just as they do in **awk**, as a degenerate case. Both BEGIN and CHECK blocks are run when you use the **-c** switch for a compile-only syntax check, although your main code is not.

The **begincheck** program makes it all clear, eventually:

```
#!/usr/bin/perl

# begincheck

print         " 8. Ordinary code runs at runtime.\n";

END { print   "14.   So this is the end of the tale.\n" }
INIT { print  " 5. INIT blocks run FIFO just before runtime.\n" }
CHECK { print " 4.   So this is the fourth line.\n" }

print         " 9.   It runs in order, of course.\n";

BEGIN { print " 1. BEGIN blocks run FIFO during compilation.\n" }
END { print   "13.   Read perlmod for the rest of the story.\n" }
CHECK { print " 3. CHECK blocks run LIFO at compilation's end.\n" }
INIT { print  " 6.   Run this again, using Perl's -c switch.\n" }

print         "10.   This is anti-obfuscated code.\n";

END { print   "12. END blocks run LIFO at quitting time.\n" }
BEGIN { print " 2.   So this line comes out second.\n" }
INIT { print  " 7.   You'll see the difference right away.\n" }

print         "11.   It merely _looks_ like it should be confusing.\n";

__END__
```

57.1.4 Perl Classes

There is no special class syntax in Perl, but a package may act as a class if it provides subroutines to act as methods. Such a package may also derive some of its methods from another class (package) by listing the other package name(s) in its global @ISA array (which must be a package global, not a lexical).

For more on this, see *perltoot* and *perlobj*.

57.1.5 Perl Modules

A module is just a set of related functions in a library file, i.e., a Perl package with the same name as the file. It is specifically designed to be reusable by other modules or programs. It may do this by providing a mechanism for exporting some of its symbols into the symbol table of any package using it, or it may function as a class definition and make its semantics available implicitly through method calls on the class and its objects, without explicitly exporting anything. Or it can do a little of both.

For example, to start a traditional, non-OO module called Some::Module, create a file called *Some/Module.pm* and start with this template:

```
package Some::Module;  # assumes Some/Module.pm

use strict;
use warnings;

BEGIN {
    use Exporter   ();
    our ($VERSION, @ISA, @EXPORT, @EXPORT_OK, %EXPORT_TAGS);

    # set the version for version checking
    $VERSION     = 1.00;
    # if using RCS/CVS, this may be preferred
    $VERSION = sprintf "%d.%03d", q$Revision: 1.1 $ =~ /(\d+)/g;

    @ISA         = qw(Exporter);
    @EXPORT      = qw(&func1 &func2 &func4);
    %EXPORT_TAGS = ( );     # eg: TAG => [ qw!name1 name2! ],

    # your exported package globals go here,
    # as well as any optionally exported functions
    @EXPORT_OK   = qw($Var1 %Hashit &func3);
}
our @EXPORT_OK;

# exported package globals go here
our $Var1;
our %Hashit;

# non-exported package globals go here
our @more;
our $stuff;

# initialize package globals, first exported ones
$Var1   = '';
%Hashit = ();

# then the others (which are still accessible as $Some::Module::stuff)
$stuff  = '';
@more   = ();

# all file-scoped lexicals must be created before
# the functions below that use them.

# file-private lexicals go here
my $priv_var    = '';
my %secret_hash = ();
```

```
    # here's a file-private function as a closure,
    # callable as &$priv_func;  it cannot be prototyped.
    my $priv_func = sub {
        # stuff goes here.
    };

    # make all your functions, whether exported or not;
    # remember to put something interesting in the {} stubs
    sub func1      {}    # no prototype
    sub func2()    {}    # proto'd void
    sub func3($$)  {}    # proto'd to 2 scalars

    # this one isn't exported, but could be called!
    sub func4(\%)  {}    # proto'd to 1 hash ref

    END { }       # module clean-up code here (global destructor)

    ## YOUR CODE GOES HERE

    1;  # don't forget to return a true value from the file
```

Then go on to declare and use your variables in functions without any qualifications. See *Exporter* and the *perlmodlib* for details on mechanics and style issues in module creation.

Perl modules are included into your program by saying

```
    use Module;
```

or

```
    use Module LIST;
```

This is exactly equivalent to

```
    BEGIN { require Module; import Module; }
```

or

```
    BEGIN { require Module; import Module LIST; }
```

As a special case

```
    use Module ();
```

is exactly equivalent to

```
    BEGIN { require Module; }
```

All Perl module files have the extension *.pm*. The `use` operator assumes this so you don't have to spell out "*Module.pm*" in quotes. This also helps to differentiate new modules from old *.pl* and *.ph* files. Module names are also capitalized unless they're functioning as pragmas; pragmas are in effect compiler directives, and are sometimes called "pragmatic modules" (or even "pragmata" if you're a classicist).

The two statements:

```
    require SomeModule;
    require "SomeModule.pm";
```

differ from each other in two ways. In the first case, any double colons in the module name, such as `Some::Module`, are translated into your system's directory separator, usually "/". The second case does not, and would have to be specified literally. The other difference is that seeing the first `require` clues in the compiler that uses of indirect object notation involving "SomeModule", as in `$ob = purge SomeModule`, are method calls, not function calls. (Yes, this really can make a difference.)

Because the `use` statement implies a `BEGIN` block, the importing of semantics happens as soon as the `use` statement is compiled, before the rest of the file is compiled. This is how it is able to function as a pragma mechanism, and also how modules are able to declare subroutines that are then visible as list or unary operators for the rest of the current file. This will not work if you use `require` instead of `use`. With `require` you can get into this problem:

```
    require Cwd;                # make Cwd:: accessible
    $here = Cwd::getcwd();

    use Cwd;                    # import names from Cwd::
    $here = getcwd();

    require Cwd;                # make Cwd:: accessible
    $here = getcwd();           # oops! no main::getcwd()
```

In general, `use Module ()` is recommended over `require Module`, because it determines module availability at compile time, not in the middle of your program's execution. An exception would be if two modules each tried to `use` each other, and each also called a function from that other module. In that case, it's easy to use `require` instead.

Perl packages may be nested inside other package names, so we can have package names containing `::`. But if we used that package name directly as a filename it would make for unwieldy or impossible filenames on some systems. Therefore, if a module's name is, say, `Text::Soundex`, then its definition is actually found in the library file *Text/Soundex.pm*.

Perl modules always have a *.pm* file, but there may also be dynamically linked executables (often ending in *.so*) or autoloaded subroutine definitions (often ending in *.al*) associated with the module. If so, these will be entirely transparent to the user of the module. It is the responsibility of the *.pm* file to load (or arrange to autoload) any additional functionality. For example, although the POSIX module happens to do both dynamic loading and autoloading, the user can say just `use POSIX` to get it all.

57.1.6 Making your module threadsafe

Since 5.6.0, Perl has had support for a new type of threads called interpreter threads (ithreads). These threads can be used explicitly and implicitly.

Ithreads work by cloning the data tree so that no data is shared between different threads. These threads can be used by using the `threads` module or by doing fork() on win32 (fake fork() support). When a thread is cloned all Perl data is cloned, however non-Perl data cannot be cloned automatically. Perl after 5.7.2 has support for the `CLONE` special subroutine. In `CLONE` you can do whatever you need to do, like for example handle the cloning of non-Perl data, if necessary. `CLONE` will be called once as a class method for every package that has it defined (or inherits it). It will be called in the context of the new thread, so all modifications are made in the new area. Currently CLONE is called with no parameters other than the invocant package name, but code should not assume that this will remain unchanged, as it is likely that in future extra parameters will be passed in to give more information about the state of cloning.

If you want to CLONE all objects you will need to keep track of them per package. This is simply done using a hash and Scalar::Util::weaken().

Chapter 58

perlmodlib

Constructing new Perl modules and finding existing ones

58.1 THE PERL MODULE LIBRARY

Many modules are included in the Perl distribution. These are described below, and all end in *.pm*. You may discover compiled library files (usually ending in *.so*) or small pieces of modules to be autoloaded (ending in *.al*); these were automatically generated by the installation process. You may also discover files in the library directory that end in either *.pl* or *.ph*. These are old libraries supplied so that old programs that use them still run. The *.pl* files will all eventually be converted into standard modules, and the *.ph* files made by **h2ph** will probably end up as extension modules made by **h2xs**. (Some *.ph* values may already be available through the POSIX, Errno, or Fcntl modules.) The **pl2pm** file in the distribution may help in your conversion, but it's just a mechanical process and therefore far from bulletproof.

58.1.1 Pragmatic Modules

They work somewhat like compiler directives (pragmata) in that they tend to affect the compilation of your program, and thus will usually work well only when used within a `use`, or `no`. Most of these are lexically scoped, so an inner BLOCK may countermand them by saying:

```
    no integer;
    no strict 'refs';
    no warnings;
```

which lasts until the end of that BLOCK.

Some pragmas are lexically scoped–typically those that affect the `$^H` hints variable. Others affect the current package instead, like `use vars` and `use subs`, which allow you to predeclare a variables or subroutines within a particular *file* rather than just a block. Such declarations are effective for the entire file for which they were declared. You cannot rescind them with `no vars` or `no subs`.

The following pragmas are defined (and have their own documentation).

attributes

Get/set subroutine or variable attributes

attrs

Set/get attributes of a subroutine (deprecated)

autouse

Postpone load of modules until a function is used

base

Establish IS-A relationship with base class at compile time

bigint

Transparent BigInteger support for Perl

bignum

Transparent BigNumber support for Perl

bigrat

Transparent BigNumber/BigRational support for Perl

blib

Use MakeMaker's uninstalled version of a package

bytes

Force byte semantics rather than character semantics

charnames

Define character names for `\N{named}` string literal escapes

constant

Declare constants

diagnostics

Produce verbose warning diagnostics

encoding

Allows you to write your script in non-ascii or non-utf8

fields

Compile-time class fields

filetest

Control the filetest permission operators

if

`use` a Perl module if a condition holds

integer

Use integer arithmetic instead of floating point

less

Request less of something from the compiler

lib

Manipulate @INC at compile time

locale

Use and avoid POSIX locales for built-in operations

open

Set default PerlIO layers for input and output

ops

Restrict unsafe operations when compiling

overload

Package for overloading perl operations

re

Alter regular expression behaviour

sigtrap

Enable simple signal handling

sort

Control sort() behaviour

strict

Restrict unsafe constructs

subs

Predeclare sub names

threads

Perl extension allowing use of interpreter based threads from perl

threads::shared

Perl extension for sharing data structures between threads

utf8

Enable/disable UTF-8 (or UTF-EBCDIC) in source code

vars

Predeclare global variable names (obsolete)

vmsish

Control VMS-specific language features

warnings

Control optional warnings

warnings::register

Warnings import function

58.1.2 Standard Modules

Standard, bundled modules are all expected to behave in a well-defined manner with respect to namespace pollution because they use the Exporter module. See their own documentation for details.

It's possible that not all modules listed below are installed on your system. For example, the GDBM_File module will not be installed if you don't have the gdbm library.

AnyDBM_File

Provide framework for multiple DBMs

Attribute::Handlers

Simpler definition of attribute handlers

AutoLoader

Load subroutines only on demand

AutoSplit

Split a package for autoloading

B

The Perl Compiler

B::Asmdata

Autogenerated data about Perl ops, used to generate bytecode

B::Assembler

Assemble Perl bytecode

B::Bblock

Walk basic blocks

B::Bytecode

Perl compiler's bytecode backend

B::C

Perl compiler's C backend

B::CC

Perl compiler's optimized C translation backend

B::Concise

Walk Perl syntax tree, printing concise info about ops

B::Debug

Walk Perl syntax tree, printing debug info about ops

B::Deparse

Perl compiler backend to produce perl code

B::Disassembler

Disassemble Perl bytecode

B::Lint

Perl lint

B::Showlex

Show lexical variables used in functions or files

B::Stackobj

Helper module for CC backend

B::Stash

Show what stashes are loaded

B::Terse

Walk Perl syntax tree, printing terse info about ops

B::Xref

Generates cross reference reports for Perl programs

Benchmark

Benchmark running times of Perl code

ByteLoader

Load byte compiled perl code

CGI

Simple Common Gateway Interface Class

CGI::Apache

Backward compatibility module for CGI.pm

CGI::Carp

CGI routines for writing to the HTTPD (or other) error log

CGI::Cookie

Interface to Netscape Cookies

CGI::Fast

CGI Interface for Fast CGI

CGI::Pretty

Module to produce nicely formatted HTML code

CGI::Push

Simple Interface to Server Push

CGI::Switch

Backward compatibility module for defunct CGI::Switch

CGI::Util

Internal utilities used by CGI module

CPAN

Query, download and build perl modules from CPAN sites

CPAN::FirstTime

Utility for CPAN::Config file Initialization

CPAN::Nox

Wrapper around CPAN.pm without using any XS module

Carp

Warn of errors (from perspective of caller)

Carp::Heavy

No user serviceable parts inside

Class::ISA

Report the search path for a class's ISA tree

Class::Struct

Declare struct-like datatypes as Perl classes

Config

Access Perl configuration information

Cwd

Get pathname of current working directory

DB

Programmatic interface to the Perl debugging API (draft, subject to

DB_File

Perl5 access to Berkeley DB version 1.x

Data::Dumper

Stringified perl data structures, suitable for both printing and `eval`

Devel::DProf

A Perl code profiler

Devel::PPPort

Perl/Pollution/Portability

Devel::Peek

A data debugging tool for the XS programmer

Devel::SelfStubber

Generate stubs for a SelfLoading module

Digest

Modules that calculate message digests

Digest::MD5

Perl interface to the MD5 Algorithm

Digest::base

Digest base class

DirHandle

Supply object methods for directory handles

Dumpvalue

Provides screen dump of Perl data.

DynaLoader

Dynamically load C libraries into Perl code

Encode

Character encodings

Encode::Alias

Alias definitions to encodings

Encode::Byte

Single Byte Encodings

Encode::CJKConstants

Internally used by Encode::??::ISO_2022_*

Encode::CN

China-based Chinese Encodings

Encode::CN::HZ

Internally used by Encode::CN

Encode::Config

Internally used by Encode

Encode::EBCDIC

EBCDIC Encodings

Encode::Encoder

Object Oriented Encoder

Encode::Encoding

Encode Implementation Base Class

Encode::Guess

Guesses encoding from data

Encode::JP

Japanese Encodings

Encode::JP::H2Z

Internally used by Encode::JP::2022_JP*

Encode::JP::JIS7

Internally used by Encode::JP

Encode::KR

Korean Encodings

Encode::KR::2022_KR

Internally used by Encode::KR

Encode::MIME::Header

MIME ’B’ and ’Q’ header encoding

Encode::PerlIO

A detailed document on Encode and PerlIO

Encode::Supported

Encodings supported by Encode

Encode::Symbol

Symbol Encodings

Encode::TW

Taiwan-based Chinese Encodings

Encode::Unicode

Various Unicode Transformation Formats

Encode::Unicode::UTF7

UTF-7 encoding

English

Use nice English (or awk) names for ugly punctuation variables

Env

Perl module that imports environment variables as scalars or arrays

Errno

System errno constants

Exporter

Implements default import method for modules

Exporter::Heavy

Exporter guts

ExtUtils::Command

Utilities to replace common UNIX commands in Makefiles etc.

ExtUtils::Command::MM

Commands for the MM’s to use in Makefiles

ExtUtils::Constant

Generate XS code to import C header constants

ExtUtils::Embed

Utilities for embedding Perl in C/C++ applications

ExtUtils::Install

Install files from here to there

ExtUtils::Installed

Inventory management of installed modules

ExtUtils::Liblist

Determine libraries to use and how to use them

ExtUtils::MM

OS adjusted ExtUtils::MakeMaker subclass

ExtUtils::MM_Any

Platform-agnostic MM methods

ExtUtils::MM_BeOS

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_Cygwin

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_DOS

DOS specific subclass of ExtUtils::MM_Unix

ExtUtils::MM_MacOS

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_NW5

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_OS2

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_UWIN

U/WIN specific subclass of ExtUtils::MM_Unix

ExtUtils::MM_Unix

Methods used by ExtUtils::MakeMaker

ExtUtils::MM_VMS

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_Win32

Methods to override UN*X behaviour in ExtUtils::MakeMaker

ExtUtils::MM_Win95

Method to customize MakeMaker for Win9X

ExtUtils::MY

ExtUtils::MakeMaker subclass for customization

ExtUtils::MakeMaker

Create a module Makefile

ExtUtils::MakeMaker::FAQ

Frequently Asked Questions About MakeMaker

ExtUtils::MakeMaker::Tutorial

Writing a module with MakeMaker

ExtUtils::MakeMaker::bytes

Version-agnostic bytes.pm

ExtUtils::MakeMaker::vmsish

Platform-agnostic vmsish.pm

ExtUtils::Manifest

Utilities to write and check a MANIFEST file

ExtUtils::Mkbootstrap

Make a bootstrap file for use by DynaLoader

ExtUtils::Mksymlists

Write linker options files for dynamic extension

ExtUtils::Packlist

Manage .packlist files

ExtUtils::testlib

Add blib/* directories to @INC

Fatal

Replace functions with equivalents which succeed or die

Fcntl

Load the C Fcntl.h defines

File::Basename

Split a pathname into pieces

File::CheckTree

Run many filetest checks on a tree

File::Compare

Compare files or filehandles

File::Copy

Copy files or filehandles

File::DosGlob

DOS like globbing and then some

File::Find

Traverse a directory tree.

File::Glob

Perl extension for BSD glob routine

File::Path

Create or remove directory trees

File::Spec

Portably perform operations on file names

File::Spec::Cygwin

Methods for Cygwin file specs

File::Spec::Epoc

Methods for Epoc file specs

File::Spec::Functions

Portably perform operations on file names

File::Spec::Mac

File::Spec for Mac OS (Classic)

File::Spec::OS2

Methods for OS/2 file specs

File::Spec::Unix

File::Spec for Unix, base for other File::Spec modules

File::Spec::VMS

Methods for VMS file specs

File::Spec::Win32

Methods for Win32 file specs

File::Temp

Return name and handle of a temporary file safely

File::stat

By-name interface to Perl's built-in stat() functions

FileCache

Keep more files open than the system permits

FileHandle

Supply object methods for filehandles

Filter::Simple

Simplified source filtering

Filter::Util::Call

Perl Source Filter Utility Module

FindBin

Locate directory of original perl script

GDBM_File

Perl5 access to the gdbm library.

Getopt::Long

Extended processing of command line options

Getopt::Std

Process single-character switches with switch clustering

Hash::Util

A selection of general-utility hash subroutines

I18N::Collate

Compare 8-bit scalar data according to the current locale

I18N::LangTags

Functions for dealing with RFC3066-style language tags

I18N::LangTags::List

Tags and names for human languages

I18N::Langinfo

Query locale information

IO

Load various IO modules

IO::Dir

Supply object methods for directory handles

IO::File

Supply object methods for filehandles

IO::Handle

Supply object methods for I/O handles

IO::Pipe

Supply object methods for pipes

IO::Poll

Object interface to system poll call

IO::Seekable

Supply seek based methods for I/O objects

IO::Select

OO interface to the select system call

IO::Socket
: Object interface to socket communications

IO::Socket::INET
: Object interface for AF_INET domain sockets

IO::Socket::UNIX
: Object interface for AF_UNIX domain sockets

IPC::Open2
: Open a process for both reading and writing

IPC::Open3
: Open a process for reading, writing, and error handling

IPC::SysV
: SysV IPC constants

IPC::SysV::Msg
: SysV Msg IPC object class

IPC::SysV::Semaphore
: SysV Semaphore IPC object class

List::Util
: A selection of general-utility list subroutines

Locale::Constants
: Constants for Locale codes

Locale::Country
: ISO codes for country identification (ISO 3166)

Locale::Currency
: ISO three letter codes for currency identification (ISO 4217)

Locale::Language
: ISO two letter codes for language identification (ISO 639)

Locale::Maketext
: Framework for localization

Locale::Maketext::TPJ13
: Article about software localization

Locale::Script
: ISO codes for script identification (ISO 15924)

MIME::Base64
: Encoding and decoding of base64 strings

MIME::Base64::QuotedPrint
: Encoding and decoding of quoted-printable strings

Math::BigFloat
: Arbitrary size floating point math package

Math::BigInt
: Arbitrary size integer math package

Math::BigInt::Calc
: Pure Perl module to support Math::BigInt

Math::BigRat
: Arbitrarily big rationals

Math::Complex
: Complex numbers and associated mathematical functions

Math::Trig
: Trigonometric functions

Memoize
: Make functions faster by trading space for time

Memoize::AnyDBM_File
: Glue to provide EXISTS for AnyDBM_File for Storable use

Memoize::Expire
: Plug-in module for automatic expiration of memoized values

Memoize::ExpireFile
: Test for Memoize expiration semantics

Memoize::ExpireTest
: Test for Memoize expiration semantics

Memoize::NDBM_File
: Glue to provide EXISTS for NDBM_File for Storable use

Memoize::SDBM_File
: Glue to provide EXISTS for SDBM_File for Storable use

Memoize::Storable
: Store Memoized data in Storable database

NDBM_File
: Tied access to ndbm files

NEXT
: Provide a pseudo-class NEXT (et al) that allows method redispatch

Net::Cmd
: Network Command class (as used by FTP, SMTP etc)

Net::Config
: Local configuration data for libnet

Net::Domain
: Attempt to evaluate the current host's internet name and domain

Net::FTP
: FTP Client class

Net::NNTP

NNTP Client class

Net::Netrc

OO interface to users netrc file

Net::POP3

Post Office Protocol 3 Client class (RFC1939)

Net::Ping

Check a remote host for reachability

Net::SMTP

Simple Mail Transfer Protocol Client

Net::Time

Time and daytime network client interface

Net::hostent

By-name interface to Perl's built-in gethost*() functions

Net::libnetFAQ

Libnet Frequently Asked Questions

Net::netent

By-name interface to Perl's built-in getnet*() functions

Net::protoent

By-name interface to Perl's built-in getproto*() functions

Net::servent

By-name interface to Perl's built-in getserv*() functions

O

Generic interface to Perl Compiler backends

ODBM_File

Tied access to odbm files

Opcode

Disable named opcodes when compiling perl code

POSIX

Perl interface to IEEE Std 1003.1

PerlIO

On demand loader for PerlIO layers and root of PerlIO::* name space

PerlIO::encoding

Encoding layer

PerlIO::scalar

In-memory IO, scalar IO

PerlIO::via

Helper class for PerlIO layers implemented in perl

PerlIO::via::QuotedPrint
: PerlIO layer for quoted-printable strings

Pod::Checker
: Check pod documents for syntax errors

Pod::Find
: Find POD documents in directory trees

Pod::Functions
: Group Perl's functions a la perlfunc.pod

Pod::Html
: Module to convert pod files to HTML

Pod::InputObjects
: Objects representing POD input paragraphs, commands, etc.

Pod::LaTeX
: Convert Pod data to formatted Latex

Pod::Man
: Convert POD data to formatted *roff input

Pod::ParseLink
: Parse an L<> formatting code in POD text

Pod::ParseUtils
: Helpers for POD parsing and conversion

Pod::Parser
: Base class for creating POD filters and translators

Pod::Perldoc::ToChecker
: Let Perldoc check Pod for errors

Pod::Perldoc::ToMan
: Let Perldoc render Pod as man pages

Pod::Perldoc::ToNroff
: Let Perldoc convert Pod to nroff

Pod::Perldoc::ToPod
: Let Perldoc render Pod as ... Pod!

Pod::Perldoc::ToRtf
: Let Perldoc render Pod as RTF

Pod::Perldoc::ToText
: Let Perldoc render Pod as plaintext

Pod::Perldoc::ToTk
: Let Perldoc use Tk::Pod to render Pod

Pod::Perldoc::ToXml
: Let Perldoc render Pod as XML

Pod::PlainText

Convert POD data to formatted ASCII text

Pod::Plainer

Perl extension for converting Pod to old style Pod.

Pod::Select

Extract selected sections of POD from input

Pod::Text

Convert POD data to formatted ASCII text

Pod::Text::Color

Convert POD data to formatted color ASCII text

Pod::Text::Overstrike

Convert POD data to formatted overstrike text

Pod::Text::Termcap

Convert POD data to ASCII text with format escapes

Pod::Usage

Print a usage message from embedded pod documentation

SDBM_File

Tied access to sdbm files

Safe

Compile and execute code in restricted compartments

Scalar::Util

A selection of general-utility scalar subroutines

Search::Dict

Search for key in dictionary file

SelectSaver

Save and restore selected file handle

SelfLoader

Load functions only on demand

Shell

Run shell commands transparently within perl

Socket

Load the C socket.h defines and structure manipulators

Storable

Persistence for Perl data structures

Switch

A switch statement for Perl

Symbol

Manipulate Perl symbols and their names

Sys::Hostname

Try every conceivable way to get hostname

Sys::Syslog

Perl interface to the UNIX syslog(3) calls

Term::ANSIColor

Color screen output using ANSI escape sequences

Term::Cap

Perl termcap interface

Term::Complete

Perl word completion module

Term::ReadLine

Perl interface to various `readline` packages.

Test

Provides a simple framework for writing test scripts

Test::Builder

Backend for building test libraries

Test::Harness

Run Perl standard test scripts with statistics

Test::Harness::Assert

Simple assert

Test::Harness::Iterator

Internal Test::Harness Iterator

Test::Harness::Straps

Detailed analysis of test results

Test::More

Yet another framework for writing test scripts

Test::Simple

Basic utilities for writing tests.

Test::Tutorial

A tutorial about writing really basic tests

Text::Abbrev

Create an abbreviation table from a list

Text::Balanced

Extract delimited text sequences from strings.

Text::ParseWords

Parse text into an array of tokens or array of arrays

Text::Soundex

Implementation of the Soundex Algorithm as Described by Knuth

Text::Tabs
Expand and unexpand tabs per the unix expand(1) and unexpand(1)

Text::Wrap
Line wrapping to form simple paragraphs

Thread
Manipulate threads in Perl (for old code only)

Thread::Queue
Thread-safe queues

Thread::Semaphore
Thread-safe semaphores

Thread::Signal
Start a thread which runs signal handlers reliably (for old code)

Thread::Specific
Thread-specific keys

Tie::Array
Base class for tied arrays

Tie::File
Access the lines of a disk file via a Perl array

Tie::Handle
Base class definitions for tied handles

Tie::Hash
Base class definitions for tied hashes

Tie::Memoize
Add data to hash when needed

Tie::RefHash
Use references as hash keys

Tie::Scalar
Base class definitions for tied scalars

Tie::SubstrHash
Fixed-table-size, fixed-key-length hashing

Time::HiRes
High resolution alarm, sleep, gettimeofday, interval timers

Time::Local
Efficiently compute time from local and GMT time

Time::gmtime
By-name interface to Perl's built-in gmtime() function

Time::localtime
By-name interface to Perl's built-in localtime() function

Time::tm

Internal object used by Time::gmtime and Time::localtime

UNIVERSAL

Base class for ALL classes (blessed references)

Unicode::Collate

Unicode Collation Algorithm

Unicode::Normalize

Unicode Normalization Forms

Unicode::UCD

Unicode character database

User::grent

By-name interface to Perl's built-in getgr*() functions

User::pwent

By-name interface to Perl's built-in getpw*() functions

Win32

Interfaces to some Win32 API Functions

XS::APItest

Test the perl C API

XS::Typemap

Module to test the XS typemaps distributed with perl

XSLoader

Dynamically load C libraries into Perl code

To find out *all* modules installed on your system, including those without documentation or outside the standard release, just use the following command (under the default win32 shell, double quotes should be used instead of single quotes).

```
% perl -MFile::Find=find -MFile::Spec::Functions -Tlwe \
  'find { wanted => sub { print canonpath $_ if /\.pm\z/ },
  no_chdir => 1 }, @INC'
```

(The -T is here to prevent '.' from being listed in @INC.) They should all have their own documentation installed and accessible via your system man(1) command. If you do not have a **find** program, you can use the Perl **find2perl** program instead, which generates Perl code as output you can run through perl. If you have a **man** program but it doesn't find your modules, you'll have to fix your manpath. See *perl* for details. If you have no system **man** command, you might try the **perldoc** program.

Note also that the command `perldoc perllocal` gives you a (possibly incomplete) list of the modules that have been further installed on your system. (The perllocal.pod file is updated by the standard MakeMaker install process.)

58.1.3 Extension Modules

Extension modules are written in C (or a mix of Perl and C). They are usually dynamically loaded into Perl if and when you need them, but may also be linked in statically. Supported extension modules include Socket, Fcntl, and POSIX.

Many popular C extension modules do not come bundled (at least, not completely) due to their sizes, volatility, or simply lack of time for adequate testing and configuration across the multitude of platforms on which Perl was beta-tested. You are encouraged to look for them on CPAN (described below), or using web search engines like Alta Vista or Google.

58.2 CPAN

CPAN stands for Comprehensive Perl Archive Network; it's a globally replicated trove of Perl materials, including documentation, style guides, tricks and traps, alternate ports to non-Unix systems and occasional binary distributions for these. Search engines for CPAN can be found at http://www.cpan.org/

Most importantly, CPAN includes around a thousand unbundled modules, some of which require a C compiler to build. Major categories of modules are:

- Language Extensions and Documentation Tools
- Development Support
- Operating System Interfaces
- Networking, Device Control (modems) and InterProcess Communication
- Data Types and Data Type Utilities
- Database Interfaces
- User Interfaces
- Interfaces to / Emulations of Other Programming Languages
- File Names, File Systems and File Locking (see also File Handles)
- String Processing, Language Text Processing, Parsing, and Searching
- Option, Argument, Parameter, and Configuration File Processing
- Internationalization and Locale
- Authentication, Security, and Encryption
- World Wide Web, HTML, HTTP, CGI, MIME
- Server and Daemon Utilities
- Archiving and Compression
- Images, Pixmap and Bitmap Manipulation, Drawing, and Graphing
- Mail and Usenet News
- Control Flow Utilities (callbacks and exceptions etc)
- File Handle and Input/Output Stream Utilities
- Miscellaneous Modules

The list of the registered CPAN sites as of this writing follows. Please note that the sorting order is alphabetical on fields:

Continent | |–>Country | |–>[state/province] | |–>ftp | |–>[http]

and thus the North American servers happen to be listed between the European and the South American sites.

You should try to choose one close to you.

58.2.1 Africa

South Africa

```

58.3 Modules: Creation, Use, and Abuse

(The following section is borrowed directly from Tim Bunce's modules file, available at your nearest CPAN site.)

Perl implements a class using a package, but the presence of a package doesn't imply the presence of a class. A package is just a namespace. A class is a package that provides subroutines that can be used as methods. A method is just a subroutine that expects, as its first argument, either the name of a package (for "static" methods), or a reference to something (for "virtual" methods).

A module is a file that (by convention) provides a class of the same name (sans the .pm), plus an import method in that class that can be called to fetch exported symbols. This module may implement some of its methods by loading dynamic C or C++ objects, but that should be totally transparent to the user of the module. Likewise, the module might set up an AUTOLOAD function to slurp in subroutine definitions on demand, but this is also transparent. Only the *.pm* file is required to exist. See *perlsub*, *perltoot*, and *AutoLoader* for details about the AUTOLOAD mechanism.

58.3.1 Guidelines for Module Creation

- Do similar modules already exist in some form?

  If so, please try to reuse the existing modules either in whole or by inheriting useful features into a new class. If this is not practical try to get together with the module authors to work on extending or enhancing the functionality of the existing modules. A perfect example is the plethora of packages in perl4 for dealing with command line options.

If you are writing a module to expand an already existing set of modules, please coordinate with the author of the package. It helps if you follow the same naming scheme and module interaction scheme as the original author.

- Try to design the new module to be easy to extend and reuse.

  Try to `use warnings;` (or `use warnings qw(...);`). Remember that you can add `no warnings qw(...);` to individual blocks of code that need less warnings.

  Use blessed references. Use the two argument form of bless to bless into the class name given as the first parameter of the constructor, e.g.,:

```
sub new {
    my $class = shift;
    return bless {}, $class;
}
```

  or even this if you'd like it to be used as either a static or a virtual method.

```
sub new {
    my $self  = shift;
    my $class = ref($self) || $self;
    return bless {}, $class;
}
```

  Pass arrays as references so more parameters can be added later (it's also faster). Convert functions into methods where appropriate. Split large methods into smaller more flexible ones. Inherit methods from other modules if appropriate.

  Avoid class name tests like: `die "Invalid" unless ref $ref eq 'FOO'`. Generally you can delete the `eq 'FOO'` part with no harm at all. Let the objects look after themselves! Generally, avoid hard-wired class names as far as possible.

  Avoid `$r->Class::func()` where using `@ISA=qw(... Class ...)` and `$r->func()` would work (see *perlbot* for more details).

  Use autosplit so little used or newly added functions won't be a burden to programs that don't use them. Add test functions to the module after __END__ either using AutoSplit or by saying:

```
eval join('',<main::DATA>) || die $@ unless caller();
```

  Does your module pass the 'empty subclass' test? If you say `@SUBCLASS::ISA = qw(YOURCLASS);` your applications should be able to use SUBCLASS in exactly the same way as YOURCLASS. For example, does your application still work if you change: `$obj = new YOURCLASS;` into: `$obj = new SUBCLASS;` ?

  Avoid keeping any state information in your packages. It makes it difficult for multiple other packages to use yours. Keep state information in objects.

  Always use **-w**.

  Try to `use strict;` (or `use strict qw(...);`). Remember that you can add `no strict qw(...);` to individual blocks of code that need less strictness.

  Always use **-w**.

  Follow the guidelines in the perlstyle(1) manual.

  Always use **-w**.

- Some simple style guidelines

  The perlstyle manual supplied with Perl has many helpful points.

  Coding style is a matter of personal taste. Many people evolve their style over several years as they learn what helps them write and maintain good code. Here's one set of assorted suggestions that seem to be widely used by experienced developers:

Use underscores to separate words. It is generally easier to read $var_names_like_this than $VarNamesLikeThis, especially for non-native speakers of English. It's also a simple rule that works consistently with VAR_NAMES_LIKE_THIS.

Package/Module names are an exception to this rule. Perl informally reserves lowercase module names for 'pragma' modules like integer and strict. Other modules normally begin with a capital letter and use mixed case with no underscores (need to be short and portable).

You may find it helpful to use letter case to indicate the scope or nature of a variable. For example:

```
$ALL_CAPS_HERE   constants only (beware clashes with Perl vars)
$Some_Caps_Here  package-wide global/static
$no_caps_here    function scope my() or local() variables
```

Function and method names seem to work best as all lowercase. e.g., `$obj->as_string()`.

You can use a leading underscore to indicate that a variable or function should not be used outside the package that defined it.

- Select what to export.

  Do NOT export method names!

  Do NOT export anything else by default without a good reason!

  Exports pollute the namespace of the module user. If you must export try to use @EXPORT_OK in preference to @EXPORT and avoid short or common names to reduce the risk of name clashes.

  Generally anything not exported is still accessible from outside the module using the ModuleName::item_name (or `$blessed_ref->method`) syntax. By convention you can use a leading underscore on names to indicate informally that they are 'internal' and not for public use.

  (It is actually possible to get private functions by saying: `my $subref = sub { ...  }; &$subref;`. But there's no way to call that directly as a method, because a method must have a name in the symbol table.)

  As a general rule, if the module is trying to be object oriented then export nothing. If it's just a collection of functions then @EXPORT_OK anything but use @EXPORT with caution.

- Select a name for the module.

  This name should be as descriptive, accurate, and complete as possible. Avoid any risk of ambiguity. Always try to use two or more whole words. Generally the name should reflect what is special about what the module does rather than how it does it. Please use nested module names to group informally or categorize a module. There should be a very good reason for a module not to have a nested name. Module names should begin with a capital letter.

  Having 57 modules all called Sort will not make life easy for anyone (though having 23 called Sort::Quick is only marginally better :-). Imagine someone trying to install your module alongside many others. If in any doubt ask for suggestions in comp.lang.perl.misc.

  If you are developing a suite of related modules/classes it's good practice to use nested classes with a common prefix as this will avoid namespace clashes. For example: Xyz::Control, Xyz::View, Xyz::Model etc. Use the modules in this list as a naming guide.

  If adding a new module to a set, follow the original author's standards for naming modules and the interface to methods in those modules.

  If developing modules for private internal or project specific use, that will never be released to the public, then you should ensure that their names will not clash with any future public module. You can do this either by using the reserved Local::* category or by using a category name that includes an underscore like Foo_Corp::*.

  To be portable each component of a module name should be limited to 11 characters. If it might be used on MS-DOS then try to ensure each is unique in the first 8 characters. Nested modules make this easier.

- Have you got it right?

  How do you know that you've made the right decisions? Have you picked an interface design that will cause problems later? Have you picked the most appropriate name? Do you have any questions?

The best way to know for sure, and pick up many helpful suggestions, is to ask someone who knows. Comp.lang.perl.misc is read by just about all the people who develop modules and it's the best place to ask.

All you need to do is post a short summary of the module, its purpose and interfaces. A few lines on each of the main methods is probably enough. (If you post the whole module it might be ignored by busy people - generally the very people you want to read it!)

Don't worry about posting if you can't say when the module will be ready - just say so in the message. It might be worth inviting others to help you, they may be able to complete it for you!

- README and other Additional Files.

  It's well known that software developers usually fully document the software they write. If, however, the world is in urgent need of your software and there is not enough time to write the full documentation please at least provide a README file containing:

  - A description of the module/package/extension etc.
  - A copyright notice - see below.
  - Prerequisites - what else you may need to have.
  - How to build it - possible changes to Makefile.PL etc.
  - How to install it.
  - Recent changes in this release, especially incompatibilities
  - Changes / enhancements you plan to make in the future.

  If the README file seems to be getting too large you may wish to split out some of the sections into separate files: INSTALL, Copying, ToDo etc.

  - Adding a Copyright Notice.

    How you choose to license your work is a personal decision. The general mechanism is to assert your Copyright and then make a declaration of how others may copy/use/modify your work.

    Perl, for example, is supplied with two types of licence: The GNU GPL and The Artistic Licence (see the files README, Copying, and Artistic, or *perlgpl* and *perlartistic*). Larry has good reasons for NOT just using the GNU GPL.

    My personal recommendation, out of respect for Larry, Perl, and the Perl community at large is to state something simply like:

    ```
    Copyright (c) 1995 Your Name. All rights reserved.
    This program is free software; you can redistribute it and/or
    modify it under the same terms as Perl itself.
    ```

    This statement should at least appear in the README file. You may also wish to include it in a Copying file and your source files. Remember to include the other words in addition to the Copyright.

  - Give the module a version/issue/release number.

    To be fully compatible with the Exporter and MakeMaker modules you should store your module's version number in a non-my package variable called $VERSION. This should be a floating point number with at least two digits after the decimal (i.e., hundredths, e.g, `$VERSION = "0.01"`). Don't use a "1.3.2" style version. See *Exporter* for details.

    It may be handy to add a function or method to retrieve the number. Use the number in announcements and archive file names when releasing the module (ModuleName-1.02.tar.Z). See perldoc ExtUtils::MakeMaker.pm for details.

  - How to release and distribute a module.

    It's good idea to post an announcement of the availability of your module (or the module itself if small) to the comp.lang.perl.announce Usenet newsgroup. This will at least ensure very wide once-off distribution.

    If possible, register the module with CPAN. You should include details of its location in your announcement.

    Some notes about ftp archives: Please use a long descriptive file name that includes the version number. Most incoming directories will not be readable/listable, i.e., you won't be able to see your file after uploading it. Remember to send your email notification message as soon as possible after uploading else your file may get deleted automatically. Allow time for the file to be processed and/or check the file has been processed before announcing its location.

FTP Archives for Perl Modules:

Follow the instructions and links on:

```
http://www.cpan.org/modules/00modlist.long.html
http://www.cpan.org/modules/04pause.html
```

or upload to one of these sites:

```
https://pause.kbx.de/pause/
http://pause.perl.org/pause/
```

and notify <modules@perl.org>.

By using the WWW interface you can ask the Upload Server to mirror your modules from your ftp or WWW site into your own directory on CPAN!

Please remember to send me an updated entry for the Module list!

- Take care when changing a released module.

  Always strive to remain compatible with previous released versions. Otherwise try to add a mechanism to revert to the old behavior if people rely on it. Document incompatible changes.

58.3.2 Guidelines for Converting Perl 4 Library Scripts into Modules

- There is no requirement to convert anything.

  If it ain't broke, don't fix it! Perl 4 library scripts should continue to work with no problems. You may need to make some minor changes (like escaping non-array @'s in double quoted strings) but there is no need to convert a .pl file into a Module for just that.

- Consider the implications.

  All Perl applications that make use of the script will need to be changed (slightly) if the script is converted into a module. Is it worth it unless you plan to make other changes at the same time?

- Make the most of the opportunity.

  If you are going to convert the script to a module you can use the opportunity to redesign the interface. The guidelines for module creation above include many of the issues you should consider.

- The pl2pm utility will get you started.

  This utility will read *.pl files (given as parameters) and write corresponding *.pm files. The pl2pm utilities does the following:

  - Adds the standard Module prologue lines
  - Converts package specifiers from ' to ::
  - Converts die(...) to croak(...)
  - Several other minor changes

  Being a mechanical process pl2pm is not bullet proof. The converted code will need careful checking, especially any package statements. Don't delete the original .pl file till the new .pm one works!

58.3.3 Guidelines for Reusing Application Code

- Complete applications rarely belong in the Perl Module Library.
- Many applications contain some Perl code that could be reused.
  Help save the world! Share your code in a form that makes it easy to reuse.
- Break-out the reusable code into one or more separate module files.
- Take the opportunity to reconsider and redesign the interfaces.
- In some cases the 'application' can then be reduced to a small
  fragment of code built on top of the reusable modules. In these cases the application could invoked as:

```
     % perl -e 'use Module::Name; method(@ARGV)' ...
or
     % perl -mModule::Name ...    (in perl5.002 or higher)
```

58.4 NOTE

Perl does not enforce private and public parts of its modules as you may have been used to in other languages like C++, Ada, or Modula-17. Perl doesn't have an infatuation with enforced privacy. It would prefer that you stayed out of its living room because you weren't invited, not because it has a shotgun.

The module and its user have a contract, part of which is common law, and part of which is "written". Part of the common law contract is that a module doesn't pollute any namespace it wasn't asked to. The written contract for the module (A.K.A. documentation) may make other provisions. But then you know when you `use RedefineTheWorld` that you're redefining the world and willing to take the consequences.

Chapter 59

perlmodstyle

Perl module style guide

59.1 INTRODUCTION

This document attempts to describe the Perl Community's "best practice" for writing Perl modules. It extends the recommendations found in *perlstyle* , which should be considered required reading before reading this document.

While this document is intended to be useful to all module authors, it is particularly aimed at authors who wish to publish their modules on CPAN.

The focus is on elements of style which are visible to the users of a module, rather than those parts which are only seen by the module's developers. However, many of the guidelines presented in this document can be extrapolated and applied successfully to a module's internals.

This document differs from *perlnewmod* in that it is a style guide rather than a tutorial on creating CPAN modules. It provides a checklist against which modules can be compared to determine whether they conform to best practice, without necessarily describing in detail how to achieve this.

All the advice contained in this document has been gleaned from extensive conversations with experienced CPAN authors and users. Every piece of advice given here is the result of previous mistakes. This information is here to help you avoid the same mistakes and the extra work that would inevitably be required to fix them.

The first section of this document provides an itemized checklist; subsequent sections provide a more detailed discussion of the items on the list. The final section, "Common Pitfalls", describes some of the most popular mistakes made by CPAN authors.

59.2 QUICK CHECKLIST

For more detail on each item in this checklist, see below.

59.2.1 Before you start

- Don't re-invent the wheel
- Patch, extend or subclass an existing module where possible
- Do one thing and do it well
- Choose an appropriate name

59.2.2 The API

- API should be understandable by the average programmer
- Simple methods for simple tasks
- Separate functionality from output
- Consistent naming of subroutines or methods
- Use named parameters (a hash or hashref) when there are more than two parameters

59.2.3 Stability

- Ensure your module works under `use strict` and `-w`
- Stable modules should maintain backwards compatibility

59.2.4 Documentation

- Write documentation in POD
- Document purpose, scope and target applications
- Document each publically accessible method or subroutine, including params and return values
- Give examples of use in your documentation
- Provide a README file and perhaps also release notes, changelog, etc
- Provide links to further information (URL, email)

59.2.5 Release considerations

- Specify pre-requisites in Makefile.PL or Build.PL
- Specify Perl version requirements with `use`
- Include tests with your module
- Choose a sensible and consistent version numbering scheme (X.YY is the common Perl module numbering scheme)
- Increment the version number for every change, no matter how small
- Package the module using "make dist"
- Choose an appropriate license (GPL/Artistic is a good default)

59.3 BEFORE YOU START WRITING A MODULE

Try not to launch headlong into developing your module without spending some time thinking first. A little forethought may save you a vast amount of effort later on.

59.3.1 Has it been done before?

You may not even need to write the module. Check whether it's already been done in Perl, and avoid re-inventing the wheel unless you have a good reason.

Good places to look for pre-existing modules include http://search.cpan.org/ and asking on modules@perl.org

If an existing module **almost** does what you want, consider writing a patch, writing a subclass, or otherwise extending the existing module rather than rewriting it.

59.3.2 Do one thing and do it well

At the risk of stating the obvious, modules are intended to be modular. A Perl developer should be able to use modules to put together the building blocks of their application. However, it's important that the blocks are the right shape, and that the developer shouldn't have to use a big block when all they need is a small one.

Your module should have a clearly defined scope which is no longer than a single sentence. Can your module be broken down into a family of related modules?

Bad example:

"FooBar.pm provides an implementation of the FOO protocol and the related BAR standard."

Good example:

"Foo.pm provides an implementation of the FOO protocol. Bar.pm implements the related BAR protocol."

This means that if a developer only needs a module for the BAR standard, they should not be forced to install libraries for FOO as well.

59.3.3 What's in a name?

Make sure you choose an appropriate name for your module early on. This will help people find and remember your module, and make programming with your module more intuitive.

When naming your module, consider the following:

- Be descriptive (i.e. accurately describes the purpose of the module).
- Be consistent with existing modules.
- Reflect the functionality of the module, not the implementation.
- Avoid starting a new top-level hierarchy, especially if a suitable hierarchy already exists under which you could place your module.

You should contact modules@perl.org to ask them about your module name before publishing your module. You should also try to ask people who are already familiar with the module's application domain and the CPAN naming system. Authors of similar modules, or modules with similar names, may be a good place to start.

59.4 DESIGNING AND WRITING YOUR MODULE

Considerations for module design and coding:

59.4.1 To OO or not to OO?

Your module may be object oriented (OO) or not, or it may have both kinds of interfaces available. There are pros and cons of each technique, which should be considered when you design your API.

According to Damian Conway, you should consider using OO:

- When the system is large or likely to become so
- When the data is aggregated in obvious structures that will become objects
- When the types of data form a natural hierarchy that can make use of inheritance
- When operations on data vary according to data type (making polymorphic invocation of methods feasible)
- When it is likely that new data types may be later introduced into the system, and will need to be handled by existing code

- When interactions between data are best represented by overloaded operators
- When the implementation of system components is likely to change over time (and hence should be encapsulated)
- When the system design is itself object-oriented
- When large amounts of client code will use the software (and should be insulated from changes in its implementation)
- When many separate operations will need to be applied to the same set of data

Think carefully about whether OO is appropriate for your module. Gratuitous object orientation results in complex APIs which are difficult for the average module user to understand or use.

59.4.2 Designing your API

Your interfaces should be understandable by an average Perl programmer. The following guidelines may help you judge whether your API is sufficiently straightforward:

Write simple routines to do simple things.

It's better to have numerous simple routines than a few monolithic ones. If your routine changes its behaviour significantly based on its arguments, it's a sign that you should have two (or more) separate routines.

Separate functionality from output.

Return your results in the most generic form possible and allow the user to choose how to use them. The most generic form possible is usually a Perl data structure which can then be used to generate a text report, HTML, XML, a database query, or whatever else your users require.

If your routine iterates through some kind of list (such as a list of files, or records in a database) you may consider providing a callback so that users can manipulate each element of the list in turn. File::Find provides an example of this with its `find(\&wanted, $dir)` syntax.

Provide sensible shortcuts and defaults.

Don't require every module user to jump through the same hoops to achieve a simple result. You can always include optional parameters or routines for more complex or non-standard behaviour. If most of your users have to type a few almost identical lines of code when they start using your module, it's a sign that you should have made that behaviour a default. Another good indicator that you should use defaults is if most of your users call your routines with the same arguments.

Naming conventions

Your naming should be consistent. For instance, it's better to have:

```
display_day();
display_week();
display_year();
```

than

```
display_day();
week_display();
show_year();
```

This applies equally to method names, parameter names, and anything else which is visible to the user (and most things that aren't!)

Parameter passing

Use named parameters. It's easier to use a hash like this:

```
$obj->do_something(
        name => "wibble",
        type => "text",
        size => 1024,
);
```

... than to have a long list of unnamed parameters like this:

```
$obj->do_something("wibble", "text", 1024);
```

While the list of arguments might work fine for one, two or even three arguments, any more arguments become hard for the module user to remember, and hard for the module author to manage. If you want to add a new parameter you will have to add it to the end of the list for backward compatibility, and this will probably make your list order unintuitive. Also, if many elements may be undefined you may see the following unattractive method calls:

```
$obj->do_something(undef, undef, undef, undef, undef, undef, 1024);
```

Provide sensible defaults for parameters which have them. Don't make your users specify parameters which will almost always be the same.

The issue of whether to pass the arguments in a hash or a hashref is largely a matter of personal style.

The use of hash keys starting with a hyphen (`-name`) or entirely in upper case (`NAME`) is a relic of older versions of Perl in which ordinary lower case strings were not handled correctly by the => operator. While some modules retain uppercase or hyphenated argument keys for historical reasons or as a matter of personal style, most new modules should use simple lower case keys. Whatever you choose, be consistent!

59.4.3 Strictness and warnings

Your module should run successfully under the strict pragma and should run without generating any warnings. Your module should also handle taint-checking where appropriate, though this can cause difficulties in many cases.

59.4.4 Backwards compatibility

Modules which are "stable" should not break backwards compatibility without at least a long transition phase and a major change in version number.

59.4.5 Error handling and messages

When your module encounters an error it should do one or more of:

- Return an undefined value.
- set `$Module::errstr` or similar (`errstr` is a common name used by DBI and other popular modules; if you choose something else, be sure to document it clearly).
- `warn()` or `carp()` a message to STDERR.
- `croak()` only when your module absolutely cannot figure out what to do. (`croak()` is a better version of `die()` for use within modules, which reports its errors from the perspective of the caller. See *Carp* for details of `croak()`, `carp()` and other useful routines.)
- As an alternative to the above, you may prefer to throw exceptions using the Error module.

Configurable error handling can be very useful to your users. Consider offering a choice of levels for warning and debug messages, an option to send messages to a separate file, a way to specify an error-handling routine, or other such features. Be sure to default all these options to the commonest use.

59.5 DOCUMENTING YOUR MODULE

59.5.1 POD

Your module should include documentation aimed at Perl developers. You should use Perl's "plain old documentation" (POD) for your general technical documentation, though you may wish to write additional documentation (white papers, tutorials, etc) in some other format. You need to cover the following subjects:

- A synopsis of the common uses of the module
- The purpose, scope and target applications of your module
- Use of each publically accessible method or subroutine, including parameters and return values
- Examples of use
- Sources of further information
- A contact email address for the author/maintainer

The level of detail in Perl module documentation generally goes from less detailed to more detailed. Your SYNOPSIS section should contain a minimal example of use (perhaps as little as one line of code; skip the unusual use cases or anything not needed by most users); the DESCRIPTION should describe your module in broad terms, generally in just a few paragraphs; more detail of the module's routines or methods, lengthy code examples, or other in-depth material should be given in subsequent sections.

Ideally, someone who's slightly familiar with your module should be able to refresh their memory without hitting "page down". As your reader continues through the document, they should receive a progressively greater amount of knowledge.

The recommended order of sections in Perl module documentation is:

- NAME
- SYNOPSIS
- DESCRIPTION
- One or more sections or subsections giving greater detail of available methods and routines and any other relevant information.
- BUGS/CAVEATS/etc
- AUTHOR
- SEE ALSO
- COPYRIGHT and LICENSE

Keep your documentation near the code it documents ("inline" documentation). Include POD for a given method right above that method's subroutine. This makes it easier to keep the documentation up to date, and avoids having to document each piece of code twice (once in POD and once in comments).

59.5.2 README, INSTALL, release notes, changelogs

Your module should also include a README file describing the module and giving pointers to further information (website, author email).

An INSTALL file should be included, and should contain simple installation instructions. When using ExtUtils::MakeMaker this will usually be:

perl Makefile.PL

make

make test

make install

When using Module::Build, this will usually be:

perl Build.PL

perl Build

perl Build test

perl Build install

Release notes or changelogs should be produced for each release of your software describing user-visible changes to your module, in terms relevant to the user.

59.6 RELEASE CONSIDERATIONS

59.6.1 Version numbering

Version numbers should indicate at least major and minor releases, and possibly sub-minor releases. A major release is one in which most of the functionality has changed, or in which major new functionality is added. A minor release is one in which a small amount of functionality has been added or changed. Sub-minor version numbers are usually used for changes which do not affect functionality, such as documentation patches.

The most common CPAN version numbering scheme looks like this:

```
    1.00, 1.10, 1.11, 1.20, 1.30, 1.31, 1.32
```

A correct CPAN version number is a floating point number with at least 2 digits after the decimal. You can test whether it conforms to CPAN by using

```
    perl -MExtUtils::MakeMaker -le 'print MM->parse_version(shift)' 'Foo.pm'
```

If you want to release a 'beta' or 'alpha' version of a module but don't want CPAN.pm to list it as most recent use an '_' after the regular version number followed by at least 2 digits, eg. 1.20_01. If you do this, the following idiom is recommended:

```
  $VERSION = "1.12_01";
  $XS_VERSION = $VERSION; # only needed if you have XS code
  $VERSION = eval $VERSION;
```

With that trick MakeMaker will only read the first line and thus read the underscore, while the perl interpreter will evaluate the $VERSION and convert the string into a number. Later operations that treat $VERSION as a number will then be able to do so without provoking a warning about $VERSION not being a number.

Never release anything (even a one-word documentation patch) without incrementing the number. Even a one-word documentation patch should result in a change in version at the sub-minor level.

59.6.2 Pre-requisites

Module authors should carefully consider whether to rely on other modules, and which modules to rely on.

Most importantly, choose modules which are as stable as possible. In order of preference:

- Core Perl modules
- Stable CPAN modules
- Unstable CPAN modules
- Modules not available from CPAN

Specify version requirements for other Perl modules in the pre-requisites in your Makefile.PL or Build.PL.

Be sure to specify Perl version requirements both in Makefile.PL or Build.PL and with `require 5.6.1` or similar. See the section on `use VERSION` of require in *perlfunc* for details.

59.6.3 Testing

All modules should be tested before distribution (using "make disttest"), and the tests should also be available to people installing the modules (using "make test"). For Module::Build you would use the `make test` equivalent `perl Build test`.

The importance of these tests is proportional to the alleged stability of a module – a module which purports to be stable or which hopes to achieve wide use should adhere to as strict a testing regime as possible.

Useful modules to help you write tests (with minimum impact on your development process or your time) include Test::Simple, Carp::Assert and Test::Inline. For more sophisticated test suites there are Test::More and Test::MockObject.

59.6.4 Packaging

Modules should be packaged using one of the standard packaging tools. Currently you have the choice between ExtUtils::MakeMaker and the more platform independent Module::Build, allowing modules to be installed in a consistent manner. When using ExtUtils::MakeMaker, you can use "make dist" to create your package. Tools exist to help you to build your module in a MakeMaker-friendly style. These include ExtUtils::ModuleMaker and h2xs. See also *perlnewmod*.

59.6.5 Licensing

Make sure that your module has a license, and that the full text of it is included in the distribution (unless it's a common one and the terms of the license don't require you to include it).

If you don't know what license to use, dual licensing under the GPL and Artistic licenses (the same as Perl itself) is a good idea. See *perlgpl* and *perlartistic*.

59.7 COMMON PITFALLS

59.7.1 Reinventing the wheel

There are certain application spaces which are already very, very well served by CPAN. One example is templating systems, another is date and time modules, and there are many more. While it is a rite of passage to write your own version of these things, please consider carefully whether the Perl world really needs you to publish it.

59.7.2 Trying to do too much

Your module will be part of a developer's toolkit. It will not, in itself, form the **entire** toolkit. It's tempting to add extra features until your code is a monolithic system rather than a set of modular building blocks.

59.7.3 Inappropriate documentation

Don't fall into the trap of writing for the wrong audience. Your primary audience is a reasonably experienced developer with at least a moderate understanding of your module's application domain, who's just downloaded your module and wants to start using it as quickly as possible.

Tutorials, end-user documentation, research papers, FAQs etc are not appropriate in a module's main documentation. If you really want to write these, include them as sub-documents such as `My::Module::Tutorial` or `My::Module::FAQ` and provide a link in the SEE ALSO section of the main documentation.

Chapter 60

perlmodinstall

Installing CPAN Modules

60.1 DESCRIPTION

You can think of a module as the fundamental unit of reusable Perl code; see *perlmod* for details. Whenever anyone creates a chunk of Perl code that they think will be useful to the world, they register as a Perl developer at http://www.cpan.org/modules/04pause.html so that they can then upload their code to the CPAN. The CPAN is the Comprehensive Perl Archive Network and can be accessed at http://www.cpan.org/ , and searched at http://search.cpan.org/ .

This documentation is for people who want to download CPAN modules and install them on their own computer.

60.1.1 PREAMBLE

First, are you sure that the module isn't already on your system? Try `perl -MFoo -e 1`. (Replace "Foo" with the name of the module; for instance, `perl -MCGI::Carp -e 1`.

If you don't see an error message, you have the module. (If you do see an error message, it's still possible you have the module, but that it's not in your path, which you can display with `perl -e "print qq(@INC)"`.) For the remainder of this document, we'll assume that you really honestly truly lack an installed module, but have found it on the CPAN.

So now you have a file ending in .tar.gz (or, less often, .zip). You know there's a tasty module inside. There are four steps you must now take:

DECOMPRESS the file

UNPACK the file into a directory

BUILD the module (sometimes unnecessary)

INSTALL the module.

Here's how to perform each step for each operating system. This is <not> a substitute for reading the README and INSTALL files that might have come with your module!

Also note that these instructions are tailored for installing the module into your system's repository of Perl modules – but you can install modules into any directory you wish. For instance, where I say `perl Makefile.PL`, you can substitute `perl Makefile.PL PREFIX=/my/perl_directory` to install the modules into `/my/perl_directory`. Then you can use the modules from your Perl programs with `use lib "/my/perl_directory/lib/site_perl";` or sometimes just `use "/my/perl_directory";`. If you're on a system that requires superuser/root access to install modules into the directories you see when you type `perl -e "print qq(@INC)"`, you'll want to install them into a local directory (such as your home directory) and use this approach.

- **If you're on a Unix or Linux system,**

  You can use Andreas Koenig's CPAN module (http://www.cpan.org/modules/by-module/CPAN) to automate the following steps, from DECOMPRESS through INSTALL.

  A. DECOMPRESS

  Decompress the file with `gzip -d yourmodule.tar.gz`

  You can get gzip from ftp://prep.ai.mit.edu/pub/gnu/

  Or, you can combine this step with the next to save disk space:

  ```
  gzip -dc yourmodule.tar.gz | tar -xof -
  ```

  B. UNPACK

  Unpack the result with `tar -xof yourmodule.tar`

  C. BUILD

  Go into the newly-created directory and type:

  ```
  perl Makefile.PL
  make test
  ```

  or

  ```
  perl Makefile.PL PREFIX=/my/perl_directory
  ```

  to install it locally. (Remember that if you do this, you'll have to put `use lib "/my/perl_directory";` near the top of the program that is to use this module.

  D. INSTALL

  While still in that directory, type:

  ```
  make install
  ```

  Make sure you have the appropriate permissions to install the module in your Perl 5 library directory. Often, you'll need to be root.

  That's all you need to do on Unix systems with dynamic linking. Most Unix systems have dynamic linking – if yours doesn't, or if for another reason you have a statically-linked perl, **and** the module requires compilation, you'll need to build a new Perl binary that includes the module. Again, you'll probably need to be root.

- **If you're running ActivePerl (Win95/98/2K/NT/XP, Linux, Solaris)**

  First, type `ppm` from a shell and see whether ActiveState's PPM repository has your module. If so, you can install it with `ppm` and you won't have to bother with any of the other steps here. You might be able to use the CPAN instructions from the "Unix or Linux" section above as well; give it a try. Otherwise, you'll have to follow the steps below.

  ```
  A. DECOMPRESS
  ```

  You can use the shareware Winzip (http://www.winzip.com) to decompress and unpack modules.

  ```
  B. UNPACK
  ```

  If you used WinZip, this was already done for you.

  ```
  C. BUILD
  ```

You'll need the `nmake` utility, available at http://download.microsoft.com/download/vc15/Patch/1.52/W95/EN-US/nmake15.exe or dmake, available on CPAN. http://search.cpan.org/dist/dmake/

Does the module require compilation (i.e. does it have files that end in .xs, .c, .h, .y, .cc, .cxx, or .C)? If it does, life is now officially tough for you, because you have to compile the module yourself – no easy feat on Windows. You'll need a compiler such as Visual C++. Alternatively, you can download a pre-built PPM package from ActiveState. http://aspn.activestate.com/ASPN/Downloads/ActivePerl/PPM/

Go into the newly-created directory and type:

```
    perl Makefile.PL
    nmake test
```

```
  D. INSTALL
```

While still in that directory, type:

```
    nmake install
```

- **If you're using a Macintosh,**

  A. DECOMPRESS

  First, make sure you have the latest **cpan-mac** distribution (http://www.cpan.org/authors/id/CNANDOR/), which has utilities for doing all of the steps. Read the cpan-mac directions carefully and install it. If you choose not to use cpan-mac for some reason, there are alternatives listed here.

  After installing cpan-mac, drop the module archive on the **untarzipme** droplet, which will decompress and unpack for you.

  Or, you can either use the shareware **StuffIt Expander** program (http://www.aladdinsys.com/expander/) in combination with **DropStuff with Expander Enhancer** (http://www.aladdinsys.com/dropstuff/) or the freeware **MacGzip** program (http://persephone.cps.unizar.es/general/gente/spd/gzip/gzip.html).

  B. UNPACK

  If you're using untarzipme or StuffIt, the archive should be extracted now. **Or**, you can use the freeware **suntar** or *Tar* (http://hyperarchive.lcs.mit.edu/HyperArchive/Archive/cmp/).

  C. BUILD

  Check the contents of the distribution. Read the module's documentation, looking for reasons why you might have trouble using it with MacPerl. Look for *.xs* and *.c* files, which normally denote that the distribution must be compiled, and you cannot install it "out of the box." (See §60.2.)

  If a module does not work on MacPerl but should, or needs to be compiled, see if the module exists already as a port on the MacPerl Module Porters site (http://pudge.net/mmp/). For more information on doing XS with MacPerl yourself, see Arved Sandstrom's XS tutorial (http://macperl.com/depts/Tutorials/), and then consider uploading your binary to the CPAN and registering it on the MMP site.

  D. INSTALL

  If you are using cpan-mac, just drop the folder on the **installme** droplet, and use the module.

  Or, if you aren't using cpan-mac, do some manual labor.

  Make sure the newlines for the modules are in Mac format, not Unix format. If they are not then you might have decompressed them incorrectly. Check your decompression and unpacking utilities settings to make sure they are translating text files properly.

  As a last resort, you can use the perl one-liner:

```
  perl -i.bak -pe 's/(?:\015)?\012/\015/g' <filenames>
```

on the source files.

Then move the files (probably just the *.pm* files, though there may be some additional ones, too; check the module documentation) to their final destination: This will most likely be in `$ENV{MACPERL}site_lib:` (i.e., `HD:MacPerl folder:site_lib:`). You can add new paths to the default `@INC` in the Preferences menu item in the MacPerl application (`$ENV{MACPERL}site_lib:` is added automagically). Create whatever directory structures are required (i.e., for `Some::Module`, create `$ENV{MACPERL}site_lib:Some:` and put `Module.pm` in that directory).

Then run the following script (or something like it):

```
    #!perl -w
    use AutoSplit;
    my $dir = "${MACPERL}site_perl";
    autosplit("$dir:Some:Module.pm", "$dir:auto", 0, 1, 1);
```

- **If you're on the DJGPP port of DOS,**

```
  A. DECOMPRESS
```

  djtarx (ftp://ftp.simtel.net/pub/simtelnet/gnu/djgpp/v2/) will both uncompress and unpack.

```
  B. UNPACK
```

  See above.

```
  C. BUILD
```

  Go into the newly-created directory and type:

```
     perl Makefile.PL
     make test
```

  You will need the packages mentioned in *README.dos* in the Perl distribution.

```
  D. INSTALL
```

  While still in that directory, type:

```
    make install
```

  You will need the packages mentioned in *README.dos* in the Perl distribution.

- **If you're on OS/2,**

  Get the EMX development suite and gzip/tar, from either Hobbes (http://hobbes.nmsu.edu) or Leo (http://www.leo.org), and then follow the instructions for Unix.

- **If you're on VMS,**

  When downloading from CPAN, save your file with a `.tgz` extension instead of `.tar.gz`. All other periods in the filename should be replaced with underscores. For example, `Your-Module-1.33.tar.gz` should be downloaded as `Your-Module-1_33.tgz`.

  A. DECOMPRESS

  Type

```
   gzip -d Your-Module.tgz
```

or, for zipped modules, type

```
unzip Your-Module.zip
```

Executables for gzip, zip, and VMStar:

```
http://www.openvms.digital.com/freeware/
http://www.crinoid.com/utils/
```

and their source code:

```
http://www.fsf.org/order/ftp.html
```

Note that GNU's gzip/gunzip is not the same as Info-ZIP's zip/unzip package. The former is a simple compression tool; the latter permits creation of multi-file archives.

B. UNPACK

If you're using VMStar:

```
 VMStar xf Your-Module.tar
```

Or, if you're fond of VMS command syntax:

```
 tar/extract/verbose Your_Module.tar
```

C. BUILD

Make sure you have MMS (from Digital) or the freeware MMK (available from MadGoat at http://www.madgoat.com). Then type this to create the DESCRIP.MMS for the module:

```
perl Makefile.PL
```

Now you're ready to build:

```
mms test
```

Substitute `mmk` for `mms` above if you're using MMK.

D. INSTALL

Type

```
mms install
```

Substitute `mmk` for `mms` above if you're using MMK.

- **If you're on MVS**,

  Introduce the *.tar.gz* file into an HFS as binary; don't translate from ASCII to EBCDIC.

  A. DECOMPRESS

  Decompress the file with `gzip -d yourmodule.tar.gz`

  You can get gzip from http://www.s390.ibm.com/products/oe/bpxqp1.html

  B. UNPACK

  Unpack the result with

```
 pax -o to=IBM-1047,from=ISO8859-1 -r < yourmodule.tar
```

  The BUILD and INSTALL steps are identical to those for Unix. Some modules generate Makefiles that work better with GNU make, which is available from http://www.mks.com/s390/gnu/

60.2 PORTABILITY

Note that not all modules will work with on all platforms. See *perlport* for more information on portability issues. Read the documentation to see if the module will work on your system. There are basically three categories of modules that will not work "out of the box" with all platforms (with some possibility of overlap):

- **Those that should, but don't.** These need to be fixed; consider contacting the author and possibly writing a patch.
- **Those that need to be compiled, where the target platform doesn't have compilers readily available.** (These modules contain *.xs* or *.c* files, usually.) You might be able to find existing binaries on the CPAN or elsewhere, or you might want to try getting compilers and building it yourself, and then release the binary for other poor souls to use.
- **Those that are targeted at a specific platform.** (Such as the Win32:: modules.) If the module is targeted specifically at a platform other than yours, you're out of luck, most likely.

Check the CPAN Testers if a module should work with your platform but it doesn't behave as you'd expect, or you aren't sure whether or not a module will work under your platform. If the module you want isn't listed there, you can test it yourself and let CPAN Testers know, you can join CPAN Testers, or you can request it be tested.

```
http://testers.cpan.org/
```

60.3 HEY

If you have any suggested changes for this page, let me know. Please don't send me mail asking for help on how to install your modules. There are too many modules, and too few Orwants, for me to be able to answer or even acknowledge all your questions. Contact the module author instead, or post to comp.lang.perl.modules, or ask someone familiar with Perl on your operating system.

Chapter 61

perlnewmod

Preparing a new module for distribution

61.1 DESCRIPTION

This document gives you some suggestions about how to go about writing Perl modules, preparing them for distribution, and making them available via CPAN.

One of the things that makes Perl really powerful is the fact that Perl hackers tend to want to share the solutions to problems they've faced, so you and I don't have to battle with the same problem again.

The main way they do this is by abstracting the solution into a Perl module. If you don't know what one of these is, the rest of this document isn't going to be much use to you. You're also missing out on an awful lot of useful code; consider having a look at *perlmod*, *perlmodlib* and *perlmodinstall* before coming back here.

When you've found that there isn't a module available for what you're trying to do, and you've had to write the code yourself, consider packaging up the solution into a module and uploading it to CPAN so that others can benefit.

61.1.1 Warning

We're going to primarily concentrate on Perl-only modules here, rather than XS modules. XS modules serve a rather different purpose, and you should consider different things before distributing them - the popularity of the library you are gluing, the portability to other operating systems, and so on. However, the notes on preparing the Perl side of the module and packaging and distributing it will apply equally well to an XS module as a pure-Perl one.

61.1.2 What should I make into a module?

You should make a module out of any code that you think is going to be useful to others. Anything that's likely to fill a hole in the communal library and which someone else can slot directly into their program. Any part of your code which you can isolate and extract and plug into something else is a likely candidate.

Let's take an example. Suppose you're reading in data from a local format into a hash-of-hashes in Perl, turning that into a tree, walking the tree and then piping each node to an Acme Transmogrifier Server.

Now, quite a few people have the Acme Transmogrifier, and you've had to write something to talk the protocol from scratch - you'd almost certainly want to make that into a module. The level at which you pitch it is up to you: you might want protocol-level modules analogous to Net::SMTP which then talk to higher level modules analogous to Mail::Send. The choice is yours, but you do want to get a module out for that server protocol.

Nobody else on the planet is going to talk your local data format, so we can ignore that. But what about the thing in the middle? Building tree structures from Perl variables and then traversing them is a nice, general problem, and if nobody's already written a module that does that, you might want to modularise that code too.

So hopefully you've now got a few ideas about what's good to modularise. Let's now see how it's done.

61.1.3 Step-by-step: Preparing the ground

Before we even start scraping out the code, there are a few things we'll want to do in advance.

Look around

Dig into a bunch of modules to see how they're written. I'd suggest starting with Text::Tabs, since it's in the standard library and is nice and simple, and then looking at something like Time::Zone, File::Copy and then some of the `Mail::*` modules if you're planning on writing object oriented code.

These should give you an overall feel for how modules are laid out and written.

Check it's new

There are a lot of modules on CPAN, and it's easy to miss one that's similar to what you're planning on contributing. Have a good plough through the modules list and the *by-module* directories, and make sure you're not the one reinventing the wheel!

Discuss the need

You might love it. You might feel that everyone else needs it. But there might not actually be any real demand for it out there. If you're unsure about the demand your module will have, consider sending out feelers on the `comp.lang.perl.modules` newsgroup, or as a last resort, ask the modules list at `modules@perl.org`. Remember that this is a closed list with a very long turn-around time - be prepared to wait a good while for a response from them.

Choose a name

Perl modules included on CPAN have a naming hierarchy you should try to fit in with. See *perlmodlib* for more details on how this works, and browse around CPAN and the modules list to get a feel of it. At the very least, remember this: modules should be title capitalised, (This::Thing) fit in with a category, and explain their purpose succinctly.

Check again

While you're doing that, make really sure you haven't missed a module similar to the one you're about to write.

When you've got your name sorted out and you're sure that your module is wanted and not currently available, it's time to start coding.

61.1.4 Step-by-step: Making the module

Start with *h2xs*

Originally a utility to convert C header files into XS modules, h2xs has become a useful utility for churning out skeletons for Perl-only modules as well. If you don't want to use the Autoloader which splits up big modules into smaller subroutine-sized chunks, you'll say something like this:

```
h2xs -AX -n Net::Acme
```

The `-A` omits the Autoloader code, `-X` omits XS elements, and `-n` specifies the name of the module.

Use strict and warnings

A module's code has to be warning and strict-clean, since you can't guarantee the conditions that it'll be used under. Besides, you wouldn't want to distribute code that wasn't warning or strict-clean anyway, right?

Use Carp

The Carp module allows you to present your error messages from the caller's perspective; this gives you a way to signal a problem with the caller and not your module. For instance, if you say this:

```
warn "No hostname given";
```

the user will see something like this:

```
    No hostname given at /usr/local/lib/perl5/site_perl/5.6.0/Net/Acme.pm
    line 123.
```

which looks like your module is doing something wrong. Instead, you want to put the blame on the user, and say this:

```
    No hostname given at bad_code, line 10.
```

You do this by using Carp and replacing your `warn`s with `carp`s. If you need to `die`, say `croak` instead. However, keep `warn` and `die` in place for your sanity checks - where it really is your module at fault.

Use Exporter - wisely!

`h2xs` provides stubs for Exporter, which gives you a standard way of exporting symbols and subroutines from your module into the caller's namespace. For instance, saying `use Net::Acme qw(&frob)` would import the `frob` subroutine.

The package variable `@EXPORT` will determine which symbols will get exported when the caller simply says `use Net::Acme` - you will hardly ever want to put anything in there. `@EXPORT_OK`, on the other hand, specifies which symbols you're willing to export. If you do want to export a bunch of symbols, use the `%EXPORT_TAGS` and define a standard export set - look at *Exporter* for more details.

Use plain old documentation

The work isn't over until the paperwork is done, and you're going to need to put in some time writing some documentation for your module. `h2xs` will provide a stub for you to fill in; if you're not sure about the format, look at *perlpod* for an introduction. Provide a good synopsis of how your module is used in code, a description, and then notes on the syntax and function of the individual subroutines or methods. Use Perl comments for developer notes and POD for end-user notes.

Write tests

You're encouraged to create self-tests for your module to ensure it's working as intended on the myriad platforms Perl supports; if you upload your module to CPAN, a host of testers will build your module and send you the results of the tests. Again, `h2xs` provides a test framework which you can extend - you should do something more than just checking your module will compile.

Write the README

If you're uploading to CPAN, the automated gremlins will extract the README file and place that in your CPAN directory. It'll also appear in the main *by-module* and *by-category* directories if you make it onto the modules list. It's a good idea to put here what the module actually does in detail, and the user-visible changes since the last release.

61.1.5 Step-by-step: Distributing your module

Get a CPAN user ID

Every developer publishing modules on CPAN needs a CPAN ID. See the instructions at `http://www.cpan.org/modules/04pause.html` (or equivalent on your nearest mirror) to find out how to do this.

`perl Makefile.PL; make test; make dist`

Once again, `h2xs` has done all the work for you. It produces the standard `Makefile.PL` you'll have seen when you downloaded and installs modules, and this produces a Makefile with a `dist` target.

Once you've ensured that your module passes its own tests - always a good thing to make sure - you can `make dist`, and the Makefile will hopefully produce you a nice tarball of your module, ready for upload.

Upload the tarball

The email you got when you received your CPAN ID will tell you how to log in to PAUSE, the Perl Authors Upload SErver. From the menus there, you can upload your module to CPAN.

Announce to the modules list

Once uploaded, it'll sit unnoticed in your author directory. If you want it connected to the rest of the CPAN, you'll need to tell the modules list about it. The best way to do this is to email them a line in the style of the modules list, like this:

```
Net::Acme bdpOP   Interface to Acme Frobnicator servers      FOOBAR
^         ^^^^^   ^                                          ^
|         |||||   Module description                         Your ID
|         |||||
|         ||||\-Public Licence: (p)standard Perl, (g)GPL, (b)BSD,
|         ||||                  (l)LGPL, (a)rtistic, (o)ther
|         ||||
|         |||\- Interface: (O)OP, (r)eferences, (h)ybrid, (f)unctions
|         |||
|         ||\-- Language: (p)ure Perl, C(+)+, (h)ybrid, (C), (o)ther
|         ||
Module    |\--- Support: (d)eveloper, (m)ailing list, (u)senet, (n)one
Name      |
          \---- Development: (i)dea, (c)onstructions, (a)lpha, (b)eta,
                             (R)eleased, (M)ature, (S)tandard
```

plus a description of the module and why you think it should be included. If you hear nothing back, that means your module will probably appear on the modules list at the next update. Don't try subscribing to `modules@perl.org`; it's not another mailing list. Just have patience.

Announce to clpa

If you have a burning desire to tell the world about your release, post an announcement to the moderated `comp.lang.perl.announce` newsgroup.

Fix bugs!

Once you start accumulating users, they'll send you bug reports. If you're lucky, they'll even send you patches. Welcome to the joys of maintaining a software project...

Chapter 62

perlutil

Utilities packaged with the Perl distribution

62.1 DESCRIPTION

Along with the Perl interpreter itself, the Perl distribution installs a range of utilities on your system. There are also several utilities which are used by the Perl distribution itself as part of the install process. This document exists to list all of these utilities, explain what they are for and provide pointers to each module's documentation, if appropriate.

62.1.1 DOCUMENTATION

perldoc

The main interface to Perl's documentation is `perldoc`, although if you're reading this, it's more than likely that you've already found it. *perldoc* will extract and format the documentation from any file in the current directory, any Perl module installed on the system, or any of the standard documentation pages, such as this one. Use `perldoc <name>` to get information on any of the utilities described in this document.

pod2man and pod2text

If it's run from a terminal, *perldoc* will usually call *pod2man* to translate POD (Plain Old Documentation - see *perlpod* for an explanation) into a manpage, and then run *man* to display it; if *man* isn't available, *pod2text* will be used instead and the output piped through your favourite pager.

pod2html and pod2latex

As well as these two, there are two other converters: *pod2html* will produce HTML pages from POD, and *pod2latex*, which produces LaTeX files.

pod2usage

If you just want to know how to use the utilities described here, *pod2usage* will just extract the "USAGE" section; some of the utilities will automatically call *pod2usage* on themselves when you call them with `-help`.

podselect

pod2usage is a special case of *podselect*, a utility to extract named sections from documents written in POD. For instance, while utilities have "USAGE" sections, Perl modules usually have "SYNOPSIS" sections: `podselect -s "SYNOPSIS" ...` will extract this section for a given file.

podchecker

If you're writing your own documentation in POD, the *podchecker* utility will look for errors in your markup.

splain

splain is an interface to *perldiag* - paste in your error message to it, and it'll explain it for you.

roffitall

The `roffitall` utility is not installed on your system but lives in the *pod/* directory of your Perl source kit; it converts all the documentation from the distribution to **roff* format, and produces a typeset PostScript or text file of the whole lot.

62.1.2 CONVERTORS

To help you convert legacy programs to Perl, we've included three conversion filters:

a2p

a2p converts *awk* scripts to Perl programs; for example, `a2p -F:` on the simple *awk* script `{print $2}` will produce a Perl program based around this code:

```
while (<>) {
    ($Fld1,$Fld2) = split(/[:\n]/, $_, 9999);
    print $Fld2;
}
```

s2p

Similarly, *s2p* converts *sed* scripts to Perl programs. *s2p* run on `s/foo/bar` will produce a Perl program based around this:

```
while (<>) {
    chomp;
    s/foo/bar/g;
    print if $printit;
}
```

find2perl

Finally, *find2perl* translates `find` commands to Perl equivalents which use the File::Find module. As an example, `find2perl . -user root -perm 4000 -print` produces the following callback subroutine for `File::Find`:

```
sub wanted {
    my ($dev,$ino,$mode,$nlink,$uid,$gid);
    (($dev,$ino,$mode,$nlink,$uid,$gid) = lstat($_)) &&
    $uid == $uid{'root'}) &&
    (($mode & 0777) == 04000);
    print("$name\n");
}
```

As well as these filters for converting other languages, the pl2pm utility will help you convert old-style Perl 4 libraries to new-style Perl5 modules.

62.1.3 Administration

libnetcfg

To display and change the libnet configuration run the libnetcfg command.

62.1.4 Development

There are a set of utilities which help you in developing Perl programs, and in particular, extending Perl with C.

perlbug

perlbug is the recommended way to report bugs in the perl interpreter itself or any of the standard library modules back to the developers; please read through the documentation for *perlbug* thoroughly before using it to submit a bug report.

h2ph

Back before Perl had the XS system for connecting with C libraries, programmers used to get library constants by reading through the C header files. You may still see `require 'syscall.ph'` or similar around - the *.ph* file should be created by running *h2ph* on the corresponding *.h* file. See the *h2ph* documentation for more on how to convert a whole bunch of header files at once.

c2ph and pstruct

c2ph and *pstruct*, which are actually the same program but behave differently depending on how they are called, provide another way of getting at C with Perl - they'll convert C structures and union declarations to Perl code. This is deprecated in favour of *h2xs* these days.

h2xs

h2xs converts C header files into XS modules, and will try and write as much glue between C libraries and Perl modules as it can. It's also very useful for creating skeletons of pure Perl modules.

dprofpp

Perl comes with a profiler, the *Devel::DProf* module. The *dprofpp* utility analyzes the output of this profiler and tells you which subroutines are taking up the most run time. See *Devel::DProf* for more information.

perlcc

perlcc is the interface to the experimental Perl compiler suite.

62.1.5 SEE ALSO

Chapter 63

perlcompile

Introduction to the Perl Compiler-Translator

63.1 DESCRIPTION

Perl has always had a compiler: your source is compiled into an internal form (a parse tree) which is then optimized before being run. Since version 5.005, Perl has shipped with a module capable of inspecting the optimized parse tree (`B`), and this has been used to write many useful utilities, including a module that lets you turn your Perl into C source code that can be compiled into a native executable.

The `B` module provides access to the parse tree, and other modules ("back ends") do things with the tree. Some write it out as bytecode, C source code, or a semi-human-readable text. Another traverses the parse tree to build a cross-reference of which subroutines, formats, and variables are used where. Another checks your code for dubious constructs. Yet another back end dumps the parse tree back out as Perl source, acting as a source code beautifier or deobfuscator.

Because its original purpose was to be a way to produce C code corresponding to a Perl program, and in turn a native executable, the `B` module and its associated back ends are known as "the compiler", even though they don't really compile anything. Different parts of the compiler are more accurately a "translator", or an "inspector", but people want Perl to have a "compiler option" not an "inspector gadget". What can you do?

This document covers the use of the Perl compiler: which modules it comprises, how to use the most important of the back end modules, what problems there are, and how to work around them.

63.1.1 Layout

The compiler back ends are in the `B::` hierarchy, and the front-end (the module that you, the user of the compiler, will sometimes interact with) is the O module. Some back ends (e.g., `B::C`) have programs (e.g., *perlcc*) to hide the modules' complexity.

Here are the important back ends to know about, with their status expressed as a number from 0 (outline for later implementation) to 10 (if there's a bug in it, we're very surprised):

B::Bytecode

Stores the parse tree in a machine-independent format, suitable for later reloading through the ByteLoader module. Status: 5 (some things work, some things don't, some things are untested).

B::C

Creates a C source file containing code to rebuild the parse tree and resume the interpreter. Status: 6 (many things work adequately, including programs using Tk).

B::CC

Creates a C source file corresponding to the run time code path in the parse tree. This is the closest to a Perl-to-C translator there is, but the code it generates is almost incomprehensible because it translates the parse tree into a giant switch structure that manipulates Perl structures. Eventual goal is to reduce (given sufficient type information in the Perl program) some of the Perl data structure manipulations into manipulations of C-level ints, floats, etc. Status: 5 (some things work, including uncomplicated Tk examples).

B::Lint

Complains if it finds dubious constructs in your source code. Status: 6 (it works adequately, but only has a very limited number of areas that it checks).

B::Deparse

Recreates the Perl source, making an attempt to format it coherently. Status: 8 (it works nicely, but a few obscure things are missing).

B::Xref

Reports on the declaration and use of subroutines and variables. Status: 8 (it works nicely, but still has a few lingering bugs).

63.2 Using The Back Ends

The following sections describe how to use the various compiler back ends. They're presented roughly in order of maturity, so that the most stable and proven back ends are described first, and the most experimental and incomplete back ends are described last.

The O module automatically enabled the **-c** flag to Perl, which prevents Perl from executing your code once it has been compiled. This is why all the back ends print:

```
  myperlprogram syntax OK
```

before producing any other output.

63.2.1 The Cross Referencing Back End

The cross referencing back end (B::Xref) produces a report on your program, breaking down declarations and uses of subroutines and variables (and formats) by file and subroutine. For instance, here's part of the report from the *pod2man* program that comes with Perl:

```
  Subroutine clear_noremap
    Package (lexical)
      $ready_to_print   i1069, 1079
    Package main
      $&                1086
      $.                1086
      $0                1086
      $1                1087
      $2                1085, 1085
      $3                1085, 1085
      $ARGV             1086
      %HTML_Escapes     1085, 1085
```

This shows the variables used in the subroutine `clear_noremap`. The variable `$ready_to_print` is a my() (lexical) variable, **i**ntroduced (first declared with my()) on line 1069, and used on line 1079. The variable `$&` from the main package is used on 1086, and so on.

A line number may be prefixed by a single letter:

i

Lexical variable introduced (declared with my()) for the first time.

&

Subroutine or method call.

s

Subroutine defined.

r

Format defined.

The most useful option the cross referencer has is to save the report to a separate file. For instance, to save the report on *myperlprogram* to the file *report*:

```
$ perl -MO=Xref,-oreport myperlprogram
```

63.2.2 The Decompiling Back End

The Deparse back end turns your Perl source back into Perl source. It can reformat along the way, making it useful as a de-obfuscator. The most basic way to use it is:

```
$ perl -MO=Deparse myperlprogram
```

You'll notice immediately that Perl has no idea of how to paragraph your code. You'll have to separate chunks of code from each other with newlines by hand. However, watch what it will do with one-liners:

```
$ perl -MO=Deparse -e '$op=shift||die "usage: $0
code [...]";chomp(@ARGV=<>)unless@ARGV; for(@ARGV){$was=$_;eval$op;
die$@ if$@; rename$was,$_ unless$was eq $_}'
-e syntax OK
$op = shift @ARGV || die("usage: $0 code [...]");
chomp(@ARGV = <ARGV>) unless @ARGV;
foreach $_ (@ARGV) {
    $was = $_;
    eval $op;
    die $@ if $@;
    rename $was, $_ unless $was eq $_;
}
```

The decompiler has several options for the code it generates. For instance, you can set the size of each indent from 4 (as above) to 2 with:

```
$ perl -MO=Deparse,-si2 myperlprogram
```

The **-p** option adds parentheses where normally they are omitted:

```
$ perl -MO=Deparse -e 'print "Hello, world\n"'
-e syntax OK
print "Hello, world\n";
$ perl -MO=Deparse,-p -e 'print "Hello, world\n"'
-e syntax OK
print("Hello, world\n");
```

See *B::Deparse* for more information on the formatting options.

63.2.3 The Lint Back End

The lint back end (B::Lint) inspects programs for poor style. One programmer's bad style is another programmer's useful tool, so options let you select what is complained about.

To run the style checker across your source code:

```
  $ perl -MO=Lint myperlprogram
```

To disable context checks and undefined subroutines:

```
  $ perl -MO=Lint,-context,-undefined-subs myperlprogram
```

See *B::Lint* for information on the options.

63.2.4 The Simple C Back End

This module saves the internal compiled state of your Perl program to a C source file, which can be turned into a native executable for that particular platform using a C compiler. The resulting program links against the Perl interpreter library, so it will not save you disk space (unless you build Perl with a shared library) or program size. It may, however, save you startup time.

The `perlcc` tool generates such executables by default.

```
  perlcc myperlprogram.pl
```

63.2.5 The Bytecode Back End

This back end is only useful if you also have a way to load and execute the bytecode that it produces. The ByteLoader module provides this functionality.

To turn a Perl program into executable byte code, you can use `perlcc` with the `-B` switch:

```
  perlcc -B myperlprogram.pl
```

The byte code is machine independent, so once you have a compiled module or program, it is as portable as Perl source (assuming that the user of the module or program has a modern-enough Perl interpreter to decode the byte code).

See **B::Bytecode** for information on options to control the optimization and nature of the code generated by the Bytecode module.

63.2.6 The Optimized C Back End

The optimized C back end will turn your Perl program's run time code-path into an equivalent (but optimized) C program that manipulates the Perl data structures directly. The program will still link against the Perl interpreter library, to allow for eval(), `s///e`, `require`, etc.

The `perlcc` tool generates such executables when using the -O switch. To compile a Perl program (ending in `.pl` or `.p`):

```
  perlcc -O myperlprogram.pl
```

To produce a shared library from a Perl module (ending in `.pm`):

```
  perlcc -O Myperlmodule.pm
```

For more information, see *perlcc* and *B::CC*.

63.3 Module List for the Compiler Suite

B

This module is the introspective ("reflective" in Java terms) module, which allows a Perl program to inspect its innards. The back end modules all use this module to gain access to the compiled parse tree. You, the user of a back end module, will not need to interact with B.

O

This module is the front-end to the compiler's back ends. Normally called something like this:

```
$ perl -MO=Deparse myperlprogram
```

This is like saying `use O 'Deparse'` in your Perl program.

B::Asmdata

This module is used by the B::Assembler module, which is in turn used by the B::Bytecode module, which stores a parse-tree as bytecode for later loading. It's not a back end itself, but rather a component of a back end.

B::Assembler

This module turns a parse-tree into data suitable for storing and later decoding back into a parse-tree. It's not a back end itself, but rather a component of a back end. It's used by the *assemble* program that produces bytecode.

B::Bblock

This module is used by the B::CC back end. It walks "basic blocks". A basic block is a series of operations which is known to execute from start to finish, with no possibility of branching or halting.

B::Bytecode

This module is a back end that generates bytecode from a program's parse tree. This bytecode is written to a file, from where it can later be reconstructed back into a parse tree. The goal is to do the expensive program compilation once, save the interpreter's state into a file, and then restore the state from the file when the program is to be executed. See §63.2.5 for details about usage.

B::C

This module writes out C code corresponding to the parse tree and other interpreter internal structures. You compile the corresponding C file, and get an executable file that will restore the internal structures and the Perl interpreter will begin running the program. See §63.2.4 for details about usage.

B::CC

This module writes out C code corresponding to your program's operations. Unlike the B::C module, which merely stores the interpreter and its state in a C program, the B::CC module makes a C program that does not involve the interpreter. As a consequence, programs translated into C by B::CC can execute faster than normal interpreted programs. See §63.2.6 for details about usage.

B::Concise

This module prints a concise (but complete) version of the Perl parse tree. Its output is more customizable than the one of B::Terse or B::Debug (and it can emulate them). This module useful for people who are writing their own back end, or who are learning about the Perl internals. It's not useful to the average programmer.

B::Debug

This module dumps the Perl parse tree in verbose detail to STDOUT. It's useful for people who are writing their own back end, or who are learning about the Perl internals. It's not useful to the average programmer.

B::Deparse

This module produces Perl source code from the compiled parse tree. It is useful in debugging and deconstructing other people's code, also as a pretty-printer for your own source. See §63.2.2 for details about usage.

B::Disassembler

This module turns bytecode back into a parse tree. It's not a back end itself, but rather a component of a back end. It's used by the *disassemble* program that comes with the bytecode.

B::Lint

This module inspects the compiled form of your source code for things which, while some people frown on them, aren't necessarily bad enough to justify a warning. For instance, use of an array in scalar context without explicitly saying `scalar(@array)` is something that Lint can identify. See §63.2.3 for details about usage.

B::Showlex

This module prints out the my() variables used in a function or a file. To get a list of the my() variables used in the subroutine mysub() defined in the file myperlprogram:

```
$ perl -MO=Showlex,mysub myperlprogram
```

To get a list of the my() variables used in the file myperlprogram:

```
$ perl -MO=Showlex myperlprogram
```

[BROKEN]

B::Stackobj

This module is used by the B::CC module. It's not a back end itself, but rather a component of a back end.

B::Stash

This module is used by the *perlcc* program, which compiles a module into an executable. B::Stash prints the symbol tables in use by a program, and is used to prevent B::CC from producing C code for the B::* and O modules. It's not a back end itself, but rather a component of a back end.

B::Terse

This module prints the contents of the parse tree, but without as much information as B::Debug. For comparison, `print "Hello, world."` produced 96 lines of output from B::Debug, but only 6 from B::Terse.

This module is useful for people who are writing their own back end, or who are learning about the Perl internals. It's not useful to the average programmer.

B::Xref

This module prints a report on where the variables, subroutines, and formats are defined and used within a program and the modules it loads. See §63.2.1 for details about usage.

63.4 KNOWN PROBLEMS

The simple C backend currently only saves typeglobs with alphanumeric names.

The optimized C backend outputs code for more modules than it should (e.g., DirHandle). It also has little hope of properly handling `goto LABEL` outside the running subroutine (`goto &sub` is okay). `goto LABEL` currently does not work at all in this backend. It also creates a huge initialization function that gives C compilers headaches. Splitting the initialization function gives better results. Other problems include: unsigned math does not work correctly; some opcodes are handled incorrectly by default opcode handling mechanism.

BEGIN{} blocks are executed while compiling your code. Any external state that is initialized in BEGIN{}, such as opening files, initiating database connections etc., do not behave properly. To work around this, Perl has an INIT{} block that corresponds to code being executed before your program begins running but after your program has finished being compiled. Execution order: BEGIN{}, (possible save of state through compiler back-end), INIT{}, program runs, END{}.

Chapter 64

perlfilter

Source Filters

64.1 DESCRIPTION

This article is about a little-known feature of Perl called *source filters*. Source filters alter the program text of a module before Perl sees it, much as a C preprocessor alters the source text of a C program before the compiler sees it. This article tells you more about what source filters are, how they work, and how to write your own.

The original purpose of source filters was to let you encrypt your program source to prevent casual piracy. This isn't all they can do, as you'll soon learn. But first, the basics.

64.2 CONCEPTS

Before the Perl interpreter can execute a Perl script, it must first read it from a file into memory for parsing and compilation. If that script itself includes other scripts with a `use` or `require` statement, then each of those scripts will have to be read from their respective files as well.

Now think of each logical connection between the Perl parser and an individual file as a *source stream*. A source stream is created when the Perl parser opens a file, it continues to exist as the source code is read into memory, and it is destroyed when Perl is finished parsing the file. If the parser encounters a `require` or `use` statement in a source stream, a new and distinct stream is created just for that file.

The diagram below represents a single source stream, with the flow of source from a Perl script file on the left into the Perl parser on the right. This is how Perl normally operates.

```
    file -------> parser
```

There are two important points to remember:

1. Although there can be any number of source streams in existence at any given time, only one will be active.
2. Every source stream is associated with only one file.

A source filter is a special kind of Perl module that intercepts and modifies a source stream before it reaches the parser. A source filter changes our diagram like this:

```
    file ----> filter ----> parser
```

If that doesn't make much sense, consider the analogy of a command pipeline. Say you have a shell script stored in the compressed file *trial.gz*. The simple pipeline command below runs the script without needing to create a temporary file to hold the uncompressed file.

```
    gunzip -c trial.gz | sh
```

In this case, the data flow from the pipeline can be represented as follows:

```
    trial.gz ----> gunzip ----> sh
```

With source filters, you can store the text of your script compressed and use a source filter to uncompress it for Perl's parser:

```
     compressed           gunzip
    Perl program ---> source filter ---> parser
```

64.3 USING FILTERS

So how do you use a source filter in a Perl script? Above, I said that a source filter is just a special kind of module. Like all Perl modules, a source filter is invoked with a use statement.

Say you want to pass your Perl source through the C preprocessor before execution. You could use the existing `-P` command line option to do this, but as it happens, the source filters distribution comes with a C preprocessor filter module called Filter::cpp. Let's use that instead.

Below is an example program, `cpp_test`, which makes use of this filter. Line numbers have been added to allow specific lines to be referenced easily.

```
    1: use Filter::cpp ;
    2: #define TRUE 1
    3: $a = TRUE ;
    4: print "a = $a\n" ;
```

When you execute this script, Perl creates a source stream for the file. Before the parser processes any of the lines from the file, the source stream looks like this:

```
    cpp_test ---------> parser
```

Line 1, `use Filter::cpp`, includes and installs the `cpp` filter module. All source filters work this way. The use statement is compiled and executed at compile time, before any more of the file is read, and it attaches the cpp filter to the source stream behind the scenes. Now the data flow looks like this:

```
    cpp_test ----> cpp filter ----> parser
```

As the parser reads the second and subsequent lines from the source stream, it feeds those lines through the `cpp` source filter before processing them. The `cpp` filter simply passes each line through the real C preprocessor. The output from the C preprocessor is then inserted back into the source stream by the filter.

```
                  .-> cpp --.
                  |         |
                  |         |
                  |       <-'
   cpp_test ----> cpp filter ----> parser
```

The parser then sees the following code:

```
    use Filter::cpp ;
    $a = 1 ;
    print "a = $a\n" ;
```

Let's consider what happens when the filtered code includes another module with use:

```
1: use Filter::cpp ;
2: #define TRUE 1
3: use Fred ;
4: $a = TRUE ;
5: print "a = $a\n" ;
```

The `cpp` filter does not apply to the text of the Fred module, only to the text of the file that used it (`cpp_test`). Although the use statement on line 3 will pass through the cpp filter, the module that gets included (`Fred`) will not. The source streams look like this after line 3 has been parsed and before line 4 is parsed:

```
cpp_test ---> cpp filter ---> parser (INACTIVE)

Fred.pm ----> parser
```

As you can see, a new stream has been created for reading the source from `Fred.pm`. This stream will remain active until all of `Fred.pm` has been parsed. The source stream for `cpp_test` will still exist, but is inactive. Once the parser has finished reading Fred.pm, the source stream associated with it will be destroyed. The source stream for `cpp_test` then becomes active again and the parser reads line 4 and subsequent lines from `cpp_test`.

You can use more than one source filter on a single file. Similarly, you can reuse the same filter in as many files as you like.

For example, if you have a uuencoded and compressed source file, it is possible to stack a uudecode filter and an uncompression filter like this:

```
use Filter::uudecode ; use Filter::uncompress ;
M'XL(".H<US4''V9I;F%L')Q;>7/;1I;_>_I3=&E=%:F*I"T?22Q/
M6]9*<IQCO*XFT"0[PL%%'Y+IG?WN^ZYN-$'J.[.JE$,20/?K=_[>
...
```

Once the first line has been processed, the flow will look like this:

```
file ---> uudecode ---> uncompress ---> parser
           filter         filter
```

Data flows through filters in the same order they appear in the source file. The uudecode filter appeared before the uncompress filter, so the source file will be uudecoded before it's uncompressed.

64.4 WRITING A SOURCE FILTER

There are three ways to write your own source filter. You can write it in C, use an external program as a filter, or write the filter in Perl. I won't cover the first two in any great detail, so I'll get them out of the way first. Writing the filter in Perl is most convenient, so I'll devote the most space to it.

64.5 WRITING A SOURCE FILTER IN C

The first of the three available techniques is to write the filter completely in C. The external module you create interfaces directly with the source filter hooks provided by Perl.

The advantage of this technique is that you have complete control over the implementation of your filter. The big disadvantage is the increased complexity required to write the filter - not only do you need to understand the source filter hooks, but you also need a reasonable knowledge of Perl guts. One of the few times it is worth going to this trouble is when writing a source scrambler. The `decrypt` filter (which unscrambles the source before Perl parses it) included with the source filter distribution is an example of a C source filter (see Decryption Filters, below).

Decryption Filters

All decryption filters work on the principle of "security through obscurity." Regardless of how well you write a decryption filter and how strong your encryption algorithm, anyone determined enough can retrieve the original source code. The reason is quite simple - once the decryption filter has decrypted the source back to its original form, fragments of it will be stored in the computer's memory as Perl parses it. The source might only be in memory for a short period of time, but anyone possessing a debugger, skill, and lots of patience can eventually reconstruct your program.

That said, there are a number of steps that can be taken to make life difficult for the potential cracker. The most important: Write your decryption filter in C and statically link the decryption module into the Perl binary. For further tips to make life difficult for the potential cracker, see the file *decrypt.pm* in the source filters module.

64.6 CREATING A SOURCE FILTER AS A SEPARATE EXECUTABLE

An alternative to writing the filter in C is to create a separate executable in the language of your choice. The separate executable reads from standard input, does whatever processing is necessary, and writes the filtered data to standard output. `Filter:cpp` is an example of a source filter implemented as a separate executable - the executable is the C preprocessor bundled with your C compiler.

The source filter distribution includes two modules that simplify this task: `Filter::exec` and `Filter::sh`. Both allow you to run any external executable. Both use a coprocess to control the flow of data into and out of the external executable. (For details on coprocesses, see Stephens, W.R. "Advanced Programming in the UNIX Environment." Addison-Wesley, ISBN 0-210-56317-7, pages 441-445.) The difference between them is that `Filter::exec` spawns the external command directly, while `Filter::sh` spawns a shell to execute the external command. (Unix uses the Bourne shell; NT uses the cmd shell.) Spawning a shell allows you to make use of the shell metacharacters and redirection facilities.

Here is an example script that uses `Filter::sh`:

```
use Filter::sh 'tr XYZ PQR' ;
$a = 1 ;
print "XYZ a = $a\n" ;
```

The output you'll get when the script is executed:

```
PQR a = 1
```

Writing a source filter as a separate executable works fine, but a small performance penalty is incurred. For example, if you execute the small example above, a separate subprocess will be created to run the Unix `tr` command. Each use of the filter requires its own subprocess. If creating subprocesses is expensive on your system, you might want to consider one of the other options for creating source filters.

64.7 WRITING A SOURCE FILTER IN PERL

The easiest and most portable option available for creating your own source filter is to write it completely in Perl. To distinguish this from the previous two techniques, I'll call it a Perl source filter.

To help understand how to write a Perl source filter we need an example to study. Here is a complete source filter that performs rot13 decoding. (Rot13 is a very simple encryption scheme used in Usenet postings to hide the contents of offensive posts. It moves every letter forward thirteen places, so that A becomes N, B becomes O, and Z becomes M.)

```
package Rot13 ;

use Filter::Util::Call ;
```

```
sub import {
   my ($type) = @_ ;
   my ($ref) = [] ;
   filter_add(bless $ref) ;
}

sub filter {
   my ($self) = @_ ;
   my ($status) ;

   tr/n-za-mN-ZA-M/a-zA-Z/
      if ($status = filter_read()) > 0 ;
   $status ;
}

1;
```

All Perl source filters are implemented as Perl classes and have the same basic structure as the example above.

First, we include the `Filter::Util::Call` module, which exports a number of functions into your filter's namespace. The filter shown above uses two of these functions, `filter_add()` and `filter_read()`.

Next, we create the filter object and associate it with the source stream by defining the `import` function. If you know Perl well enough, you know that `import` is called automatically every time a module is included with a use statement. This makes `import` the ideal place to both create and install a filter object.

In the example filter, the object (`$ref`) is blessed just like any other Perl object. Our example uses an anonymous array, but this isn't a requirement. Because this example doesn't need to store any context information, we could have used a scalar or hash reference just as well. The next section demonstrates context data.

The association between the filter object and the source stream is made with the `filter_add()` function. This takes a filter object as a parameter (`$ref` in this case) and installs it in the source stream.

Finally, there is the code that actually does the filtering. For this type of Perl source filter, all the filtering is done in a method called `filter()`. (It is also possible to write a Perl source filter using a closure. See the `Filter::Util::Call` manual page for more details.) It's called every time the Perl parser needs another line of source to process. The `filter()` method, in turn, reads lines from the source stream using the `filter_read()` function.

If a line was available from the source stream, `filter_read()` returns a status value greater than zero and appends the line to `$_`. A status value of zero indicates end-of-file, less than zero means an error. The filter function itself is expected to return its status in the same way, and put the filtered line it wants written to the source stream in `$_`. The use of `$_` accounts for the brevity of most Perl source filters.

In order to make use of the rot13 filter we need some way of encoding the source file in rot13 format. The script below, `mkrot13`, does just that.

```
die "usage mkrot13 filename\n" unless @ARGV ;
my $in = $ARGV[0] ;
my $out = "$in.tmp" ;
open(IN, "<$in") or die "Cannot open file $in: $!\n";
open(OUT, ">$out") or die "Cannot open file $out: $!\n";

print OUT "use Rot13;\n" ;
while (<IN>) {
   tr/a-zA-Z/n-za-mN-ZA-M/ ;
   print OUT ;
}

close IN;
close OUT;
unlink $in;
rename $out, $in;
```

If we encrypt this with `mkrot13`:

```
print " hello fred \n" ;
```

the result will be this:

```
use Rot13;
cevag "uryyb serq\a" ;
```

Running it produces this output:

```
hello fred
```

64.8 USING CONTEXT: THE DEBUG FILTER

The rot13 example was a trivial example. Here's another demonstration that shows off a few more features.

Say you wanted to include a lot of debugging code in your Perl script during development, but you didn't want it available in the released product. Source filters offer a solution. In order to keep the example simple, let's say you wanted the debugging output to be controlled by an environment variable, `DEBUG`. Debugging code is enabled if the variable exists, otherwise it is disabled.

Two special marker lines will bracket debugging code, like this:

```
## DEBUG_BEGIN
if ($year > 1999) {
   warn "Debug: millennium bug in year $year\n" ;
}
## DEBUG_END
```

When the `DEBUG` environment variable exists, the filter ensures that Perl parses only the code between the `DEBUG_BEGIN` and `DEBUG_END` markers. That means that when `DEBUG` does exist, the code above should be passed through the filter unchanged. The marker lines can also be passed through as-is, because the Perl parser will see them as comment lines. When `DEBUG` isn't set, we need a way to disable the debug code. A simple way to achieve that is to convert the lines between the two markers into comments:

```
## DEBUG_BEGIN
#if ($year > 1999) {
#     warn "Debug: millennium bug in year $year\n" ;
#}
## DEBUG_END
```

Here is the complete Debug filter:

```
package Debug;

use strict;
use warnings;
use Filter::Util::Call ;

use constant TRUE => 1 ;
use constant FALSE => 0 ;
```

```
sub import {
   my ($type) = @_ ;
   my (%context) = (
     Enabled => defined $ENV{DEBUG},
     InTraceBlock => FALSE,
     Filename => (caller)[1],
     LineNo => 0,
     LastBegin => 0,
   ) ;
   filter_add(bless \%context) ;
}

sub Die {
   my ($self) = shift ;
   my ($message) = shift ;
   my ($line_no) = shift || $self->{LastBegin} ;
   die "$message at $self->{Filename} line $line_no.\n"
}

sub filter {
   my ($self) = @_ ;
   my ($status) ;
   $status = filter_read() ;
   ++ $self->{LineNo} ;

   # deal with EOF/error first
   if ($status <= 0) {
       $self->Die("DEBUG_BEGIN has no DEBUG_END")
           if $self->{InTraceBlock} ;
       return $status ;
   }

   if ($self->{InTraceBlock}) {
      if (/^\s*##\s*DEBUG_BEGIN/ ) {
          $self->Die("Nested DEBUG_BEGIN", $self->{LineNo})
      } elsif (/^\s*##\s*DEBUG_END/) {
          $self->{InTraceBlock} = FALSE ;
      }

      # comment out the debug lines when the filter is disabled
      s/^/#/ if ! $self->{Enabled} ;
   } elsif ( /^\s*##\s*DEBUG_BEGIN/ ) {
      $self->{InTraceBlock} = TRUE ;
      $self->{LastBegin} = $self->{LineNo} ;
   } elsif ( /^\s*##\s*DEBUG_END/ ) {
      $self->Die("DEBUG_END has no DEBUG_BEGIN", $self->{LineNo});
   }
   return $status ;
}

1 ;
```

The big difference between this filter and the previous example is the use of context data in the filter object. The filter object is based on a hash reference, and is used to keep various pieces of context information between calls to the filter function. All but two of the hash fields are used for error reporting. The first of those two, Enabled, is used by the filter to determine whether the debugging code should be given to the Perl parser. The second, InTraceBlock, is true when the filter has encountered a `DEBUG_BEGIN` line, but has not yet encountered the following `DEBUG_END` line.

If you ignore all the error checking that most of the code does, the essence of the filter is as follows:

```
    sub filter {
       my ($self) = @_ ;
       my ($status) ;
       $status = filter_read() ;

       # deal with EOF/error first
       return $status if $status <= 0 ;
       if ($self->{InTraceBlock}) {
          if (/^\s*##\s*DEBUG_END/) {
             $self->{InTraceBlock} = FALSE
          }

          # comment out debug lines when the filter is disabled
          s/^/#/ if ! $self->{Enabled} ;
       } elsif ( /^\s*##\s*DEBUG_BEGIN/ ) {
          $self->{InTraceBlock} = TRUE ;
       }
       return $status ;
    }
```

Be warned: just as the C-preprocessor doesn't know C, the Debug filter doesn't know Perl. It can be fooled quite easily:

```
    print <<EOM;
    ##DEBUG_BEGIN
    EOM
```

Such things aside, you can see that a lot can be achieved with a modest amount of code.

64.9 CONCLUSION

You now have better understanding of what a source filter is, and you might even have a possible use for them. If you feel like playing with source filters but need a bit of inspiration, here are some extra features you could add to the Debug filter.

First, an easy one. Rather than having debugging code that is all-or-nothing, it would be much more useful to be able to control which specific blocks of debugging code get included. Try extending the syntax for debug blocks to allow each to be identified. The contents of the DEBUG environment variable can then be used to control which blocks get included.

Once you can identify individual blocks, try allowing them to be nested. That isn't difficult either.

Here is an interesting idea that doesn't involve the Debug filter. Currently Perl subroutines have fairly limited support for formal parameter lists. You can specify the number of parameters and their type, but you still have to manually take them out of the @_ array yourself. Write a source filter that allows you to have a named parameter list. Such a filter would turn this:

```
    sub MySub ($first, $second, @rest) { ... }
```

into this:

```
    sub MySub($$@) {
       my ($first) = shift ;
       my ($second) = shift ;
       my (@rest) = @_ ;
       ...
    }
```

Finally, if you feel like a real challenge, have a go at writing a full-blown Perl macro preprocessor as a source filter. Borrow the useful features from the C preprocessor and any other macro processors you know. The tricky bit will be choosing how much knowledge of Perl's syntax you want your filter to have.

64.10 THINGS TO LOOK OUT FOR

Some Filters Clobber the `DATA` Handle

Some source filters use the `DATA` handle to read the calling program. When using these source filters you cannot rely on this handle, nor expect any particular kind of behavior when operating on it. Filters based on Filter::Util::Call (and therefore Filter::Simple) do not alter the `DATA` filehandle.

64.11 REQUIREMENTS

The Source Filters distribution is available on CPAN, in

```
    CPAN/modules/by-module/Filter
```

Starting from Perl 5.8 Filter::Util::Call (the core part of the Source Filters distribution) is part of the standard Perl distribution. Also included is a friendlier interface called Filter::Simple, by Damian Conway.

Part IV

Internals and C Language Interface

Chapter 65

perlembed

How to embed perl in your C program

65.1 DESCRIPTION

65.1.1 PREAMBLE

Do you want to:

Use C from Perl?
: Read *perlxstut*, *perlxs*, *h2xs*, *perlguts*, and *perlapi*.

Use a Unix program from Perl?
: Read about back-quotes and about `system` and `exec` in *perlfunc*.

Use Perl from Perl?
: Read about do in *perlfunc* and eval in *perlfunc* and require in *perlfunc* and use in *perlfunc*.

Use C from C?
: Rethink your design.

Use Perl from C?
: Read on...

65.1.2 ROADMAP

- Compiling your C program
- Adding a Perl interpreter to your C program
- Calling a Perl subroutine from your C program
- Evaluating a Perl statement from your C program
- Performing Perl pattern matches and substitutions from your C program
- Fiddling with the Perl stack from your C program
- Maintaining a persistent interpreter
- Maintaining multiple interpreter instances
- Using Perl modules, which themselves use C libraries, from your C program
- Embedding Perl under Win32

65.1.3 Compiling your C program

If you have trouble compiling the scripts in this documentation, you're not alone. The cardinal rule: COMPILE THE PROGRAMS IN EXACTLY THE SAME WAY THAT YOUR PERL WAS COMPILED. (Sorry for yelling.)

Also, every C program that uses Perl must link in the *perl library*. What's that, you ask? Perl is itself written in C; the perl library is the collection of compiled C programs that were used to create your perl executable (*/usr/bin/perl* or equivalent). (Corollary: you can't use Perl from your C program unless Perl has been compiled on your machine, or installed properly–that's why you shouldn't blithely copy Perl executables from machine to machine without also copying the *lib* directory.)

When you use Perl from C, your C program will–usually–allocate, "run", and deallocate a *PerlInterpreter* object, which is defined by the perl library.

If your copy of Perl is recent enough to contain this documentation (version 5.002 or later), then the perl library (and *EXTERN.h* and *perl.h*, which you'll also need) will reside in a directory that looks like this:

```
    /usr/local/lib/perl5/your_architecture_here/CORE
```

or perhaps just

```
    /usr/local/lib/perl5/CORE
```

or maybe something like

```
    /usr/opt/perl5/CORE
```

Execute this statement for a hint about where to find CORE:

```
    perl -MConfig -e 'print $Config{archlib}'
```

Here's how you'd compile the example in the next section, Adding a Perl interpreter to your C program, on my Linux box:

```
    % gcc -O2 -Dbool=char -DHAS_BOOL -I/usr/local/include
    -I/usr/local/lib/perl5/i586-linux/5.003/CORE
    -L/usr/local/lib/perl5/i586-linux/5.003/CORE
    -o interp interp.c -lperl -lm
```

(That's all one line.) On my DEC Alpha running old 5.003_05, the incantation is a bit different:

```
    % cc -O2 -Olimit 2900 -DSTANDARD_C -I/usr/local/include
    -I/usr/local/lib/perl5/alpha-dec_osf/5.00305/CORE
    -L/usr/local/lib/perl5/alpha-dec_osf/5.00305/CORE -L/usr/local/lib
    -D__LANGUAGE_C__ -D_NO_PROTO -o interp interp.c -lperl -lm
```

How can you figure out what to add? Assuming your Perl is post-5.001, execute a `perl -V` command and pay special attention to the "cc" and "ccflags" information.

You'll have to choose the appropriate compiler (*cc*, *gcc*, et al.) for your machine: `perl -MConfig -e 'print $Config{cc}'` will tell you what to use.

You'll also have to choose the appropriate library directory (*/usr/local/lib/...*) for your machine. If your compiler complains that certain functions are undefined, or that it can't locate *-lperl*, then you need to change the path following the `-L`. If it complains that it can't find *EXTERN.h* and *perl.h*, you need to change the path following the `-I`.

You may have to add extra libraries as well. Which ones? Perhaps those printed by

```
   perl -MConfig -e 'print $Config{libs}'
```

Provided your perl binary was properly configured and installed the **ExtUtils::Embed** module will determine all of this information for you:

```
   % cc -o interp interp.c `perl -MExtUtils::Embed -e ccopts -e ldopts`
```

If the **ExtUtils::Embed** module isn't part of your Perl distribution, you can retrieve it from http://www.perl.com/perl/CPAN/modules/by-module/ExtUtils/ (If this documentation came from your Perl distribution, then you're running 5.004 or better and you already have it.)

The **ExtUtils::Embed** kit on CPAN also contains all source code for the examples in this document, tests, additional examples and other information you may find useful.

65.1.4 Adding a Perl interpreter to your C program

In a sense, perl (the C program) is a good example of embedding Perl (the language), so I'll demonstrate embedding with *miniperlmain.c*, included in the source distribution. Here's a bastardized, nonportable version of *miniperlmain.c* containing the essentials of embedding:

```
#include <EXTERN.h>               /* from the Perl distribution     */
#include <perl.h>                 /* from the Perl distribution     */

static PerlInterpreter *my_perl;  /***    The Perl interpreter    ***/

int main(int argc, char **argv, char **env)
{
    PERL_SYS_INIT3(&argc,&argv,&env);
    my_perl = perl_alloc();
    perl_construct(my_perl);
    PL_exit_flags |= PERL_EXIT_DESTRUCT_END;
    perl_parse(my_perl, NULL, argc, argv, (char **)NULL);
    perl_run(my_perl);
    perl_destruct(my_perl);
    perl_free(my_perl);
    PERL_SYS_TERM();
}
```

Notice that we don't use the `env` pointer. Normally handed to `perl_parse` as its final argument, `env` here is replaced by `NULL`, which means that the current environment will be used. The macros PERL_SYS_INIT3() and PERL_SYS_TERM() provide system-specific tune up of the C runtime environment necessary to run Perl interpreters; since PERL_SYS_INIT3() may change `env`, it may be more appropriate to provide `env` as an argument to perl_parse().

Now compile this program (I'll call it *interp.c*) into an executable:

```
% cc -o interp interp.c ‘perl -MExtUtils::Embed -e ccopts -e ldopts‘
```

After a successful compilation, you'll be able to use *interp* just like perl itself:

```
% interp
print "Pretty Good Perl \n";
print "10890 - 9801 is ", 10890 - 9801;
<CTRL-D>
Pretty Good Perl
10890 - 9801 is 1089
```

or

```
% interp -e ’printf("%x", 3735928559)’
deadbeef
```

You can also read and execute Perl statements from a file while in the midst of your C program, by placing the filename in *argv[1]* before calling *perl_run*.

65.1.5 Calling a Perl subroutine from your C program

To call individual Perl subroutines, you can use any of the **call_*** functions documented in *perlcall*. In this example we'll use `call_argv`.

That's shown below, in a program I'll call *showtime.c*.

```
#include <EXTERN.h>
#include <perl.h>

static PerlInterpreter *my_perl;

int main(int argc, char **argv, char **env)
{
    char *args[] = { NULL };
    PERL_SYS_INIT3(&argc,&argv,&env);
    my_perl = perl_alloc();
    perl_construct(my_perl);

    perl_parse(my_perl, NULL, argc, argv, NULL);
    PL_exit_flags |= PERL_EXIT_DESTRUCT_END;

    /*** skipping perl_run() ***/

    call_argv("showtime", G_DISCARD | G_NOARGS, args);

    perl_destruct(my_perl);
    perl_free(my_perl);
    PERL_SYS_TERM();
}
```

where *showtime* is a Perl subroutine that takes no arguments (that's the *G_NOARGS*) and for which I'll ignore the return value (that's the *G_DISCARD*). Those flags, and others, are discussed in *perlcall*.

I'll define the *showtime* subroutine in a file called *showtime.pl*:

```
print "I shan't be printed.";

sub showtime {
    print time;
}
```

Simple enough. Now compile and run:

```
% cc -o showtime showtime.c `perl -MExtUtils::Embed -e ccopts -e ldopts`

% showtime showtime.pl
818284590
```

yielding the number of seconds that elapsed between January 1, 1970 (the beginning of the Unix epoch), and the moment I began writing this sentence.

In this particular case we don't have to call *perl_run*, as we set the PL_exit_flag PERL_EXIT_DESTRUCT_END which executes END blocks in perl_destruct.

If you want to pass arguments to the Perl subroutine, you can add strings to the `NULL`-terminated `args` list passed to *call_argv*. For other data types, or to examine return values, you'll need to manipulate the Perl stack. That's demonstrated in Fiddling with the Perl stack from your C program.

65.1.6 Evaluating a Perl statement from your C program

Perl provides two API functions to evaluate pieces of Perl code. These are eval_sv in *perlapi* and eval_pv in *perlapi*.

Arguably, these are the only routines you'll ever need to execute snippets of Perl code from within your C program. Your code can be as long as you wish; it can contain multiple statements; it can employ use in *perlfunc*, require in *perlfunc*, and do in *perlfunc* to include external Perl files.

eval_pv lets us evaluate individual Perl strings, and then extract variables for coercion into C types. The following program, *string.c*, executes three Perl strings, extracting an `int` from the first, a `float` from the second, and a `char *` from the third.

```
#include <EXTERN.h>
#include <perl.h>

static PerlInterpreter *my_perl;

main (int argc, char **argv, char **env)
{
    STRLEN n_a;
    char *embedding[] = { "", "-e", "0" };

    PERL_SYS_INIT3(&argc,&argv,&env);
    my_perl = perl_alloc();
    perl_construct( my_perl );

    perl_parse(my_perl, NULL, 3, embedding, NULL);
    PL_exit_flags |= PERL_EXIT_DESTRUCT_END;
    perl_run(my_perl);

    /** Treat $a as an integer **/
    eval_pv("$a = 3; $a **= 2", TRUE);
    printf("a = %d\n", SvIV(get_sv("a", FALSE)));

    /** Treat $a as a float **/
    eval_pv("$a = 3.14; $a **= 2", TRUE);
    printf("a = %f\n", SvNV(get_sv("a", FALSE)));

    /** Treat $a as a string **/
    eval_pv("$a = 'rekcaH lreP rehtonA tsuJ'; $a = reverse($a);", TRUE);
    printf("a = %s\n", SvPV(get_sv("a", FALSE), n_a));

    perl_destruct(my_perl);
    perl_free(my_perl);
    PERL_SYS_TERM();
}
```

All of those strange functions with *sv* in their names help convert Perl scalars to C types. They're described in *perlguts* and *perlapi*.

If you compile and run *string.c*, you'll see the results of using *SvIV()* to create an `int`, *SvNV()* to create a `float`, and *SvPV()* to create a string:

```
a = 9
a = 9.859600
a = Just Another Perl Hacker
```

In the example above, we've created a global variable to temporarily store the computed value of our eval'd expression. It is also possible and in most cases a better strategy to fetch the return value from *eval_pv()* instead. Example:

```
...
STRLEN n_a;
SV *val = eval_pv("reverse 'rekcaH lreP rehtonA tsuJ'", TRUE);
printf("%s\n", SvPV(val,n_a));
...
```

This way, we avoid namespace pollution by not creating global variables and we've simplified our code as well.

65.1.7 Performing Perl pattern matches and substitutions from your C program

The *eval_sv()* function lets us evaluate strings of Perl code, so we can define some functions that use it to "specialize" in matches and substitutions: *match()*, *substitute()*, and *matches()*.

```
I32 match(SV *string, char *pattern);
```

Given a string and a pattern (e.g., `m/clasp/` or `/\b\w*\b/`, which in your C program might appear as "/\\b\\w*\\b/"), match() returns 1 if the string matches the pattern and 0 otherwise.

```
int substitute(SV **string, char *pattern);
```

Given a pointer to an `SV` and an `=~` operation (e.g., `s/bob/robert/g` or `tr[A-Z][a-z]`), substitute() modifies the string within the `SV` as according to the operation, returning the number of substitutions made.

```
int matches(SV *string, char *pattern, AV **matches);
```

Given an `SV`, a pattern, and a pointer to an empty `AV`, matches() evaluates `$string =~ $pattern` in a list context, and fills in *matches* with the array elements, returning the number of matches found.

Here's a sample program, *match.c*, that uses all three (long lines have been wrapped here):

```
#include <EXTERN.h>
#include <perl.h>

static PerlInterpreter *my_perl;

/** my_eval_sv(code, error_check)
** kinda like eval_sv(),
** but we pop the return value off the stack
**/
SV* my_eval_sv(SV *sv, I32 croak_on_error)
{
    dSP;
    SV* retval;
    STRLEN n_a;

    PUSHMARK(SP);
    eval_sv(sv, G_SCALAR);

    SPAGAIN;
    retval = POPs;
    PUTBACK;
    if (croak_on_error && SvTRUE(ERRSV))
       croak(SvPVx(ERRSV, n_a));

    return retval;
}

/** match(string, pattern)
**
** Used for matches in a scalar context.
**
** Returns 1 if the match was successful; 0 otherwise.
**/

I32 match(SV *string, char *pattern)
{
    SV *command = NEWSV(1099, 0), *retval;
    STRLEN n_a;

    sv_setpvf(command, "my $string = '%s'; $string =~ %s",
             SvPV(string,n_a), pattern);

    retval = my_eval_sv(command, TRUE);
    SvREFCNT_dec(command);

    return SvIV(retval);
}

/** substitute(string, pattern)
**
** Used for =~ operations that modify their left-hand side (s/// and tr///)
**
** Returns the number of successful matches, and
** modifies the input string if there were any.
**/

I32 substitute(SV **string, char *pattern)
{
    SV *command = NEWSV(1099, 0), *retval;
    STRLEN n_a;

    sv_setpvf(command, "$string = '%s'; ($string =~ %s)",
             SvPV(*string,n_a), pattern);

    retval = my_eval_sv(command, TRUE);
    SvREFCNT_dec(command);

    *string = get_sv("string", FALSE);
    return SvIV(retval);
}

/** matches(string, pattern, matches)
**
** Used for matches in a list context.
**
** Returns the number of matches,
** and fills in **matches with the matching substrings
**/
```

```
I32 matches(SV *string, char *pattern, AV **match_list)
{
    SV *command = NEWSV(1099, 0);
    I32 num_matches;
    STRLEN n_a;

    sv_setpvf(command, "my $string = '%s'; @array = ($string =~ %s)",
             SvPV(string,n_a), pattern);

    my_eval_sv(command, TRUE);
    SvREFCNT_dec(command);

    *match_list = get_av("array", FALSE);
    num_matches = av_len(*match_list) + 1; /** assume $[ is 0 **/

    return num_matches;
}

main (int argc, char **argv, char **env)
{
    char *embedding[] = { "", "-e", "0" };
    AV *match_list;
    I32 num_matches, i;
    SV *text;
    STRLEN n_a;

    PERL_SYS_INIT3(&argc,&argv,&env);
    my_perl = perl_alloc();
    perl_construct(my_perl);
    perl_parse(my_perl, NULL, 3, embedding, NULL);
    PL_exit_flags |= PERL_EXIT_DESTRUCT_END;

    text = NEWSV(1099,0);
    sv_setpv(text, "When he is at a convenience store and the "
       "bill comes to some amount like 76 cents, Maynard is "
       "aware that there is something he *should* do, something "
       "that will enable him to get back a quarter, but he has "
       "no idea *what*.  He fumbles through his red squeezey "
       "changepurse and gives the boy three extra pennies with "
       "his dollar, hoping that he might luck into the correct "
       "amount.  The boy gives him back two of his own pennies "
       "and then the big shiny quarter that is his prize. "
       "-RICHH");

    if (match(text, "m/quarter/")) /** Does text contain 'quarter'? **/
       printf("match: Text contains the word 'quarter'.\n\n");
    else
       printf("match: Text doesn't contain the word 'quarter'.\n\n");

    if (match(text, "m/eighth/")) /** Does text contain 'eighth'? **/
       printf("match: Text contains the word 'eighth'.\n\n");
    else
       printf("match: Text doesn't contain the word 'eighth'.\n\n");

    /** Match all occurrences of /wi../ **/
    num_matches = matches(text, "m/(wi..)/g", &match_list);
    printf("matches: m/(wi..)/g found %d matches...\n", num_matches);
    for (i = 0; i < num_matches; i++)
       printf("match: %s\n", SvPV(*av_fetch(match_list, i, FALSE),n_a));
    printf("\n");

    /** Remove all vowels from text **/
    num_matches = substitute(&text, "s/[aeiou]//gi");
    if (num_matches) {
       printf("substitute: s/[aeiou]//gi...%d substitutions made.\n",
              num_matches);
       printf("Now text is: %s\n\n", SvPV(text,n_a));
    }

    /** Attempt a substitution **/
    if (!substitute(&text, "s/Perl/C/")) {
       printf("substitute: s/Perl/C...No substitution made.\n\n");
    }

    SvREFCNT_dec(text);
    PL_perl_destruct_level = 1;
    perl_destruct(my_perl);
    perl_free(my_perl);
    PERL_SYS_TERM();
 }
```

which produces the output (again, long lines have been wrapped here)

```
match: Text contains the word 'quarter'.

match: Text doesn't contain the word 'eighth'.

matches: m/(wi..)/g found 2 matches...
match: will
match: with

substitute: s/[aeiou]//gi...139 substitutions made.
Now text is: Whn h s t  cnvnnc str nd th bll cms t sm mnt lk 76 cnts,

substitute: s/Perl/C...No substitution made.
```

65.1.8 Fiddling with the Perl stack from your C program

When trying to explain stacks, most computer science textbooks mumble something about spring-loaded columns of cafeteria plates: the last thing you pushed on the stack is the first thing you pop off. That'll do for our purposes: your C program will push some arguments onto "the Perl stack", shut its eyes while some magic happens, and then pop the results–the return value of your Perl subroutine–off the stack.

First you'll need to know how to convert between C types and Perl types, with newSViv() and sv_setnv() and newAV() and all their friends. They're described in *perlguts* and *perlapi*.

Then you'll need to know how to manipulate the Perl stack. That's described in *perlcall*.

Once you've understood those, embedding Perl in C is easy.

Because C has no builtin function for integer exponentiation, let's make Perl's ** operator available to it (this is less useful than it sounds, because Perl implements ** with C's *pow()* function). First I'll create a stub exponentiation function in *power.pl*:

```
    sub expo {
        my ($a, $b) = @_;
        return $a ** $b;
    }
```

Now I'll create a C program, *power.c*, with a function *PerlPower()* that contains all the perlguts necessary to push the two arguments into *expo()* and to pop the return value out. Take a deep breath...

```
    #include <EXTERN.h>
    #include <perl.h>

    static PerlInterpreter *my_perl;

    static void
    PerlPower(int a, int b)
    {
      dSP;                            /* initialize stack pointer      */
      ENTER;                          /* everything created after here */
      SAVETMPS;                       /* ...is a temporary variable.   */
      PUSHMARK(SP);                   /* remember the stack pointer    */
      XPUSHs(sv_2mortal(newSViv(a))); /* push the base onto the stack  */
      XPUSHs(sv_2mortal(newSViv(b))); /* push the exponent onto stack  */
      PUTBACK;                      /* make local stack pointer global */
      call_pv("expo", G_SCALAR);      /* call the function             */
      SPAGAIN;                        /* refresh stack pointer         */
                                    /* pop the return value from stack */
      printf ("%d to the %dth power is %d.\n", a, b, POPi);
      PUTBACK;
      FREETMPS;                       /* free that return value        */
      LEAVE;                       /* ...and the XPUSHed "mortal" args.*/
    }

    int main (int argc, char **argv, char **env)
    {
      char *my_argv[] = { "", "power.pl" };

      PERL_SYS_INIT3(&argc,&argv,&env);
      my_perl = perl_alloc();
      perl_construct( my_perl );

      perl_parse(my_perl, NULL, 2, my_argv, (char **)NULL);
      PL_exit_flags |= PERL_EXIT_DESTRUCT_END;
      perl_run(my_perl);

      PerlPower(3, 4);                      /*** Compute 3 ** 4 ***/

      perl_destruct(my_perl);
      perl_free(my_perl);
      PERL_SYS_TERM();
    }
```

Compile and run:

```
    % cc -o power power.c `perl -MExtUtils::Embed -e ccopts -e ldopts`

    % power
    3 to the 4th power is 81.
```

65.1.9 Maintaining a persistent interpreter

When developing interactive and/or potentially long-running applications, it's a good idea to maintain a persistent interpreter rather than allocating and constructing a new interpreter multiple times. The major reason is speed: since Perl will only be loaded into memory once.

However, you have to be more cautious with namespace and variable scoping when using a persistent interpreter. In previous examples we've been using global variables in the default package `main`. We knew exactly what code would be run, and assumed we could avoid variable collisions and outrageous symbol table growth.

Let's say your application is a server that will occasionally run Perl code from some arbitrary file. Your server has no way of knowing what code it's going to run. Very dangerous.

If the file is pulled in by `perl_parse()`, compiled into a newly constructed interpreter, and subsequently cleaned out with `perl_destruct()` afterwards, you're shielded from most namespace troubles.

One way to avoid namespace collisions in this scenario is to translate the filename into a guaranteed-unique package name, and then compile the code into that package using eval in *perlfunc*. In the example below, each file will only be compiled once. Or, the application might choose to clean out the symbol table associated with the file after it's no longer needed. Using call_argv in *perlapi*, We'll call the subroutine `Embed::Persistent::eval_file` which lives in the file `persistent.pl` and pass the filename and boolean cleanup/cache flag as arguments.

Note that the process will continue to grow for each file that it uses. In addition, there might be `AUTOLOAD`ed subroutines and other conditions that cause Perl's symbol table to grow. You might want to add some logic that keeps track of the process size, or restarts itself after a certain number of requests, to ensure that memory consumption is minimized. You'll also want to scope your variables with my in *perlfunc* whenever possible.

```
package Embed::Persistent;
#persistent.pl

use strict;
our %Cache;
use Symbol qw(delete_package);

sub valid_package_name {
    my($string) = @_;
    $string =~ s/([^A-Za-z0-9\/])/sprintf("_%2x",unpack("C",$1))/eg;
    # second pass only for words starting with a digit
    $string =~ s|/(\d)|sprintf("/_%2x",unpack("C",$1))|eg;

    # Dress it up as a real package name
    $string =~ s|/|::|g;
    return "Embed" . $string;
}

sub eval_file {
    my($filename, $delete) = @_;
    my $package = valid_package_name($filename);
    my $mtime = -M $filename;
    if(defined $Cache{$package}{mtime}
       &&
       $Cache{$package}{mtime} <= $mtime)
    {
       # we have compiled this subroutine already,
       # it has not been updated on disk, nothing left to do
       print STDERR "already compiled $package->handler\n";
    }
    else {
       local *FH;
```

```
        open FH, $filename or die "open '$filename' $!";
        local($/) = undef;
        my $sub = <FH>;
        close FH;

        #wrap the code into a subroutine inside our unique package
        my $eval = qq{package $package; sub handler { $sub; }};
        {
            # hide our variables within this block
            my($filename,$mtime,$package,$sub);
            eval $eval;
        }
        die $@ if $@;

        #cache it unless we're cleaning out each time
        $Cache{$package}{mtime} = $mtime unless $delete;
    }

    eval {$package->handler;};
    die $@ if $@;

    delete_package($package) if $delete;

    #take a look if you want
    #print Devel::Symdump->rnew($package)->as_string, $/;
}

1;

__END__

/* persistent.c */
#include <EXTERN.h>
#include <perl.h>

/* 1 = clean out filename's symbol table after each request, 0 = don't */
#ifndef DO_CLEAN
#define DO_CLEAN 0
#endif

#define BUFFER_SIZE 1024

static PerlInterpreter *my_perl = NULL;

int
main(int argc, char **argv, char **env)
{
    char *embedding[] = { "", "persistent.pl" };
    char *args[] = { "", DO_CLEAN, NULL };
    char filename[BUFFER_SIZE];
    int exitstatus = 0;
    STRLEN n_a;
    PERL_SYS_INIT3(&argc,&argv,&env);
    if((my_perl = perl_alloc()) == NULL) {
       fprintf(stderr, "no memory!");
       exit(1);
    }
    perl_construct(my_perl);

    exitstatus = perl_parse(my_perl, NULL, 2, embedding, NULL);
    PL_exit_flags |= PERL_EXIT_DESTRUCT_END;
    if(!exitstatus) {
       exitstatus = perl_run(my_perl);

       while(printf("Enter file name: ") &&
             fgets(filename, BUFFER_SIZE, stdin)) {

           filename[strlen(filename)-1] = '\0'; /* strip \n */
           /* call the subroutine, passing it the filename as an argument */
           args[0] = filename;
           call_argv("Embed::Persistent::eval_file",
                          G_DISCARD | G_EVAL, args);

           /* check $@ */
           if(SvTRUE(ERRSV))
               fprintf(stderr, "eval error: %s\n", SvPV(ERRSV,n_a));
       }
    }

    PL_perl_destruct_level = 0;
    perl_destruct(my_perl);
    perl_free(my_perl);
    PERL_SYS_TERM();
    exit(exitstatus);
}
```

Now compile:

```
% cc -o persistent persistent.c `perl -MExtUtils::Embed -e ccopts -e ldopts`
```

Here's an example script file:

```
#test.pl
my $string = "hello";
foo($string);

sub foo {
    print "foo says: @_\n";
}
```

Now run:

```
% persistent
Enter file name: test.pl
foo says: hello
Enter file name: test.pl
already compiled Embed::test_2epl->handler
foo says: hello
Enter file name: ^C
```

65.1.10 Execution of END blocks

Traditionally END blocks have been executed at the end of the perl_run. This causes problems for applications that never call perl_run. Since perl 5.7.2 you can specify `PL_exit_flags |= PERL_EXIT_DESTRUCT_END` to get the new behaviour. This also enables the running of END blocks if the perl_parse fails and `perl_destruct` will return the exit value.

65.1.11 Maintaining multiple interpreter instances

Some rare applications will need to create more than one interpreter during a session. Such an application might sporadically decide to release any resources associated with the interpreter.

The program must take care to ensure that this takes place *before* the next interpreter is constructed. By default, when perl is not built with any special options, the global variable `PL_perl_destruct_level` is set to `0`, since extra cleaning isn't usually needed when a program only ever creates a single interpreter in its entire lifetime.

Setting `PL_perl_destruct_level` to 1 makes everything squeaky clean:

```
while(1) {
    ...
    /* reset global variables here with PL_perl_destruct_level = 1 */
    PL_perl_destruct_level = 1;
    perl_construct(my_perl);
    ...
    /* clean and reset _everything_ during perl_destruct */
    PL_perl_destruct_level = 1;
    perl_destruct(my_perl);
    perl_free(my_perl);
    ...
    /* let's go do it again! */
}
```

When *perl_destruct()* is called, the interpreter's syntax parse tree and symbol tables are cleaned up, and global variables are reset. The second assignment to `PL_perl_destruct_level` is needed because perl_construct resets it to `0`.

Now suppose we have more than one interpreter instance running at the same time. This is feasible, but only if you used the Configure option `-Dusemultiplicity` or the options `-Dusethreads -Duseithreads` when building perl. By default, enabling one of these Configure options sets the per-interpreter global variable `PL_perl_destruct_level` to 1, so that thorough cleaning is automatic and interpreter variables are initialized correctly. Even if you don't intend to run two or more interpreters at the same time, but to run them sequentially, like in the above example, it is recommended to build perl with the `-Dusemultiplicity` option otherwise some interpreter variables may not be initialized correctly between consecutive runs and your application may crash.

Using `-Dusethreads -Duseithreads` rather than `-Dusemultiplicity` is more appropriate if you intend to run multiple interpreters concurrently in different threads, because it enables support for linking in the thread libraries of your system with the interpreter.

Let's give it a try:

```
#include <EXTERN.h>
#include <perl.h>

/* we're going to embed two interpreters */
/* we're going to embed two interpreters */

#define SAY_HELLO "-e", "print qq(Hi, I'm $^X\n)"
```

```
int main(int argc, char **argv, char **env)
{
    PerlInterpreter *one_perl, *two_perl;
    char *one_args[] = { "one_perl", SAY_HELLO };
    char *two_args[] = { "two_perl", SAY_HELLO };

    PERL_SYS_INIT3(&argc,&argv,&env);
    one_perl = perl_alloc();
    two_perl = perl_alloc();

    PERL_SET_CONTEXT(one_perl);
    perl_construct(one_perl);
    PERL_SET_CONTEXT(two_perl);
    perl_construct(two_perl);

    PERL_SET_CONTEXT(one_perl);
    perl_parse(one_perl, NULL, 3, one_args, (char **)NULL);
    PERL_SET_CONTEXT(two_perl);
    perl_parse(two_perl, NULL, 3, two_args, (char **)NULL);

    PERL_SET_CONTEXT(one_perl);
    perl_run(one_perl);
    PERL_SET_CONTEXT(two_perl);
    perl_run(two_perl);

    PERL_SET_CONTEXT(one_perl);
    perl_destruct(one_perl);
    PERL_SET_CONTEXT(two_perl);
    perl_destruct(two_perl);

    PERL_SET_CONTEXT(one_perl);
    perl_free(one_perl);
    PERL_SET_CONTEXT(two_perl);
    perl_free(two_perl);
    PERL_SYS_TERM();
}
```

Note the calls to PERL_SET_CONTEXT(). These are necessary to initialize the global state that tracks which interpreter is the "current" one on the particular process or thread that may be running it. It should always be used if you have more than one interpreter and are making perl API calls on both interpreters in an interleaved fashion.

PERL_SET_CONTEXT(interp) should also be called whenever `interp` is used by a thread that did not create it (using either perl_alloc(), or the more esoteric perl_clone()).

Compile as usual:

```
% cc -o multiplicity multiplicity.c ‘perl -MExtUtils::Embed -e ccopts -e ldopts‘
```

Run it, Run it:

```
% multiplicity
Hi, I’m one_perl
Hi, I’m two_perl
```

65.1.12 Using Perl modules, which themselves use C libraries, from your C program

If you've played with the examples above and tried to embed a script that *use()*s a Perl module (such as *Socket*) which itself uses a C or C++ library, this probably happened:

```
Can't load module Socket, dynamic loading not available in this perl.
 (You may need to build a new perl executable which either supports
 dynamic loading or has the Socket module statically linked into it.)
```

What's wrong?

Your interpreter doesn't know how to communicate with these extensions on its own. A little glue will help. Up until now you've been calling *perl_parse()*, handing it NULL for the second argument:

```
perl_parse(my_perl, NULL, argc, my_argv, NULL);
```

That's where the glue code can be inserted to create the initial contact between Perl and linked C/C++ routines. Let's take a look some pieces of *perlmain.c* to see how Perl does this:

```
static void xs_init (pTHX);

EXTERN_C void boot_DynaLoader (pTHX_ CV* cv);
EXTERN_C void boot_Socket (pTHX_ CV* cv);

EXTERN_C void
xs_init(pTHX)
{
       char *file = __FILE__;
       /* DynaLoader is a special case */
       newXS("DynaLoader::boot_DynaLoader", boot_DynaLoader, file);
       newXS("Socket::bootstrap", boot_Socket, file);
}
```

Simply put: for each extension linked with your Perl executable (determined during its initial configuration on your computer or when adding a new extension), a Perl subroutine is created to incorporate the extension's routines. Normally, that subroutine is named *Module::bootstrap()* and is invoked when you say *use Module*. In turn, this hooks into an XSUB, *boot_Module*, which creates a Perl counterpart for each of the extension's XSUBs. Don't worry about this part; leave that to the *xsubpp* and extension authors. If your extension is dynamically loaded, DynaLoader creates *Module::bootstrap()* for you on the fly. In fact, if you have a working DynaLoader then there is rarely any need to link in any other extensions statically.

Once you have this code, slap it into the second argument of *perl_parse()*:

```
perl_parse(my_perl, xs_init, argc, my_argv, NULL);
```

Then compile:

```
% cc -o interp interp.c `perl -MExtUtils::Embed -e ccopts -e ldopts`

% interp
  use Socket;
  use SomeDynamicallyLoadedModule;

  print "Now I can use extensions!\n"'
```

ExtUtils::Embed can also automate writing the *xs_init* glue code.

```
% perl -MExtUtils::Embed -e xsinit -- -o perlxsi.c
% cc -c perlxsi.c `perl -MExtUtils::Embed -e ccopts`
% cc -c interp.c  `perl -MExtUtils::Embed -e ccopts`
% cc -o interp perlxsi.o interp.o `perl -MExtUtils::Embed -e ldopts`
```

Consult *perlxs*, *perlguts*, and *perlapi* for more details.

65.2 Embedding Perl under Win32

In general, all of the source code shown here should work unmodified under Windows.

However, there are some caveats about the command-line examples shown. For starters, backticks won't work under the Win32 native command shell. The ExtUtils::Embed kit on CPAN ships with a script called **genmake**, which generates a simple makefile to build a program from a single C source file. It can be used like this:

```
C:\ExtUtils-Embed\eg> perl genmake interp.c
C:\ExtUtils-Embed\eg> nmake
C:\ExtUtils-Embed\eg> interp -e "print qq{I'm embedded in Win32!\n}"
```

You may wish to use a more robust environment such as the Microsoft Developer Studio. In this case, run this to generate perlxsi.c:

```
perl -MExtUtils::Embed -e xsinit
```

Create a new project and Insert -> Files into Project: perlxsi.c, perl.lib, and your own source files, e.g. interp.c. Typically you'll find perl.lib in **C:\perl\lib\CORE**, if not, you should see the **CORE** directory relative to `perl -V:archlib`. The studio will also need this path so it knows where to find Perl include files. This path can be added via the Tools -> Options -> Directories menu. Finally, select Build -> Build interp.exe and you're ready to go.

65.3 Hiding Perl_

If you completely hide the short forms forms of the Perl public API, add -DPERL_NO_SHORT_NAMES to the compilation flags. This means that for example instead of writing

```
    warn("%d bottles of beer on the wall", bottlecount);
```

you will have to write the explicit full form

```
    Perl_warn(aTHX_ "%d bottles of beer on the wall", bottlecount);
```

(See Background and PERL_IMPLICIT_CONTEXT for the explanation of the `aTHX_`. in *perlguts*) Hiding the short forms is very useful for avoiding all sorts of nasty (C preprocessor or otherwise) conflicts with other software packages (Perl defines about 2400 APIs with these short names, take or leave few hundred, so there certainly is room for conflict.)

65.4 MORAL

You can sometimes *write faster code* in C, but you can always *write code faster* in Perl. Because you can use each from the other, combine them as you wish.

65.5 AUTHOR

Jon Orwant <*orwant@media.mit.edu*> and Doug MacEachern <*dougm@covalent.net*>, with small contributions from Tim Bunce, Tom Christiansen, Guy Decoux, Hallvard Furuseth, Dov Grobgeld, and Ilya Zakharevich.

Doug MacEachern has an article on embedding in Volume 1, Issue 4 of The Perl Journal (http://www.tpj.com/). Doug is also the developer of the most widely-used Perl embedding: the mod_perl system (perl.apache.org), which embeds Perl in the Apache web server. Oracle, Binary Evolution, ActiveState, and Ben Sugars's nsapi_perl have used this model for Oracle, Netscape and Internet Information Server Perl plugins.

Chapter 66

perldebguts

Guts of Perl debugging

66.1 DESCRIPTION

This is not the perldebug(1) manpage, which tells you how to use the debugger. This manpage describes low-level details concerning the debugger's internals, which range from difficult to impossible to understand for anyone who isn't incredibly intimate with Perl's guts. Caveat lector.

66.2 Debugger Internals

Perl has special debugging hooks at compile-time and run-time used to create debugging environments. These hooks are not to be confused with the *perl -Dxxx* command described in *perlrun*, which is usable only if a special Perl is built per the instructions in the *INSTALL* podpage in the Perl source tree.

For example, whenever you call Perl's built-in `caller` function from the package `DB`, the arguments that the corresponding stack frame was called with are copied to the `@DB::args` array. These mechanisms are enabled by calling Perl with the **-d** switch. Specifically, the following additional features are enabled (cf. `$^P` in *perlvar*):

- Perl inserts the contents of `$ENV{PERL5DB}` (or `BEGIN {require 'perl5db.pl'}` if not present) before the first line of your program.
- Each array `@{"_<$filename"}` holds the lines of $filename for a file compiled by Perl. The same is also true for `eval`ed strings that contain subroutines, or which are currently being executed. The $filename for `eval`ed strings looks like `(eval 34)`. Code assertions in regexes look like `(re_eval 19)`.

  Values in this array are magical in numeric context: they compare equal to zero only if the line is not breakable.
- Each hash `%{"_<$filename"}` contains breakpoints and actions keyed by line number. Individual entries (as opposed to the whole hash) are settable. Perl only cares about Boolean true here, although the values used by *perl5db.pl* have the form `"$break_condition\0$action"`.

  The same holds for evaluated strings that contain subroutines, or which are currently being executed. The $filename for `eval`ed strings looks like `(eval 34)` or `(re_eval 19)`.
- Each scalar `${"_<$filename"}` contains `"_<$filename"`. This is also the case for evaluated strings that contain subroutines, or which are currently being executed. The $filename for `eval`ed strings looks like `(eval 34)` or `(re_eval 19)`.
- After each `required` file is compiled, but before it is executed, `DB::postponed(*{"_<$filename"})` is called if the subroutine `DB::postponed` exists. Here, the $filename is the expanded name of the `required` file, as found in the values of %INC.

- After each subroutine `subname` is compiled, the existence of `$DB::postponed{subname}` is checked. If this key exists, `DB::postponed(subname)` is called if the `DB::postponed` subroutine also exists.
- A hash `%DB::sub` is maintained, whose keys are subroutine names and whose values have the form `filename:startline-endline`. `filename` has the form `(eval 34)` for subroutines defined inside `eval`s, or `(re_eval 19)` for those within regex code assertions.
- When the execution of your program reaches a point that can hold a breakpoint, the `DB::DB()` subroutine is called if any of the variables `$DB::trace`, `$DB::single`, or `$DB::signal` is true. These variables are not `local`izable. This feature is disabled when executing inside `DB::DB()`, including functions called from it unless `$^D & (1<<30)` is true.
- When execution of the program reaches a subroutine call, a call to `&DB::sub`(*args*) is made instead, with `$DB::sub` holding the name of the called subroutine. (This doesn't happen if the subroutine was compiled in the `DB` package.)

Note that if `&DB::sub` needs external data for it to work, no subroutine call is possible without it. As an example, the standard debugger's `&DB::sub` depends on the `$DB::deep` variable (it defines how many levels of recursion deep into the debugger you can go before a mandatory break). If `$DB::deep` is not defined, subroutine calls are not possible, even though `&DB::sub` exists.

66.2.1 Writing Your Own Debugger

Environment Variables

The `PERL5DB` environment variable can be used to define a debugger. For example, the minimal "working" debugger (it actually doesn't do anything) consists of one line:

```
sub DB::DB {}
```

It can easily be defined like this:

```
$ PERL5DB="sub DB::DB {}" perl -d your-script
```

Another brief debugger, slightly more useful, can be created with only the line:

```
sub DB::DB {print ++$i; scalar <STDIN>}
```

This debugger prints a number which increments for each statement encountered and waits for you to hit a newline before continuing to the next statement.

The following debugger is actually useful:

```
{
  package DB;
  sub DB  {}
  sub sub {print ++$i, " $sub\n"; &$sub}
}
```

It prints the sequence number of each subroutine call and the name of the called subroutine. Note that `&DB::sub` is being compiled into the package `DB` through the use of the `package` directive.

When it starts, the debugger reads your rc file (*./.perldb* or *~/.perldb* under Unix), which can set important options. (A subroutine (`&afterinit`) can be defined here as well; it is executed after the debugger completes its own initialization.)

After the rc file is read, the debugger reads the PERLDB_OPTS environment variable and uses it to set debugger options. The contents of this variable are treated as if they were the argument of an `o ...` debugger command (q.v. in Options in *perldebug*).

Debugger internal variables In addition to the file and subroutine-related variables mentioned above, the debugger also maintains various magical internal variables.

- `@DB::dbline` is an alias for `@{"::_<current_file"}`, which holds the lines of the currently-selected file (compiled by Perl), either explicitly chosen with the debugger's `f` command, or implicitly by flow of execution.

  Values in this array are magical in numeric context: they compare equal to zero only if the line is not breakable.

- `%DB::dbline`, is an alias for `%{"::_<current_file"}`, which contains breakpoints and actions keyed by line number in the currently-selected file, either explicitly chosen with the debugger's `f` command, or implicitly by flow of execution.

  As previously noted, individual entries (as opposed to the whole hash) are settable. Perl only cares about Boolean true here, although the values used by *perl5db.pl* have the form `"$break_condition\0$action"`.

Debugger customization functions

Some functions are provided to simplify customization.

- See Options in *perldebug* for description of options parsed by `DB::parse_options(string)` parses debugger options; see Options in *pperldebug* for a description of options recognized.
- `DB::dump_trace(skip[,count])` skips the specified number of frames and returns a list containing information about the calling frames (all of them, if `count` is missing). Each entry is reference to a hash with keys `context` (either `.`, `$`, or `@`), `sub` (subroutine name, or info about `eval`), `args` (`undef` or a reference to an array), `file`, and `line`.
- `DB::print_trace(FH, skip[, count[, short]])` prints formatted info about caller frames. The last two functions may be convenient as arguments to <, << commands.

Note that any variables and functions that are not documented in this manpages (or in *perldebug*) are considered for internal use only, and as such are subject to change without notice.

66.3 Frame Listing Output Examples

The `frame` option can be used to control the output of frame information. For example, contrast this expression trace:

```
$ perl -de 42
Stack dump during die enabled outside of evals.

Loading DB routines from perl5db.pl patch level 0.94
Emacs support available.

Enter h or ‘h h’ for help.

main::(-e:1):   0
  DB<1> sub foo { 14 }

  DB<2> sub bar { 3 }

  DB<3> t print foo() * bar()
main::((eval 172):3):   print foo() + bar();
main::foo((eval 168):2):
main::bar((eval 170):2):
42
```

with this one, once the option `frame=2` has been set:

```
   DB<4> o f=2
                frame = '2'
   DB<5> t print foo() * bar()
 3:      foo() * bar()
 entering main::foo
  2:     sub foo { 14 };
 exited main::foo
 entering main::bar
  2:     sub bar { 3 };
 exited main::bar
 42
```

By way of demonstration, we present below a laborious listing resulting from setting your `PERLDB_OPTS` environment variable to the value `f=n N`, and running *perl -d -V* from the command line. Examples use various values of `n` are shown to give you a feel for the difference between settings. Long those it may be, this is not a complete listing, but only excerpts.

         scalar context return from Exporter::export: ''
        out $=Exporter::import('Config', 'myconfig', 'config_vars') from /dev/null:0
        scalar context return from Exporter::import: ''
```

In all cases shown above, the line indentation shows the call tree. If bit 2 of `frame` is set, a line is printed on exit from a subroutine as well. If bit 4 is set, the arguments are printed along with the caller info. If bit 8 is set, the arguments are printed even if they are tied or references. If bit 16 is set, the return value is printed, too.

When a package is compiled, a line like this

```
    Package lib/Carp.pm.
```

is printed with proper indentation.

66.4 Debugging regular expressions

There are two ways to enable debugging output for regular expressions.

If your perl is compiled with `-DDEBUGGING`, you may use the **-Dr** flag on the command line.

Otherwise, one can `use re 'debug'`, which has effects at compile time and run time. It is not lexically scoped.

66.4.1 Compile-time output

The debugging output at compile time looks like this:

```
  Compiling REx `[bc]d(ef*g)+h[ij]k$'
  size 45 Got 364 bytes for offset annotations.
  first at 1
  rarest char g at 0
  rarest char d at 0
     1: ANYOF[bc](12)
    12: EXACT <d>(14)
    14: CURLYX[0] {1,32767}(28)
    16:   OPEN1(18)
    18:     EXACT <e>(20)
    20:     STAR(23)
    21:       EXACT <f>(0)
    23:     EXACT <g>(25)
    25:   CLOSE1(27)
    27:   WHILEM[1/1](0)
    28: NOTHING(29)
    29: EXACT <h>(31)
    31: ANYOF[ij](42)
    42: EXACT <k>(44)
    44: EOL(45)
    45: END(0)
  anchored `de' at 1 floating `gh' at 3..2147483647 (checking floating)
```

```
        stclass ‘ANYOF[bc]’ minlen 7
  Offsets: [45]
        1[4] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 5[1]
        0[0] 12[1] 0[0] 6[1] 0[0] 7[1] 0[0] 9[1] 8[1] 0[0] 10[1] 0[0]
        11[1] 0[0] 12[0] 12[0] 13[1] 0[0] 14[4] 0[0] 0[0] 0[0] 0[0]
        0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 18[1] 0[0] 19[1] 20[0]
  Omitting $‘ $& $’ support.
```

The first line shows the pre-compiled form of the regex. The second shows the size of the compiled form (in arbitrary units, usually 4-byte words) and the total number of bytes allocated for the offset/length table, usually 4+`size`*8. The next line shows the label *id* of the first node that does a match.

The

```
  anchored ‘de’ at 1 floating ‘gh’ at 3..2147483647 (checking floating)
        stclass ‘ANYOF[bc]’ minlen 7
```

line (split into two lines above) contains optimizer information. In the example shown, the optimizer found that the match should contain a substring `de` at offset 1, plus substring `gh` at some offset between 3 and infinity. Moreover, when checking for these substrings (to abandon impossible matches quickly), Perl will check for the substring `gh` before checking for the substring `de`. The optimizer may also use the knowledge that the match starts (at the `first` *id*) with a character class, and no string shorter than 7 characters can possibly match.

The fields of interest which may appear in this line are

`anchored` *STRING* `at` *POS*

`floating` *STRING* `at` *POS1..POS2*

See above.

`matching floating/anchored`

Which substring to check first.

`minlen`

The minimal length of the match.

`stclass` *TYPE*

Type of first matching node.

`noscan`

Don’t scan for the found substrings.

`isall`

Means that the optimizer information is all that the regular expression contains, and thus one does not need to enter the regex engine at all.

`GPOS`

Set if the pattern contains `\G`.

`plus`

Set if the pattern starts with a repeated char (as in `x+y`).

`implicit`

Set if the pattern starts with `.*`.

`with eval`

Set if the pattern contain eval-groups, such as `(?{ code })` and `(??{ code })`.

`anchored(TYPE)`

If the pattern may match only at a handful of places, (with `TYPE` being `BOL`, `MBOL`, or `GPOS`. See the table below.

If a substring is known to match at end-of-line only, it may be followed by `$`, as in `floating 'k'$`.

The optimizer-specific information is used to avoid entering (a slow) regex engine on strings that will not definitely match. If the `isall` flag is set, a call to the regex engine may be avoided even when the optimizer found an appropriate place for the match.

Above the optimizer section is the list of *nodes* of the compiled form of the regex. Each line has format

id: *TYPE OPTIONAL-INFO* (*next-id*)

66.4.2 Types of nodes

Here are the possible types, with short descriptions:

```
# TYPE arg-description [num-args] [longjump-len] DESCRIPTION

# Exit points
END         no      End of program.
SUCCEED     no      Return from a subroutine, basically.

# Anchors:
BOL         no      Match "" at beginning of line.
MBOL        no      Same, assuming multiline.
SBOL        no      Same, assuming singleline.
EOS         no      Match "" at end of string.
EOL         no      Match "" at end of line.
MEOL        no      Same, assuming multiline.
SEOL        no      Same, assuming singleline.
BOUND       no      Match "" at any word boundary
BOUNDL      no      Match "" at any word boundary
NBOUND      no      Match "" at any word non-boundary
NBOUNDL     no      Match "" at any word non-boundary
GPOS        no      Matches where last m//g left off.

# [Special] alternatives
ANY         no      Match any one character (except newline).
SANY        no      Match any one character.
ANYOF       sv      Match character in (or not in) this class.
ALNUM       no      Match any alphanumeric character
ALNUML      no      Match any alphanumeric char in locale
NALNUM      no      Match any non-alphanumeric character
NALNUML     no      Match any non-alphanumeric char in locale
SPACE       no      Match any whitespace character
SPACEL      no      Match any whitespace char in locale
NSPACE      no      Match any non-whitespace character
NSPACEL     no      Match any non-whitespace char in locale
DIGIT       no      Match any numeric character
NDIGIT      no      Match any non-numeric character

# BRANCH    The set of branches constituting a single choice are hooked
#           together with their "next" pointers, since precedence prevents
#           anything being concatenated to any individual branch.  The
#           "next" pointer of the last BRANCH in a choice points to the
#           thing following the whole choice.  This is also where the
#           final "next" pointer of each individual branch points; each
#           branch starts with the operand node of a BRANCH node.
#
BRANCH      node    Match this alternative, or the next...

# BACK      Normal "next" pointers all implicitly point forward; BACK
#           exists to make loop structures possible.
# not used
BACK        no      Match "", "next" ptr points backward.

# Literals
EXACT       sv      Match this string (preceded by length).
EXACTF      sv      Match this string, folded (prec. by length).
EXACTFL     sv      Match this string, folded in locale (w/len).

# Do nothing
NOTHING     no      Match empty string.
# A variant of above which delimits a group, thus stops optimizations
TAIL        no      Match empty string. Can jump here from outside.

# STAR,PLUS '?', and complex '*' and '+', are implemented as circular
#           BRANCH structures using BACK.  Simple cases (one character
#           per match) are implemented with STAR and PLUS for speed
#           and to minimize recursive plunges.
#
STAR        node    Match this (simple) thing 0 or more times.
PLUS        node    Match this (simple) thing 1 or more times.

CURLY       sv 2    Match this simple thing {n,m} times.
CURLYN      no 2    Match next-after-this simple thing
#                   {n,m} times, set parens.
CURLYM      no 2    Match this medium-complex thing {n,m} times.
CURLYX      sv 2    Match this complex thing {n,m} times.

# This terminator creates a loop structure for CURLYX
WHILEM      no      Do curly processing and see if rest matches.

# OPEN,CLOSE,GROUPP ...are numbered at compile time.
OPEN        num 1   Mark this point in input as start of #n.
CLOSE       num 1   Analogous to OPEN.

REF         num 1   Match some already matched string
REFF        num 1   Match already matched string, folded
REFFL       num 1   Match already matched string, folded in loc.

# grouping assertions
IFMATCH     off 1 2 Succeeds if the following matches.
UNLESSM     off 1 2 Fails if the following matches.
SUSPEND     off 1 1 "Independent" sub-regex.
IFTHEN      off 1 1 Switch, should be preceded by switcher .
GROUPP      num 1   Whether the group matched.

# Support for long regex
LONGJMP     off 1 1 Jump far away.
BRANCHJ     off 1 1 BRANCH with long offset.
```

```
    # The heavy worker
    EVAL        evl 1   Execute some Perl code.

    # Modifiers
    MINMOD      no      Next operator is not greedy.
    LOGICAL     no      Next opcode should set the flag only.

    # This is not used yet
    RENUM       off 1 1 Group with independently numbered parens.

    # This is not really a node, but an optimized away piece of a "long" node.
    # To simplify debugging output, we mark it as if it were a node
    OPTIMIZED   off     Placeholder for dump.
```

Following the optimizer information is a dump of the offset/length table, here split across several lines:

```
  Offsets: [45]
        1[4] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 5[1]
        0[0] 12[1] 0[0] 6[1] 0[0] 7[1] 0[0] 9[1] 8[1] 0[0] 10[1] 0[0]
        11[1] 0[0] 12[0] 12[0] 13[1] 0[0] 14[4] 0[0] 0[0] 0[0] 0[0]
        0[0] 0[0] 0[0] 0[0] 0[0] 0[0] 18[1] 0[0] 19[1] 20[0]
```

The first line here indicates that the offset/length table contains 45 entries. Each entry is a pair of integers, denoted by `offset[length]`. Entries are numbered starting with 1, so entry #1 here is `1[4]` and entry #12 is `5[1]`. `1[4]` indicates that the node labeled `1:` (the `1: ANYOF[bc]`) begins at character position 1 in the pre-compiled form of the regex, and has a length of 4 characters. `5[1]` in position 12 indicates that the node labeled `12:` (the `12: EXACT <d>`) begins at character position 5 in the pre-compiled form of the regex, and has a length of 1 character. `12[1]` in position 14 indicates that the node labeled `14:` (the `14: CURLYX[0] {1,32767}`) begins at character position 12 in the pre-compiled form of the regex, and has a length of 1 character—that is, it corresponds to the + symbol in the precompiled regex.

`0[0]` items indicate that there is no corresponding node.

66.4.3 Run-time output

First of all, when doing a match, one may get no run-time output even if debugging is enabled. This means that the regex engine was never entered and that all of the job was therefore done by the optimizer.

If the regex engine was entered, the output may look like this:

```
  Matching '[bc]d(ef*g)+h[ij]k$' against 'abcdefg__gh__'
    Setting an EVAL scope, savestack=3
     2 <ab> <cdefg__gh_>    |  1: ANYOF
     3 <abc> <defg__gh_>    | 11: EXACT <d>
     4 <abcd> <efg__gh_>    | 13: CURLYX {1,32767}
     4 <abcd> <efg__gh_>    | 26:   WHILEM
                                0 out of 1..32767  cc=effff31c
     4 <abcd> <efg__gh_>    | 15:     OPEN1
     4 <abcd> <efg__gh_>    | 17:     EXACT <e>
     5 <abcde> <fg__gh_>    | 19:     STAR
                             EXACT <f> can match 1 times out of 32767...
    Setting an EVAL scope, savestack=3
     6 <bcdef> <g__gh__>    | 22:       EXACT <g>
     7 <bcdefg> <__gh__>    | 24:       CLOSE1
     7 <bcdefg> <__gh__>    | 26:       WHILEM
                                    1 out of 1..32767  cc=effff31c
    Setting an EVAL scope, savestack=12
     7 <bcdefg> <__gh__>    | 15:         OPEN1
     7 <bcdefg> <__gh__>    | 17:         EXACT <e>
       restoring \1 to 4(4)..7
                                    failed, try continuation...
     7 <bcdefg> <__gh__>    | 27:         NOTHING
     7 <bcdefg> <__gh__>    | 28:         EXACT <h>
                                    failed...
                                failed...
```

The most significant information in the output is about the particular *node* of the compiled regex that is currently being tested against the target string. The format of these lines is

STRING-OFFSET <PRE-STRING> <POST-STRING> |ID: *TYPE*

The *TYPE* info is indented with respect to the backtracking level. Other incidental information appears interspersed within.

66.5 Debugging Perl memory usage

Perl is a profligate wastrel when it comes to memory use. There is a saying that to estimate memory usage of Perl, assume a reasonable algorithm for memory allocation, multiply that estimate by 10, and while you still may miss the mark, at least you won't be quite so astonished. This is not absolutely true, but may provide a good grasp of what happens.

Assume that an integer cannot take less than 20 bytes of memory, a float cannot take less than 24 bytes, a string cannot take less than 32 bytes (all these examples assume 32-bit architectures, the result are quite a bit worse on 64-bit architectures). If a variable is accessed in two of three different ways (which require an integer, a float, or a string), the memory footprint may increase yet another 20 bytes. A sloppy malloc(3) implementation can inflate these numbers dramatically.

On the opposite end of the scale, a declaration like

```
  sub foo;
```

may take up to 500 bytes of memory, depending on which release of Perl you're running.

Anecdotal estimates of source-to-compiled code bloat suggest an eightfold increase. This means that the compiled form of reasonable (normally commented, properly indented etc.) code will take about eight times more space in memory than the code took on disk.

The **-DL** command-line switch is obsolete since circa Perl 5.6.0 (it was available only if Perl was built with `-DDEBUGGING`). The switch was used to track Perl's memory allocations and possible memory leaks. These days the use of malloc debugging tools like *Purify* or *valgrind* is suggested instead.

One way to find out how much memory is being used by Perl data structures is to install the Devel::Size module from CPAN: it gives you the minimum number of bytes required to store a particular data structure. Please be mindful of the difference between the size() and total_size().

If Perl has been compiled using Perl's malloc you can analyze Perl memory usage by setting the $ENV{PERL_DEBUG_MSTATS}.

66.5.1 Using `$ENV{PERL_DEBUG_MSTATS}`

If your perl is using Perl's malloc() and was compiled with the necessary switches (this is the default), then it will print memory usage statistics after compiling your code when `$ENV{PERL_DEBUG_MSTATS} > 1`, and before termination of the program when `$ENV{PERL_DEBUG_MSTATS} >= 1`. The report format is similar to the following example:

```
  $ PERL_DEBUG_MSTATS=2 perl -e "require Carp"
  Memory allocation statistics after compilation: (buckets 4(4)..8188(8192)
     14216 free:   130   117    28     7     9   0   2     2   1 0 0
                437    61    36     0     5
     60924 used:   125   137   161    55     7   8   6    16   2 0 1
                74   109   304    84    20
  Total sbrk(): 77824/21:119. Odd ends: pad+heads+chain+tail: 0+636+0+2048.
  Memory allocation statistics after execution:   (buckets 4(4)..8188(8192)
     30888 free:   245    78    85    13     6   2   1     3   2 0 1
               315   162    39    42    11
    175816 used:   265   176  1112   111    26  22  11    27   2 1 1
               196   178  1066   798    39
  Total sbrk(): 215040/47:145. Odd ends: pad+heads+chain+tail: 0+2192+0+6144.
```

It is possible to ask for such a statistic at arbitrary points in your execution using the mstat() function out of the standard Devel::Peek module.

Here is some explanation of that format:

`buckets SMALLEST(APPROX)..GREATEST(APPROX)`

Perl's malloc() uses bucketed allocations. Every request is rounded up to the closest bucket size available, and a bucket is taken from the pool of buckets of that size.

The line above describes the limits of buckets currently in use. Each bucket has two sizes: memory footprint and the maximal size of user data that can fit into this bucket. Suppose in the above example that the smallest bucket were size 4. The biggest bucket would have usable size 8188, and the memory footprint would be 8192.

In a Perl built for debugging, some buckets may have negative usable size. This means that these buckets cannot (and will not) be used. For larger buckets, the memory footprint may be one page greater than a power of 2. If so, case the corresponding power of two is printed in the `APPROX` field above.

Free/Used

The 1 or 2 rows of numbers following that correspond to the number of buckets of each size between `SMALLEST` and `GREATEST`. In the first row, the sizes (memory footprints) of buckets are powers of two–or possibly one page greater. In the second row, if present, the memory footprints of the buckets are between the memory footprints of two buckets "above".

For example, suppose under the previous example, the memory footprints were

```
     free:    8     16    32    64    128  256 512 1024 2048 4096 8192
           4     12    24    48    80
```

With non-`DEBUGGING` perl, the buckets starting from `128` have a 4-byte overhead, and thus an 8192-long bucket may take up to 8188-byte allocations.

`Total sbrk():  SBRKed/SBRKs:CONTINUOUS`

The first two fields give the total amount of memory perl sbrk(2)ed (ess-broken? :-) and number of sbrk(2)s used. The third number is what perl thinks about continuity of returned chunks. So long as this number is positive, malloc() will assume that it is probable that sbrk(2) will provide continuous memory.

Memory allocated by external libraries is not counted.

`pad:  0`

The amount of sbrk(2)ed memory needed to keep buckets aligned.

`heads:  2192`

Although memory overhead of bigger buckets is kept inside the bucket, for smaller buckets, it is kept in separate areas. This field gives the total size of these areas.

`chain:  0`

malloc() may want to subdivide a bigger bucket into smaller buckets. If only a part of the deceased bucket is left unsubdivided, the rest is kept as an element of a linked list. This field gives the total size of these chunks.

`tail:  6144`

To minimize the number of sbrk(2)s, malloc() asks for more memory. This field gives the size of the yet unused part, which is sbrk(2)ed, but never touched.

66.5.2 Example of using -DL switch

(Note that -DL is obsolete since circa 5.6.0, and even before that Perl needed to be compiled with -DDEBUGGING.)

Below we show how to analyse memory usage by

```
do 'lib/auto/POSIX/autosplit.ix';
```

The file in question contains a header and 146 lines similar to

```
sub getcwd;
```

WARNING: The discussion below supposes 32-bit architecture. In newer releases of Perl, memory usage of the constructs discussed here is greatly improved, but the story discussed below is a real-life story. This story is mercilessly terse, and assumes rather more than cursory knowledge of Perl internals. Type space to continue, 'q' to quit. (Actually, you just want to skip to the next section.)

Here is the itemized list of Perl allocations performed during parsing of this file:

```
 !!! "after" at test.pl line 3.
    Id  subtot   4   8  12  16  20  24  28  32  36  40  48  56  64  72  80 80+
  0 02   13752   .   .   .   . 294   .   .   .   .   .   .   .   .   .   .   4
  0 54    5545   .   .   8 124  16   .   .   .   1   1   .   .   .   .   .   3
  5 05      32   .   .   .   .   .   .   .   1   .   .   .   .   .   .   .   .
  6 02    7152   .   .   .   .   .   .   .   .   .   . 149   .   .   .   .   .
  7 02    3600   .   .   .   .   . 150   .   .   .   .   .   .   .   .   .   .
  7 03      64   .  -1   .   1   .   .   2   .   .   .   .   .   .   .   .   .
  7 04    7056   .   .   .   .   .   .   .   .   .   .   .   .   .   .   .   7
  7 17   38404   .   .   .   .   .   .   .   1   .   . 442 149   .   . 147   .
  9 03    2078  17 249  32   .   .   .   .   2   .   .   .   .   .   .   .   .
```

To see this list, insert two `warn('!...')` statements around the call:

```
warn('!');
do 'lib/auto/POSIX/autosplit.ix';
warn('!!! "after"');
```

and run it with Perl's **-DL** option. The first warn() will print memory allocation info before parsing the file and will memorize the statistics at this point (we ignore what it prints). The second warn() prints increments with respect to these memorized data. This is the printout shown above.

Different *Id*s on the left correspond to different subsystems of the perl interpreter. They are just the first argument given to the perl memory allocation API named New(). To find what `9 03` means, just **grep** the perl source for `903`. You'll find it in *util.c*, function savepvn(). (I know, you wonder why we told you to **grep** and then gave away the answer. That's because grepping the source is good for the soul.) This function is used to store a copy of an existing chunk of memory. Using a C debugger, one can see that the function was called either directly from gv_init() or via sv_magic(), and that gv_init() is called from gv_fetchpv()–which was itself called from newSUB(). Please stop to catch your breath now.

NOTE: To reach this point in the debugger and skip the calls to savepvn() during the compilation of the main program, you should set a C breakpoint in Perl_warn(), continue until this point is reached, and *then* set a C breakpoint in Perl_savepvn(). Note that you may need to skip a handful of Perl_savepvn() calls that do not correspond to mass production of CVs (there are more `903` allocations than 146 similar lines of *lib/auto/POSIX/autosplit.ix*). Note also that `Perl_` prefixes are added by macroization code in perl header files to avoid conflicts with external libraries.

Anyway, we see that `903` ids correspond to creation of globs, twice per glob - for glob name, and glob stringification magic.

Here are explanations for other *Id*s above:

`717`

Creates bigger `XPV*` structures. In the case above, it creates 3 `AV`s per subroutine, one for a list of lexical variable names, one for a scratchpad (which contains lexical variables and `targets`), and one for the array of scratchpads needed for recursion.

It also creates a `GV` and a `CV` per subroutine, all called from start_subparse().

`002`

Creates a C array corresponding to the `AV` of scratchpads and the scratchpad itself. The first fake entry of this scratchpad is created though the subroutine itself is not defined yet.

It also creates C arrays to keep data for the stash. This is one HV, but it grows; thus, there are 4 big allocations: the big chunks are not freed, but are kept as additional arenas for `SV` allocations.

`054`

Creates a `HEK` for the name of the glob for the subroutine. This name is a key in a *stash*.

Big allocations with this *Id* correspond to allocations of new arenas to keep `HE`.

`602`

Creates a `GP` for the glob for the subroutine.

`702`

Creates the `MAGIC` for the glob for the subroutine.

`704`

Creates *arenas* which keep SVs.

66.5.3 -DL details

If Perl is run with **-DL** option, then warn()s that start with '!' behave specially. They print a list of *categories* of memory allocations, and statistics of allocations of different sizes for these categories.

If warn() string starts with

`!!!`

print changed categories only, print the differences in counts of allocations.

`!!`

print grown categories only; print the absolute values of counts, and totals.

`!`

print nonempty categories, print the absolute values of counts and totals.

66.5.4 Limitations of -DL statistics

If an extension or external library does not use the Perl API to allocate memory, such allocations are not counted.

perlXStut

Tutorial for writing XSUBs

67.1 DESCRIPTION

This tutorial will educate the reader on the steps involved in creating a Perl extension. The reader is assumed to have access to *perlguts*, *perlapi* and *perlxs*.

This tutorial starts with very simple examples and becomes more complex, with each new example adding new features. Certain concepts may not be completely explained until later in the tutorial in order to slowly ease the reader into building extensions.

This tutorial was written from a Unix point of view. Where I know them to be otherwise different for other platforms (e.g. Win32), I will list them. If you find something that was missed, please let me know.

67.2 SPECIAL NOTES

67.2.1 make

This tutorial assumes that the make program that Perl is configured to use is called `make`. Instead of running "make" in the examples that follow, you may have to substitute whatever make program Perl has been configured to use. Running **perl -V:make** should tell you what it is.

67.2.2 Version caveat

When writing a Perl extension for general consumption, one should expect that the extension will be used with versions of Perl different from the version available on your machine. Since you are reading this document, the version of Perl on your machine is probably 5.005 or later, but the users of your extension may have more ancient versions.

To understand what kinds of incompatibilities one may expect, and in the rare case that the version of Perl on your machine is older than this document, see the section on "Troubleshooting these Examples" for more information.

If your extension uses some features of Perl which are not available on older releases of Perl, your users would appreciate an early meaningful warning. You would probably put this information into the *README* file, but nowadays installation of extensions may be performed automatically, guided by *CPAN.pm* module or other tools.

In MakeMaker-based installations, *Makefile.PL* provides the earliest opportunity to perform version checks. One can put something like this in *Makefile.PL* for this purpose:

```
eval { require 5.007 }
    or die <<EOD;
############
### This module uses frobnication framework which is not available before
### version 5.007 of Perl.  Upgrade your Perl before installing Kara::Mba.
############
EOD
```

67.2.3 Dynamic Loading versus Static Loading

It is commonly thought that if a system does not have the capability to dynamically load a library, you cannot build XSUBs. This is incorrect. You *can* build them, but you must link the XSUBs subroutines with the rest of Perl, creating a new executable. This situation is similar to Perl 4.

This tutorial can still be used on such a system. The XSUB build mechanism will check the system and build a dynamically-loadable library if possible, or else a static library and then, optionally, a new statically-linked executable with that static library linked in.

Should you wish to build a statically-linked executable on a system which can dynamically load libraries, you may, in all the following examples, where the command "`make`" with no arguments is executed, run the command "`make perl`" instead.

If you have generated such a statically-linked executable by choice, then instead of saying "`make test`", you should say "`make test_static`". On systems that cannot build dynamically-loadable libraries at all, simply saying "`make test`" is sufficient.

67.3 TUTORIAL

Now let’s go on with the show!

67.3.1 EXAMPLE 1

Our first extension will be very simple. When we call the routine in the extension, it will print out a well-known message and return.

Run "`h2xs -A -n Mytest`". This creates a directory named Mytest, possibly under ext/ if that directory exists in the current working directory. Several files will be created in the Mytest dir, including MANIFEST, Makefile.PL, Mytest.pm, Mytest.xs, test.pl, and Changes.

The MANIFEST file contains the names of all the files just created in the Mytest directory.

The file Makefile.PL should look something like this:

```
use ExtUtils::MakeMaker;
# See lib/ExtUtils/MakeMaker.pm for details of how to influence
# the contents of the Makefile that is written.
WriteMakefile(
    NAME         => 'Mytest',
    VERSION_FROM => 'Mytest.pm', # finds $VERSION
    LIBS         => [''],   # e.g., '-lm'
    DEFINE       => '',     # e.g., '-DHAVE_SOMETHING'
    INC          => '',     # e.g., '-I/usr/include/other'
);
```

The file Mytest.pm should start with something like this:

```
package Mytest;

use strict;
use warnings;

require Exporter;
require DynaLoader;
```

```
our @ISA = qw(Exporter DynaLoader);
# Items to export into callers namespace by default. Note: do not export
# names by default without a very good reason. Use EXPORT_OK instead.
# Do not simply export all your public functions/methods/constants.
our @EXPORT = qw(

);
our $VERSION = '0.01';

bootstrap Mytest $VERSION;

# Preloaded methods go here.

# Autoload methods go after __END__, and are processed by the autosplit program.

1;
__END__
# Below is the stub of documentation for your module. You better edit it!
```

The rest of the .pm file contains sample code for providing documentation for the extension.

Finally, the Mytest.xs file should look something like this:

```
#include "EXTERN.h"
#include "perl.h"
#include "XSUB.h"

MODULE = Mytest         PACKAGE = Mytest
```

Let's edit the .xs file by adding this to the end of the file:

```
void
hello()
    CODE:
        printf("Hello, world!\n");
```

It is okay for the lines starting at the "CODE:" line to not be indented. However, for readability purposes, it is suggested that you indent CODE: one level and the lines following one more level.

Now we'll run "`perl Makefile.PL`". This will create a real Makefile, which make needs. Its output looks something like:

```
% perl Makefile.PL
Checking if your kit is complete...
Looks good
Writing Makefile for Mytest
%
```

Now, running make will produce output that looks something like this (some long lines have been shortened for clarity and some extraneous lines have been deleted):

```
% make
umask 0 && cp Mytest.pm ./blib/Mytest.pm
perl xsubpp -typemap typemap Mytest.xs >Mytest.tc && mv Mytest.tc Mytest.c
Please specify prototyping behavior for Mytest.xs (see perlxs manual)
cc -c Mytest.c
Running Mkbootstrap for Mytest ()
```

```
chmod 644 Mytest.bs
LD_RUN_PATH="" ld -o ./blib/PA-RISC1.1/auto/Mytest/Mytest.sl -b Mytest.o
chmod 755 ./blib/PA-RISC1.1/auto/Mytest/Mytest.sl
cp Mytest.bs ./blib/PA-RISC1.1/auto/Mytest/Mytest.bs
chmod 644 ./blib/PA-RISC1.1/auto/Mytest/Mytest.bs
Manifying ./blib/man3/Mytest.3
%
```

You can safely ignore the line about "prototyping behavior" - it is explained in the section "The PROTOTYPES: Keyword" in *perlxs*.

If you are on a Win32 system, and the build process fails with linker errors for functions in the C library, check if your Perl is configured to use PerlCRT (running **perl -V:libc** should show you if this is the case). If Perl is configured to use PerlCRT, you have to make sure PerlCRT.lib is copied to the same location that msvcrt.lib lives in, so that the compiler can find it on its own. msvcrt.lib is usually found in the Visual C compiler's lib directory (e.g. C:/DevStudio/VC/lib).

Perl has its own special way of easily writing test scripts, but for this example only, we'll create our own test script. Create a file called hello that looks like this:

```
#! /opt/perl5/bin/perl

use ExtUtils::testlib;

use Mytest;

Mytest::hello();
```

Now we make the script executable (`chmod +x hello`), run the script and we should see the following output:

```
% ./hello
Hello, world!
%
```

67.3.2 EXAMPLE 2

Now let's add to our extension a subroutine that will take a single numeric argument as input and return 0 if the number is even or 1 if the number is odd.

Add the following to the end of Mytest.xs:

```
int
is_even(input)
        int     input
    CODE:
        RETVAL = (input % 2 == 0);
    OUTPUT:
        RETVAL
```

There does not need to be white space at the start of the "`int input`" line, but it is useful for improving readability. Placing a semi-colon at the end of that line is also optional. Any amount and kind of white space may be placed between the "`int`" and "`input`".

Now re-run make to rebuild our new shared library.

Now perform the same steps as before, generating a Makefile from the Makefile.PL file, and running make.

In order to test that our extension works, we now need to look at the file test.pl. This file is set up to imitate the same kind of testing structure that Perl itself has. Within the test script, you perform a number of tests to confirm the behavior of the extension, printing "ok" when the test is correct, "not ok" when it is not. Change the print statement in the BEGIN block to print "1..4", and add the following code to the end of the file:

```
        print &Mytest::is_even(0) == 1 ? "ok 2" : "not ok 2", "\n";
        print &Mytest::is_even(1) == 0 ? "ok 3" : "not ok 3", "\n";
        print &Mytest::is_even(2) == 1 ? "ok 4" : "not ok 4", "\n";
```

We will be calling the test script through the command "`make test`". You should see output that looks something like this:

```
        % make test
        PERL_DL_NONLAZY=1 /opt/perl5.004/bin/perl (lots of -I arguments) test.pl
        1..4
        ok 1
        ok 2
        ok 3
        ok 4
        %
```

67.3.3 What has gone on?

The program h2xs is the starting point for creating extensions. In later examples we'll see how we can use h2xs to read header files and generate templates to connect to C routines.

h2xs creates a number of files in the extension directory. The file Makefile.PL is a perl script which will generate a true Makefile to build the extension. We'll take a closer look at it later.

The .pm and .xs files contain the meat of the extension. The .xs file holds the C routines that make up the extension. The .pm file contains routines that tell Perl how to load your extension.

Generating the Makefile and running `make` created a directory called blib (which stands for "build library") in the current working directory. This directory will contain the shared library that we will build. Once we have tested it, we can install it into its final location.

Invoking the test script via "`make test`" did something very important. It invoked perl with all those `-I` arguments so that it could find the various files that are part of the extension. It is *very* important that while you are still testing extensions that you use "`make test`". If you try to run the test script all by itself, you will get a fatal error. Another reason it is important to use "`make test`" to run your test script is that if you are testing an upgrade to an already-existing version, using "`make test`" insures that you will test your new extension, not the already-existing version.

When Perl sees a `use extension;`, it searches for a file with the same name as the `use`'d extension that has a .pm suffix. If that file cannot be found, Perl dies with a fatal error. The default search path is contained in the `@INC` array.

In our case, Mytest.pm tells perl that it will need the Exporter and Dynamic Loader extensions. It then sets the `@ISA` and `@EXPORT` arrays and the `$VERSION` scalar; finally it tells perl to bootstrap the module. Perl will call its dynamic loader routine (if there is one) and load the shared library.

The two arrays `@ISA` and `@EXPORT` are very important. The `@ISA` array contains a list of other packages in which to search for methods (or subroutines) that do not exist in the current package. This is usually only important for object-oriented extensions (which we will talk about much later), and so usually doesn't need to be modified.

The `@EXPORT` array tells Perl which of the extension's variables and subroutines should be placed into the calling package's namespace. Because you don't know if the user has already used your variable and subroutine names, it's vitally important to carefully select what to export. Do *not* export method or variable names *by default* without a good reason.

As a general rule, if the module is trying to be object-oriented then don't export anything. If it's just a collection of functions and variables, then you can export them via another array, called `@EXPORT_OK`. This array does not automatically place its subroutine and variable names into the namespace unless the user specifically requests that this be done.

See *perlmod* for more information.

The `$VERSION` variable is used to ensure that the .pm file and the shared library are "in sync" with each other. Any time you make changes to the .pm or .xs files, you should increment the value of this variable.

67.3.4 Writing good test scripts

The importance of writing good test scripts cannot be overemphasized. You should closely follow the "ok/not ok" style that Perl itself uses, so that it is very easy and unambiguous to determine the outcome of each test case. When you find and fix a bug, make sure you add a test case for it.

By running "`make test`", you ensure that your test.pl script runs and uses the correct version of your extension. If you have many test cases, you might want to copy Perl's test style. Create a directory named "t" in the extension's directory and append the suffix ".t" to the names of your test files. When you run "`make test`", all of these test files will be executed.

67.3.5 EXAMPLE 3

Our third extension will take one argument as its input, round off that value, and set the *argument* to the rounded value.

Add the following to the end of Mytest.xs:

```
void
round(arg)
        double  arg
    CODE:
        if (arg > 0.0) {
                arg = floor(arg + 0.5);
        } else if (arg < 0.0) {
                arg = ceil(arg - 0.5);
        } else {
                arg = 0.0;
        }
    OUTPUT:
        arg
```

Edit the Makefile.PL file so that the corresponding line looks like this:

```
'LIBS'      => ['-lm'],   # e.g., '-lm'
```

Generate the Makefile and run make. Change the BEGIN block to print "1..9" and add the following to test.pl:

```
$i = -1.5; &Mytest::round($i); print $i == -2.0 ? "ok 5" : "not ok 5", "\n";
$i = -1.1; &Mytest::round($i); print $i == -1.0 ? "ok 6" : "not ok 6", "\n";
$i = 0.0; &Mytest::round($i); print $i == 0.0 ? "ok 7" : "not ok 7", "\n";
$i = 0.5; &Mytest::round($i); print $i == 1.0 ? "ok 8" : "not ok 8", "\n";
$i = 1.2; &Mytest::round($i); print $i == 1.0 ? "ok 9" : "not ok 9", "\n";
```

Running "`make test`" should now print out that all nine tests are okay.

Notice that in these new test cases, the argument passed to round was a scalar variable. You might be wondering if you can round a constant or literal. To see what happens, temporarily add the following line to test.pl:

```
&Mytest::round(3);
```

Run "`make test`" and notice that Perl dies with a fatal error. Perl won't let you change the value of constants!

67.3.6 What's new here?

- We've made some changes to Makefile.PL. In this case, we've specified an extra library to be linked into the extension's shared library, the math library libm in this case. We'll talk later about how to write XSUBs that can call every routine in a library.
- The value of the function is not being passed back as the function's return value, but by changing the value of the variable that was passed into the function. You might have guessed that when you saw that the return value of round is of type "void".

67.3.7 Input and Output Parameters

You specify the parameters that will be passed into the XSUB on the line(s) after you declare the function's return value and name. Each input parameter line starts with optional white space, and may have an optional terminating semicolon.

The list of output parameters occurs at the very end of the function, just before after the OUTPUT: directive. The use of RETVAL tells Perl that you wish to send this value back as the return value of the XSUB function. In Example 3, we wanted the "return value" placed in the original variable which we passed in, so we listed it (and not RETVAL) in the OUTPUT: section.

67.3.8 The XSUBPP Program

The **xsubpp** program takes the XS code in the .xs file and translates it into C code, placing it in a file whose suffix is .c. The C code created makes heavy use of the C functions within Perl.

67.3.9 The TYPEMAP file

The **xsubpp** program uses rules to convert from Perl's data types (scalar, array, etc.) to C's data types (int, char, etc.). These rules are stored in the typemap file ($PERLLIB/ExtUtils/typemap). This file is split into three parts.

The first section maps various C data types to a name, which corresponds somewhat with the various Perl types. The second section contains C code which **xsubpp** uses to handle input parameters. The third section contains C code which **xsubpp** uses to handle output parameters.

Let's take a look at a portion of the .c file created for our extension. The file name is Mytest.c:

```
XS(XS_Mytest_round)
{
    dXSARGS;
    if (items != 1)
        croak("Usage: Mytest::round(arg)");
    {
        double  arg = (double)SvNV(ST(0));      /* XXXXX */
        if (arg > 0.0) {
                arg = floor(arg + 0.5);
        } else if (arg < 0.0) {
                arg = ceil(arg - 0.5);
        } else {
                arg = 0.0;
        }
        sv_setnv(ST(0), (double)arg);   /* XXXXX */
    }
    XSRETURN(1);
}
```

Notice the two lines commented with "XXXXX". If you check the first section of the typemap file, you'll see that doubles are of type T_DOUBLE. In the INPUT section, an argument that is T_DOUBLE is assigned to the variable arg by calling the routine SvNV on something, then casting it to double, then assigned to the variable arg. Similarly, in the OUTPUT section, once arg has its final value, it is passed to the sv_setnv function to be passed back to the calling subroutine. These two functions are explained in *perlguts*; we'll talk more later about what that "ST(0)" means in the section on the argument stack.

67.3.10 Warning about Output Arguments

In general, it's not a good idea to write extensions that modify their input parameters, as in Example 3. Instead, you should probably return multiple values in an array and let the caller handle them (we'll do this in a later example). However, in order to better accommodate calling pre-existing C routines, which often do modify their input parameters, this behavior is tolerated.

67.3.11 EXAMPLE 4

In this example, we'll now begin to write XSUBs that will interact with pre-defined C libraries. To begin with, we will build a small library of our own, then let h2xs write our .pm and .xs files for us.

Create a new directory called Mytest2 at the same level as the directory Mytest. In the Mytest2 directory, create another directory called mylib, and cd into that directory.

Here we'll create some files that will generate a test library. These will include a C source file and a header file. We'll also create a Makefile.PL in this directory. Then we'll make sure that running make at the Mytest2 level will automatically run this Makefile.PL file and the resulting Makefile.

In the mylib directory, create a file mylib.h that looks like this:

```
        #define TESTVAL 4

        extern double   foo(int, long, const char*);
```

Also create a file mylib.c that looks like this:

```
        #include <stdlib.h>
        #include "./mylib.h"

        double
        foo(int a, long b, const char *c)
        {
                return (a + b + atof(c) + TESTVAL);
        }
```

And finally create a file Makefile.PL that looks like this:

```
        use ExtUtils::MakeMaker;
        $Verbose = 1;
        WriteMakefile(
            NAME   => 'Mytest2::mylib',
            SKIP   => [qw(all static static_lib dynamic dynamic_lib)],
            clean  => {'FILES' => 'libmylib$(LIB_EXT)'},
        );

        sub MY::top_targets {
                '
        all :: static

        pure_all :: static

        static ::       libmylib$(LIB_EXT)

        libmylib$(LIB_EXT): $(O_FILES)
                $(AR) cr libmylib$(LIB_EXT) $(O_FILES)
                $(RANLIB) libmylib$(LIB_EXT)

        ';
        }
```

Make sure you use a tab and not spaces on the lines beginning with "$(AR)" and "$(RANLIB)". Make will not function properly if you use spaces. It has also been reported that the "cr" argument to $(AR) is unnecessary on Win32 systems.

We will now create the main top-level Mytest2 files. Change to the directory above Mytest2 and run the following command:

```
% h2xs -O -n Mytest2 ./Mytest2/mylib/mylib.h
```

This will print out a warning about overwriting Mytest2, but that’s okay. Our files are stored in Mytest2/mylib, and will be untouched.

The normal Makefile.PL that h2xs generates doesn’t know about the mylib directory. We need to tell it that there is a subdirectory and that we will be generating a library in it. Let’s add the argument MYEXTLIB to the WriteMakefile call so that it looks like this:

```
WriteMakefile(
    'NAME'      => 'Mytest2',
    'VERSION_FROM' => 'Mytest2.pm', # finds $VERSION
    'LIBS'      => [''],   # e.g., '-lm'
    'DEFINE'    => '',     # e.g., '-DHAVE_SOMETHING'
    'INC'       => '',     # e.g., '-I/usr/include/other'
    'MYEXTLIB' => 'mylib/libmylib$(LIB_EXT)',
);
```

and then at the end add a subroutine (which will override the pre-existing subroutine). Remember to use a tab character to indent the line beginning with "cd"!

```
sub MY::postamble {
'
$(MYEXTLIB): mylib/Makefile
        cd mylib && $(MAKE) $(PASSTHRU)
';
}
```

Let’s also fix the MANIFEST file so that it accurately reflects the contents of our extension. The single line that says "mylib" should be replaced by the following three lines:

```
mylib/Makefile.PL
mylib/mylib.c
mylib/mylib.h
```

To keep our namespace nice and unpolluted, edit the .pm file and change the variable `@EXPORT` to `@EXPORT_OK`. Finally, in the .xs file, edit the #include line to read:

```
#include "mylib/mylib.h"
```

And also add the following function definition to the end of the .xs file:

```
double
foo(a,b,c)
        int             a
        long            b
        const char *    c
    OUTPUT:
        RETVAL
```

Now we also need to create a typemap file because the default Perl doesn’t currently support the const char * type. Create a file called typemap in the Mytest2 directory and place the following in it:

```
const char *    T_PV
```

Now run perl on the top-level Makefile.PL. Notice that it also created a Makefile in the mylib directory. Run make and watch that it does cd into the mylib directory and run make in there as well.

Now edit the test.pl script and change the BEGIN block to print "1..4", and add the following lines to the end of the script:

```
print &Mytest2::foo(1, 2, "Hello, world!") == 7 ? "ok 2\n" : "not ok 2\n";
print &Mytest2::foo(1, 2, "0.0") == 7 ? "ok 3\n" : "not ok 3\n";
print abs(&Mytest2::foo(0, 0, "-3.4") - 0.6) <= 0.01 ? "ok 4\n" : "not ok 4\n";
```

(When dealing with floating-point comparisons, it is best to not check for equality, but rather that the difference between the expected and actual result is below a certain amount (called epsilon) which is 0.01 in this case)

Run "`make test`" and all should be well.

67.3.12 What has happened here?

Unlike previous examples, we've now run h2xs on a real include file. This has caused some extra goodies to appear in both the .pm and .xs files.

- In the .xs file, there's now a #include directive with the absolute path to the mylib.h header file. We changed this to a relative path so that we could move the extension directory if we wanted to.
- There's now some new C code that's been added to the .xs file. The purpose of the `constant` routine is to make the values that are #define'd in the header file accessible by the Perl script (by calling either `TESTVAL` or `&Mytest2::TESTVAL`). There's also some XS code to allow calls to the `constant` routine.
- The .pm file originally exported the name `TESTVAL` in the `@EXPORT` array. This could lead to name clashes. A good rule of thumb is that if the #define is only going to be used by the C routines themselves, and not by the user, they should be removed from the `@EXPORT` array. Alternately, if you don't mind using the "fully qualified name" of a variable, you could move most or all of the items from the `@EXPORT` array into the `@EXPORT_OK` array.
- If our include file had contained #include directives, these would not have been processed by h2xs. There is no good solution to this right now.
- We've also told Perl about the library that we built in the mylib subdirectory. That required only the addition of the `MYEXTLIB` variable to the WriteMakefile call and the replacement of the postamble subroutine to cd into the subdirectory and run make. The Makefile.PL for the library is a bit more complicated, but not excessively so. Again we replaced the postamble subroutine to insert our own code. This code simply specified that the library to be created here was a static archive library (as opposed to a dynamically loadable library) and provided the commands to build it.

67.3.13 Anatomy of .xs file

The .xs file of §67.3.11 contained some new elements. To understand the meaning of these elements, pay attention to the line which reads

```
MODULE = Mytest2                PACKAGE = Mytest2
```

Anything before this line is plain C code which describes which headers to include, and defines some convenience functions. No translations are performed on this part, apart from having embedded POD documentation skipped over (see *perlpod*) it goes into the generated output C file as is.

Anything after this line is the description of XSUB functions. These descriptions are translated by **xsubpp** into C code which implements these functions using Perl calling conventions, and which makes these functions visible from Perl interpreter.

Pay a special attention to the function `constant`. This name appears twice in the generated .xs file: once in the first part, as a static C function, then another time in the second part, when an XSUB interface to this static C function is defined.

This is quite typical for .xs files: usually the .xs file provides an interface to an existing C function. Then this C function is defined somewhere (either in an external library, or in the first part of .xs file), and a Perl interface to this function (i.e. "Perl glue") is described in the second part of .xs file. The situation in §67.3.1, §67.3.2, and §67.3.5, when all the work is done inside the "Perl glue", is somewhat of an exception rather than the rule.

67.3.14 Getting the fat out of XSUBs

In §67.3.11 the second part of .xs file contained the following description of an XSUB:

```
double
foo(a,b,c)
        int             a
        long            b
        const char *    c
    OUTPUT:
        RETVAL
```

Note that in contrast with §67.3.1, §67.3.2 and §67.3.5, this description does not contain the actual *code* for what is done is done during a call to Perl function foo(). To understand what is going on here, one can add a CODE section to this XSUB:

```
double
foo(a,b,c)
        int             a
        long            b
        const char *    c
    CODE:
        RETVAL = foo(a,b,c);
    OUTPUT:
        RETVAL
```

However, these two XSUBs provide almost identical generated C code: **xsubpp** compiler is smart enough to figure out the `CODE:` section from the first two lines of the description of XSUB. What about `OUTPUT:` section? In fact, that is absolutely the same! The `OUTPUT:` section can be removed as well, *as far as `CODE:` section or `PPCODE:` section* is not specified: **xsubpp** can see that it needs to generate a function call section, and will autogenerate the OUTPUT section too. Thus one can shortcut the XSUB to become:

```
double
foo(a,b,c)
        int             a
        long            b
        const char *    c
```

Can we do the same with an XSUB

```
int
is_even(input)
        int     input
    CODE:
        RETVAL = (input % 2 == 0);
    OUTPUT:
        RETVAL
```

of §67.3.2? To do this, one needs to define a C function `int is_even(int input)`. As we saw in Anatomy of .xs file, a proper place for this definition is in the first part of .xs file. In fact a C function

```
int
is_even(int arg)
{
        return (arg % 2 == 0);
}
```

is probably overkill for this. Something as simple as a `#define` will do too:

```
        #define is_even(arg)    ((arg) % 2 == 0)
```

After having this in the first part of .xs file, the "Perl glue" part becomes as simple as

```
        int
        is_even(input)
                int     input
```

This technique of separation of the glue part from the workhorse part has obvious tradeoffs: if you want to change a Perl interface, you need to change two places in your code. However, it removes a lot of clutter, and makes the workhorse part independent from idiosyncrasies of Perl calling convention. (In fact, there is nothing Perl-specific in the above description, a different version of **xsubpp** might have translated this to TCL glue or Python glue as well.)

67.3.15 More about XSUB arguments

With the completion of Example 4, we now have an easy way to simulate some real-life libraries whose interfaces may not be the cleanest in the world. We shall now continue with a discussion of the arguments passed to the **xsubpp** compiler.

When you specify arguments to routines in the .xs file, you are really passing three pieces of information for each argument listed. The first piece is the order of that argument relative to the others (first, second, etc). The second is the type of argument, and consists of the type declaration of the argument (e.g., int, char*, etc). The third piece is the calling convention for the argument in the call to the library function.

While Perl passes arguments to functions by reference, C passes arguments by value; to implement a C function which modifies data of one of the "arguments", the actual argument of this C function would be a pointer to the data. Thus two C functions with declarations

```
        int string_length(char *s);
        int upper_case_char(char *cp);
```

may have completely different semantics: the first one may inspect an array of chars pointed by s, and the second one may immediately dereference `cp` and manipulate `*cp` only (using the return value as, say, a success indicator). From Perl one would use these functions in a completely different manner.

One conveys this info to **xsubpp** by replacing * before the argument by `&`. `&` means that the argument should be passed to a library function by its address. The above two function may be XSUB-ified as

```
        int
        string_length(s)
                char *  s

        int
        upper_case_char(cp)
                char    &cp
```

For example, consider:

```
        int
        foo(a,b)
                char    &a
                char *  b
```

The first Perl argument to this function would be treated as a char and assigned to the variable a, and its address would be passed into the function foo. The second Perl argument would be treated as a string pointer and assigned to the variable b. The *value* of b would be passed into the function foo. The actual call to the function foo that **xsubpp** generates would look like this:

```
foo(&a, b);
```

xsubpp will parse the following function argument lists identically:

```
char    &a
char&a
char    & a
```

However, to help ease understanding, it is suggested that you place a "&" next to the variable name and away from the variable type), and place a "*" near the variable type, but away from the variable name (as in the call to foo above). By doing so, it is easy to understand exactly what will be passed to the C function – it will be whatever is in the "last column".

You should take great pains to try to pass the function the type of variable it wants, when possible. It will save you a lot of trouble in the long run.

67.3.16 The Argument Stack

If we look at any of the C code generated by any of the examples except example 1, you will notice a number of references to ST(n), where n is usually 0. "ST" is actually a macro that points to the n'th argument on the argument stack. ST(0) is thus the first argument on the stack and therefore the first argument passed to the XSUB, ST(1) is the second argument, and so on.

When you list the arguments to the XSUB in the .xs file, that tells **xsubpp** which argument corresponds to which of the argument stack (i.e., the first one listed is the first argument, and so on). You invite disaster if you do not list them in the same order as the function expects them.

The actual values on the argument stack are pointers to the values passed in. When an argument is listed as being an OUTPUT value, its corresponding value on the stack (i.e., ST(0) if it was the first argument) is changed. You can verify this by looking at the C code generated for Example 3. The code for the round() XSUB routine contains lines that look like this:

```
double  arg = (double)SvNV(ST(0));
/* Round the contents of the variable arg */
sv_setnv(ST(0), (double)arg);
```

The arg variable is initially set by taking the value from ST(0), then is stored back into ST(0) at the end of the routine.

XSUBs are also allowed to return lists, not just scalars. This must be done by manipulating stack values ST(0), ST(1), etc, in a subtly different way. See *perlxs* for details.

XSUBs are also allowed to avoid automatic conversion of Perl function arguments to C function arguments. See *perlxs* for details. Some people prefer manual conversion by inspecting `ST(i)` even in the cases when automatic conversion will do, arguing that this makes the logic of an XSUB call clearer. Compare with §67.3.14 for a similar tradeoff of a complete separation of "Perl glue" and "workhorse" parts of an XSUB.

While experts may argue about these idioms, a novice to Perl guts may prefer a way which is as little Perl-guts-specific as possible, meaning automatic conversion and automatic call generation, as in §67.3.14. This approach has the additional benefit of protecting the XSUB writer from future changes to the Perl API.

67.3.17 Extending your Extension

Sometimes you might want to provide some extra methods or subroutines to assist in making the interface between Perl and your extension simpler or easier to understand. These routines should live in the .pm file. Whether they are automatically loaded when the extension itself is loaded or only loaded when called depends on where in the .pm file the subroutine definition is placed. You can also consult *AutoLoader* for an alternate way to store and load your extra subroutines.

67.3.18 Documenting your Extension

There is absolutely no excuse for not documenting your extension. Documentation belongs in the .pm file. This file will be fed to pod2man, and the embedded documentation will be converted to the manpage format, then placed in the blib directory. It will be copied to Perl's manpage directory when the extension is installed.

You may intersperse documentation and Perl code within the .pm file. In fact, if you want to use method autoloading, you must do this, as the comment inside the .pm file explains.

See *perlpod* for more information about the pod format.

67.3.19 Installing your Extension

Once your extension is complete and passes all its tests, installing it is quite simple: you simply run "make install". You will either need to have write permission into the directories where Perl is installed, or ask your system administrator to run the make for you.

Alternately, you can specify the exact directory to place the extension's files by placing a "PREFIX=/destination/directory" after the make install. (or in between the make and install if you have a brain-dead version of make). This can be very useful if you are building an extension that will eventually be distributed to multiple systems. You can then just archive the files in the destination directory and distribute them to your destination systems.

67.3.20 EXAMPLE 5

In this example, we'll do some more work with the argument stack. The previous examples have all returned only a single value. We'll now create an extension that returns an array.

This extension is very Unix-oriented (struct statfs and the statfs system call). If you are not running on a Unix system, you can substitute for statfs any other function that returns multiple values, you can hard-code values to be returned to the caller (although this will be a bit harder to test the error case), or you can simply not do this example. If you change the XSUB, be sure to fix the test cases to match the changes.

Return to the Mytest directory and add the following code to the end of Mytest.xs:

```
void
statfs(path)
        char *  path
    INIT:
        int i;
        struct statfs buf;

    PPCODE:
        i = statfs(path, &buf);
        if (i == 0) {
                XPUSHs(sv_2mortal(newSVnv(buf.f_bavail)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_bfree)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_blocks)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_bsize)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_ffree)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_files)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_type)));
                XPUSHs(sv_2mortal(newSVnv(buf.f_fsid[0])));
                XPUSHs(sv_2mortal(newSVnv(buf.f_fsid[1])));
        } else {
                XPUSHs(sv_2mortal(newSVnv(errno)));
        }
```

You'll also need to add the following code to the top of the .xs file, just after the include of "XSUB.h":

```
        #include <sys/vfs.h>
```

Also add the following code segment to test.pl while incrementing the "1..9" string in the BEGIN block to "1..11":

```
        @a = &Mytest::statfs("/blech");
        print ((scalar(@a) == 1 && $a[0] == 2) ? "ok 10\n" : "not ok 10\n");
        @a = &Mytest::statfs("/");
        print scalar(@a) == 9 ? "ok 11\n" : "not ok 11\n";
```

67.3.21 New Things in this Example

This example added quite a few new concepts. We'll take them one at a time.

- The INIT: directive contains code that will be placed immediately after the argument stack is decoded. C does not allow variable declarations at arbitrary locations inside a function, so this is usually the best way to declare local variables needed by the XSUB. (Alternatively, one could put the whole `PPCODE:` section into braces, and put these declarations on top.)
- This routine also returns a different number of arguments depending on the success or failure of the call to statfs. If there is an error, the error number is returned as a single-element array. If the call is successful, then a 9-element array is returned. Since only one argument is passed into this function, we need room on the stack to hold the 9 values which may be returned.

  We do this by using the PPCODE: directive, rather than the CODE: directive. This tells **xsubpp** that we will be managing the return values that will be put on the argument stack by ourselves.
- When we want to place values to be returned to the caller onto the stack, we use the series of macros that begin with "XPUSH". There are five different versions, for placing integers, unsigned integers, doubles, strings, and Perl scalars on the stack. In our example, we placed a Perl scalar onto the stack. (In fact this is the only macro which can be used to return multiple values.)

  The XPUSH* macros will automatically extend the return stack to prevent it from being overrun. You push values onto the stack in the order you want them seen by the calling program.
- The values pushed onto the return stack of the XSUB are actually mortal SV's. They are made mortal so that once the values are copied by the calling program, the SV's that held the returned values can be deallocated. If they were not mortal, then they would continue to exist after the XSUB routine returned, but would not be accessible. This is a memory leak.
- If we were interested in performance, not in code compactness, in the success branch we would not use `XPUSHs` macros, but `PUSHs` macros, and would pre-extend the stack before pushing the return values:

  ```
          EXTEND(SP, 9);
  ```

  The tradeoff is that one needs to calculate the number of return values in advance (though overextending the stack will not typically hurt anything but memory consumption).

  Similarly, in the failure branch we could use `PUSHs` *without* extending the stack: the Perl function reference comes to an XSUB on the stack, thus the stack is *always* large enough to take one return value.

67.3.22 EXAMPLE 6

In this example, we will accept a reference to an array as an input parameter, and return a reference to an array of hashes. This will demonstrate manipulation of complex Perl data types from an XSUB.

This extension is somewhat contrived. It is based on the code in the previous example. It calls the statfs function multiple times, accepting a reference to an array of filenames as input, and returning a reference to an array of hashes containing the data for each of the filesystems.

Return to the Mytest directory and add the following code to the end of Mytest.xs:

```
SV *
multi_statfs(paths)
        SV * paths
    INIT:
        AV * results;
        I32 numpaths = 0;
        int i, n;
        struct statfs buf;

        if ((!SvROK(paths))
            || (SvTYPE(SvRV(paths)) != SVt_PVAV)
            || ((numpaths = av_len((AV *)SvRV(paths))) < 0))
        {
            XSRETURN_UNDEF;
        }
        results = (AV *)sv_2mortal((SV *)newAV());
    CODE:
        for (n = 0; n <= numpaths; n++) {
            HV * rh;
            STRLEN l;
            char * fn = SvPV(*av_fetch((AV *)SvRV(paths), n, 0), l);

            i = statfs(fn, &buf);
            if (i != 0) {
                av_push(results, newSVnv(errno));
                continue;
            }

            rh = (HV *)sv_2mortal((SV *)newHV());

            hv_store(rh, "f_bavail", 8, newSVnv(buf.f_bavail), 0);
            hv_store(rh, "f_bfree",  7, newSVnv(buf.f_bfree),  0);
            hv_store(rh, "f_blocks", 8, newSVnv(buf.f_blocks), 0);
            hv_store(rh, "f_bsize",  7, newSVnv(buf.f_bsize),  0);
            hv_store(rh, "f_ffree",  7, newSVnv(buf.f_ffree),  0);
            hv_store(rh, "f_files",  7, newSVnv(buf.f_files),  0);
            hv_store(rh, "f_type",   6, newSVnv(buf.f_type),   0);

            av_push(results, newRV((SV *)rh));
        }
        RETVAL = newRV((SV *)results);
    OUTPUT:
        RETVAL
```

And add the following code to test.pl, while incrementing the "1..11" string in the BEGIN block to "1..13":

```
$results = Mytest::multi_statfs([ '/', '/blech' ]);
print ((ref $results->[0]) ? "ok 12\n" : "not ok 12\n");
print ((! ref $results->[1]) ? "ok 13\n" : "not ok 13\n");
```

67.3.23 New Things in this Example

There are a number of new concepts introduced here, described below:

- This function does not use a typemap. Instead, we declare it as accepting one SV* (scalar) parameter, and returning an SV* value, and we take care of populating these scalars within the code. Because we are only returning one value, we don't need a `PPCODE:` directive - instead, we use `CODE:` and `OUTPUT:` directives.
- When dealing with references, it is important to handle them with caution. The `INIT:` block first checks that `SvROK` returns true, which indicates that paths is a valid reference. It then verifies that the object referenced by paths is an array, using `SvRV` to dereference paths, and `SvTYPE` to discover its type. As an added test, it checks that the array referenced by paths is non-empty, using the `av_len` function (which returns -1 if the array is empty). The XSRETURN_UNDEF macro is used to abort the XSUB and return the undefined value whenever all three of these conditions are not met.
- We manipulate several arrays in this XSUB. Note that an array is represented internally by an AV* pointer. The functions and macros for manipulating arrays are similar to the functions in Perl: `av_len` returns the highest index in an AV*, much like $#array; `av_fetch` fetches a single scalar value from an array, given its index; `av_push` pushes a scalar value onto the end of the array, automatically extending the array as necessary.

  Specifically, we read pathnames one at a time from the input array, and store the results in an output array (results) in the same order. If statfs fails, the element pushed onto the return array is the value of errno after the failure. If statfs succeeds, though, the value pushed onto the return array is a reference to a hash containing some of the information in the statfs structure.

  As with the return stack, it would be possible (and a small performance win) to pre-extend the return array before pushing data into it, since we know how many elements we will return:

  ```
          av_extend(results, numpaths);
  ```
- We are performing only one hash operation in this function, which is storing a new scalar under a key using `hv_store`. A hash is represented by an HV* pointer. Like arrays, the functions for manipulating hashes from an XSUB mirror the functionality available from Perl. See *perlguts* and *perlapi* for details.
- To create a reference, we use the `newRV` function. Note that you can cast an AV* or an HV* to type SV* in this case (and many others). This allows you to take references to arrays, hashes and scalars with the same function. Conversely, the `SvRV` function always returns an SV*, which may need to be cast to the appropriate type if it is something other than a scalar (check with `SvTYPE`).
- At this point, xsubpp is doing very little work - the differences between Mytest.xs and Mytest.c are minimal.

67.3.24 EXAMPLE 7 (Coming Soon)

XPUSH args AND set RETVAL AND assign return value to array

67.3.25 EXAMPLE 8 (Coming Soon)

Setting $!

67.3.26 EXAMPLE 9 Passing open files to XSes

You would think passing files to an XS is difficult, with all the typeglobs and stuff. Well, it isn't.

Suppose that for some strange reason we need a wrapper around the standard C library function `fputs()`. This is all we need:

```
        #define PERLIO_NOT_STDIO 0
        #include "EXTERN.h"
        #include "perl.h"
        #include "XSUB.h"

        #include <stdio.h>
```

```
        int
        fputs(s, stream)
                char *          s
                FILE *          stream
```

The real work is done in the standard typemap.

But you loose all the fine stuff done by the perlio layers. This calls the stdio function `fputs()`, which knows nothing about them.

The standard typemap offers three variants of PerlIO *: `InputStream` (T_IN), `InOutStream` (T_INOUT) and `OutputStream` (T_OUT). A bare `PerlIO *` is considered a T_INOUT. If it matters in your code (see below for why it might) #define or typedef one of the specific names and use that as the argument or result type in your XS file.

The standard typemap does not contain PerlIO * before perl 5.7, but it has the three stream variants. Using a PerlIO * directly is not backwards compatible unless you provide your own typemap.

For streams coming *from* perl the main difference is that `OutputStream` will get the output PerlIO * - which may make a difference on a socket. Like in our example...

For streams being handed *to* perl a new file handle is created (i.e. a reference to a new glob) and associated with the PerlIO * provided. If the read/write state of the PerlIO * is not correct then you may get errors or warnings from when the file handle is used. So if you opened the PerlIO * as "w" it should really be an `OutputStream` if open as "r" it should be an `InputStream`.

Now, suppose you want to use perlio layers in your XS. We'll use the perlio `PerlIO_puts()` function as an example.

In the C part of the XS file (above the first MODULE line) you have

```
        #define OutputStream    PerlIO *
    or
        typedef PerlIO *        OutputStream;
```

And this is the XS code:

```
        int
        perlioputs(s, stream)
                char *          s
                OutputStream    stream
        CODE:
                RETVAL = PerlIO_puts(stream, s);
        OUTPUT:
                RETVAL
```

We have to use a `CODE` section because `PerlIO_puts()` has the arguments reversed compared to `fputs()`, and we want to keep the arguments the same.

Wanting to explore this thoroughly, we want to use the stdio `fputs()` on a PerlIO *. This means we have to ask the perlio system for a stdio `FILE *`:

```
        int
        perliofputs(s, stream)
                char *          s
                OutputStream    stream
        PREINIT:
                FILE *fp = PerlIO_findFILE(stream);
        CODE:
                if (fp != (FILE*) 0) {
                        RETVAL = fputs(s, fp);
                } else {
                        RETVAL = -1;
                }
        OUTPUT:
                RETVAL
```

Note: `PerlIO_findFILE()` will search the layers for a stdio layer. If it can't find one, it will call `PerlIO_exportFILE()` to generate a new stdio `FILE`. Please only call `PerlIO_exportFILE()` if you want a *new* `FILE`. It will generate one on each call and push a new stdio layer. So don't call it repeatedly on the same file. `PerlIO()`_findFILE will retrieve the stdio layer once it has been generated by `PerlIO_exportFILE()`.

This applies to the perlio system only. For versions before 5.7, `PerlIO_exportFILE()` is equivalent to `PerlIO_findFILE()`.

67.3.27 Troubleshooting these Examples

As mentioned at the top of this document, if you are having problems with these example extensions, you might see if any of these help you.

- In versions of 5.002 prior to the gamma version, the test script in Example 1 will not function properly. You need to change the "use lib" line to read:

```
        use lib './blib';
```

- In versions of 5.002 prior to version 5.002b1h, the test.pl file was not automatically created by h2xs. This means that you cannot say "make test" to run the test script. You will need to add the following line before the "use extension" statement:

```
        use lib './blib';
```

- In versions 5.000 and 5.001, instead of using the above line, you will need to use the following line:

```
        BEGIN { unshift(@INC, "./blib") }
```

- This document assumes that the executable named "perl" is Perl version 5. Some systems may have installed Perl version 5 as "perl5".

Chapter 68

perlxs

XS language reference manual

68.1 DESCRIPTION

68.1.1 Introduction

XS is an interface description file format used to create an extension interface between Perl and C code (or a C library) which one wishes to use with Perl. The XS interface is combined with the library to create a new library which can then be either dynamically loaded or statically linked into perl. The XS interface description is written in the XS language and is the core component of the Perl extension interface.

An **XSUB** forms the basic unit of the XS interface. After compilation by the **xsubpp** compiler, each XSUB amounts to a C function definition which will provide the glue between Perl calling conventions and C calling conventions.

The glue code pulls the arguments from the Perl stack, converts these Perl values to the formats expected by a C function, call this C function, transfers the return values of the C function back to Perl. Return values here may be a conventional C return value or any C function arguments that may serve as output parameters. These return values may be passed back to Perl either by putting them on the Perl stack, or by modifying the arguments supplied from the Perl side.

The above is a somewhat simplified view of what really happens. Since Perl allows more flexible calling conventions than C, XSUBs may do much more in practice, such as checking input parameters for validity, throwing exceptions (or returning undef/empty list) if the return value from the C function indicates failure, calling different C functions based on numbers and types of the arguments, providing an object-oriented interface, etc.

Of course, one could write such glue code directly in C. However, this would be a tedious task, especially if one needs to write glue for multiple C functions, and/or one is not familiar enough with the Perl stack discipline and other such arcana. XS comes to the rescue here: instead of writing this glue C code in long-hand, one can write a more concise short-hand *description* of what should be done by the glue, and let the XS compiler **xsubpp** handle the rest.

The XS language allows one to describe the mapping between how the C routine is used, and how the corresponding Perl routine is used. It also allows creation of Perl routines which are directly translated to C code and which are not related to a pre-existing C function. In cases when the C interface coincides with the Perl interface, the XSUB declaration is almost identical to a declaration of a C function (in K&R style). In such circumstances, there is another tool called `h2xs` that is able to translate an entire C header file into a corresponding XS file that will provide glue to the functions/macros described in the header file.

The XS compiler is called **xsubpp**. This compiler creates the constructs necessary to let an XSUB manipulate Perl values, and creates the glue necessary to let Perl call the XSUB. The compiler uses **typemaps** to determine how to map C function parameters and output values to Perl values and back. The default typemap (which comes with Perl) handles many common C types. A supplementary typemap may also be needed to handle any special structures and types for the library being linked.

A file in XS format starts with a C language section which goes until the first `MODULE =` directive. Other XS directives and XSUB definitions may follow this line. The "language" used in this part of the file is usually referred to as the XS language. **xsubpp** recognizes and skips POD (see *perlpod*) in both the C and XS language sections, which allows the XS file to contain embedded documentation.

See *perlxstut* for a tutorial on the whole extension creation process.

Note: For some extensions, Dave Beazley's SWIG system may provide a significantly more convenient mechanism for creating the extension glue code. See http://www.swig.org/ for more information.

68.1.2 On The Road

Many of the examples which follow will concentrate on creating an interface between Perl and the ONC+ RPC bind library functions. The rpcb_gettime() function is used to demonstrate many features of the XS language. This function has two parameters; the first is an input parameter and the second is an output parameter. The function also returns a status value.

```
        bool_t rpcb_gettime(const char *host, time_t *timep);
```

From C this function will be called with the following statements.

```
     #include <rpc/rpc.h>
     bool_t status;
     time_t timep;
     status = rpcb_gettime( "localhost", &timep );
```

If an XSUB is created to offer a direct translation between this function and Perl, then this XSUB will be used from Perl with the following code. The $status and $timep variables will contain the output of the function.

```
     use RPC;
     $status = rpcb_gettime( "localhost", $timep );
```

The following XS file shows an XS subroutine, or XSUB, which demonstrates one possible interface to the rpcb_gettime() function. This XSUB represents a direct translation between C and Perl and so preserves the interface even from Perl. This XSUB will be invoked from Perl with the usage shown above. Note that the first three #include statements, for `EXTERN.h`, `perl.h`, and `XSUB.h`, will always be present at the beginning of an XS file. This approach and others will be expanded later in this document.

```
     #include "EXTERN.h"
     #include "perl.h"
     #include "XSUB.h"
     #include <rpc/rpc.h>

     MODULE = RPC  PACKAGE = RPC

     bool_t
     rpcb_gettime(host,timep)
          char *host
          time_t &timep
        OUTPUT:
          timep
```

Any extension to Perl, including those containing XSUBs, should have a Perl module to serve as the bootstrap which pulls the extension into Perl. This module will export the extension's functions and variables to the Perl program and will cause the extension's XSUBs to be linked into Perl. The following module will be used for most of the examples in this document and should be used from Perl with the `use` command as shown earlier. Perl modules are explained in more detail later in this document.

```
package RPC;

require Exporter;
require DynaLoader;
@ISA = qw(Exporter DynaLoader);
@EXPORT = qw( rpcb_gettime );

bootstrap RPC;
1;
```

Throughout this document a variety of interfaces to the rpcb_gettime() XSUB will be explored. The XSUBs will take their parameters in different orders or will take different numbers of parameters. In each case the XSUB is an abstraction between Perl and the real C rpcb_gettime() function, and the XSUB must always ensure that the real rpcb_gettime() function is called with the correct parameters. This abstraction will allow the programmer to create a more Perl-like interface to the C function.

68.1.3 The Anatomy of an XSUB

The simplest XSUBs consist of 3 parts: a description of the return value, the name of the XSUB routine and the names of its arguments, and a description of types or formats of the arguments.

The following XSUB allows a Perl program to access a C library function called sin(). The XSUB will imitate the C function which takes a single argument and returns a single value.

```
double
sin(x)
  double x
```

Optionally, one can merge the description of types and the list of argument names, rewriting this as

```
double
sin(double x)
```

This makes this XSUB look similar to an ANSI C declaration. An optional semicolon is allowed after the argument list, as in

```
double
sin(double x);
```

Parameters with C pointer types can have different semantic: C functions with similar declarations

```
bool string_looks_as_a_number(char *s);
bool make_char_uppercase(char *c);
```

are used in absolutely incompatible manner. Parameters to these functions could be described **xsubpp** like this:

```
char *  s
char    &c
```

Both these XS declarations correspond to the `char*` C type, but they have different semantics, see §68.1.40.

It is convenient to think that the indirection operator * should be considered as a part of the type and the address operator & should be considered part of the variable. See §68.1.45 for more info about handling qualifiers and unary operators in C types.

The function name and the return type must be placed on separate lines and should be flush left-adjusted.

```
  INCORRECT                         CORRECT

  double sin(x)                     double
    double x                        sin(x)
                                      double x
```

The rest of the function description may be indented or left-adjusted. The following example shows a function with its body left-adjusted. Most examples in this document will indent the body for better readability.

```
  CORRECT

  double
  sin(x)
  double x
```

More complicated XSUBs may contain many other sections. Each section of an XSUB starts with the corresponding keyword, such as INIT: or CLEANUP:. However, the first two lines of an XSUB always contain the same data: descriptions of the return type and the names of the function and its parameters. Whatever immediately follows these is considered to be an INPUT: section unless explicitly marked with another keyword. (See The INPUT: Keyword.)

An XSUB section continues until another section-start keyword is found.

68.1.4 The Argument Stack

The Perl argument stack is used to store the values which are sent as parameters to the XSUB and to store the XSUB's return value(s). In reality all Perl functions (including non-XSUB ones) keep their values on this stack all the same time, each limited to its own range of positions on the stack. In this document the first position on that stack which belongs to the active function will be referred to as position 0 for that function.

XSUBs refer to their stack arguments with the macro **ST(x)**, where *x* refers to a position in this XSUB's part of the stack. Position 0 for that function would be known to the XSUB as ST(0). The XSUB's incoming parameters and outgoing return values always begin at ST(0). For many simple cases the **xsubpp** compiler will generate the code necessary to handle the argument stack by embedding code fragments found in the typemaps. In more complex cases the programmer must supply the code.

68.1.5 The RETVAL Variable

The RETVAL variable is a special C variable that is declared automatically for you. The C type of RETVAL matches the return type of the C library function. The **xsubpp** compiler will declare this variable in each XSUB with non-`void` return type. By default the generated C function will use RETVAL to hold the return value of the C library function being called. In simple cases the value of RETVAL will be placed in ST(0) of the argument stack where it can be received by Perl as the return value of the XSUB.

If the XSUB has a return type of `void` then the compiler will not declare a RETVAL variable for that function. When using a PPCODE: section no manipulation of the RETVAL variable is required, the section may use direct stack manipulation to place output values on the stack.

If PPCODE: directive is not used, `void` return value should be used only for subroutines which do not return a value, *even if* CODE: directive is used which sets ST(0) explicitly.

Older versions of this document recommended to use `void` return value in such cases. It was discovered that this could lead to segfaults in cases when XSUB was *truly* `void`. This practice is now deprecated, and may be not supported at some future version. Use the return value `SV *` in such cases. (Currently `xsubpp` contains some heuristic code which tries to disambiguate between "truly-void" and "old-practice-declared-as-void" functions. Hence your code is at mercy of this heuristics unless you use `SV *` as return value.)

68.1.6 Returning SVs, AVs and HVs through RETVAL

When you're using RETVAL to return an `SV *`, there's some magic going on behind the scenes that should be mentioned. When you're manipulating the argument stack using the ST(x) macro, for example, you usually have to pay special attention to reference counts. (For more about reference counts, see *perlguts*.) To make your life easier, the typemap file automatically makes `RETVAL` mortal when you're returning an `SV *`. Thus, the following two XSUBs are more or less equivalent:

```
void
alpha()
    PPCODE:
        ST(0) = newSVpv("Hello World",0);
        sv_2mortal(ST(0));
        XSRETURN(1);

SV *
beta()
    CODE:
        RETVAL = newSVpv("Hello World",0);
    OUTPUT:
        RETVAL
```

This is quite useful as it usually improves readability. While this works fine for an `SV *`, it's unfortunately not as easy to have `AV *` or `HV *` as a return value. You *should* be able to write:

```
AV *
array()
    CODE:
        RETVAL = newAV();
        /* do something with RETVAL */
    OUTPUT:
        RETVAL
```

But due to an unfixable bug (fixing it would break lots of existing CPAN modules) in the typemap file, the reference count of the `AV *` is not properly decremented. Thus, the above XSUB would leak memory whenever it is being called. The same problem exists for `HV *`.

When you're returning an `AV *` or a `HV *`, you have make sure their reference count is decremented by making the AV or HV mortal:

```
AV *
array()
    CODE:
        RETVAL = newAV();
        sv_2mortal((SV*)RETVAL);
        /* do something with RETVAL */
    OUTPUT:
        RETVAL
```

And also remember that you don't have to do this for an `SV *`.

68.1.7 The MODULE Keyword

The MODULE keyword is used to start the XS code and to specify the package of the functions which are being defined. All text preceding the first MODULE keyword is considered C code and is passed through to the output with POD stripped, but otherwise untouched. Every XS module will have a bootstrap function which is used to hook the XSUBs into Perl. The package name of this bootstrap function will match the value of the last MODULE statement in the XS source files. The value of MODULE should always remain constant within the same XS file, though this is not required.

The following example will start the XS code and will place all functions in a package named RPC.

```
MODULE = RPC
```

68.1.8 The PACKAGE Keyword

When functions within an XS source file must be separated into packages the PACKAGE keyword should be used. This keyword is used with the MODULE keyword and must follow immediately after it when used.

```
MODULE = RPC  PACKAGE = RPC

[ XS code in package RPC ]

MODULE = RPC  PACKAGE = RPCB

[ XS code in package RPCB ]

MODULE = RPC  PACKAGE = RPC

[ XS code in package RPC ]
```

The same package name can be used more than once, allowing for non-contiguous code. This is useful if you have a stronger ordering principle than package names.

Although this keyword is optional and in some cases provides redundant information it should always be used. This keyword will ensure that the XSUBs appear in the desired package.

68.1.9 The PREFIX Keyword

The PREFIX keyword designates prefixes which should be removed from the Perl function names. If the C function is `rpcb_gettime()` and the PREFIX value is `rpcb_` then Perl will see this function as `gettime()`.

This keyword should follow the PACKAGE keyword when used. If PACKAGE is not used then PREFIX should follow the MODULE keyword.

```
MODULE = RPC  PREFIX = rpc_

MODULE = RPC  PACKAGE = RPCB  PREFIX = rpcb_
```

68.1.10 The OUTPUT: Keyword

The OUTPUT: keyword indicates that certain function parameters should be updated (new values made visible to Perl) when the XSUB terminates or that certain values should be returned to the calling Perl function. For simple functions which have no CODE: or PPCODE: section, such as the sin() function above, the RETVAL variable is automatically designated as an output value. For more complex functions the **xsubpp** compiler will need help to determine which variables are output variables.

This keyword will normally be used to complement the CODE: keyword. The RETVAL variable is not recognized as an output variable when the CODE: keyword is present. The OUTPUT: keyword is used in this situation to tell the compiler that RETVAL really is an output variable.

The OUTPUT: keyword can also be used to indicate that function parameters are output variables. This may be necessary when a parameter has been modified within the function and the programmer would like the update to be seen by Perl.

```
bool_t
rpcb_gettime(host,timep)
     char *host
     time_t &timep
   OUTPUT:
     timep
```

The OUTPUT: keyword will also allow an output parameter to be mapped to a matching piece of code rather than to a typemap.

```
     bool_t
     rpcb_gettime(host,timep)
          char *host
          time_t &timep
        OUTPUT:
          timep sv_setnv(ST(1), (double)timep);
```

xsubpp emits an automatic `SvSETMAGIC()` for all parameters in the OUTPUT section of the XSUB, except RETVAL. This is the usually desired behavior, as it takes care of properly invoking 'set' magic on output parameters (needed for hash or array element parameters that must be created if they didn't exist). If for some reason, this behavior is not desired, the OUTPUT section may contain a `SETMAGIC: DISABLE` line to disable it for the remainder of the parameters in the OUTPUT section. Likewise, `SETMAGIC: ENABLE` can be used to reenable it for the remainder of the OUTPUT section. See *perlguts* for more details about 'set' magic.

68.1.11 The NO_OUTPUT Keyword

The NO_OUTPUT can be placed as the first token of the XSUB. This keyword indicates that while the C subroutine we provide an interface to has a non-`void` return type, the return value of this C subroutine should not be returned from the generated Perl subroutine.

With this keyword present The RETVAL Variable is created, and in the generated call to the subroutine this variable is assigned to, but the value of this variable is not going to be used in the auto-generated code.

This keyword makes sense only if `RETVAL` is going to be accessed by the user-supplied code. It is especially useful to make a function interface more Perl-like, especially when the C return value is just an error condition indicator. For example,

```
  NO_OUTPUT int
  delete_file(char *name)
    POSTCALL:
      if (RETVAL != 0)
          croak("Error %d while deleting file '%s'", RETVAL, name);
```

Here the generated XS function returns nothing on success, and will die() with a meaningful error message on error.

68.1.12 The CODE: Keyword

This keyword is used in more complicated XSUBs which require special handling for the C function. The RETVAL variable is still declared, but it will not be returned unless it is specified in the OUTPUT: section.

The following XSUB is for a C function which requires special handling of its parameters. The Perl usage is given first.

```
     $status = rpcb_gettime( "localhost", $timep );
```

The XSUB follows.

```
     bool_t
     rpcb_gettime(host,timep)
          char *host
          time_t timep
        CODE:
               RETVAL = rpcb_gettime( host, &timep );
        OUTPUT:
          timep
          RETVAL
```

68.1.13 The INIT: Keyword

The INIT: keyword allows initialization to be inserted into the XSUB before the compiler generates the call to the C function. Unlike the CODE: keyword above, this keyword does not affect the way the compiler handles RETVAL.

```
    bool_t
    rpcb_gettime(host,timep)
          char *host
          time_t &timep
        INIT:
          printf("# Host is %s\n", host );
        OUTPUT:
          timep
```

Another use for the INIT: section is to check for preconditions before making a call to the C function:

```
    long long
    lldiv(a,b)
        long long a
        long long b
      INIT:
        if (a == 0 && b == 0)
            XSRETURN_UNDEF;
        if (b == 0)
            croak("lldiv: cannot divide by 0");
```

68.1.14 The NO_INIT Keyword

The NO_INIT keyword is used to indicate that a function parameter is being used only as an output value. The **xsubpp** compiler will normally generate code to read the values of all function parameters from the argument stack and assign them to C variables upon entry to the function. NO_INIT will tell the compiler that some parameters will be used for output rather than for input and that they will be handled before the function terminates.

The following example shows a variation of the rpcb_gettime() function. This function uses the timep variable only as an output variable and does not care about its initial contents.

```
     bool_t
     rpcb_gettime(host,timep)
          char *host
          time_t &timep = NO_INIT
        OUTPUT:
          timep
```

68.1.15 Initializing Function Parameters

C function parameters are normally initialized with their values from the argument stack (which in turn contains the parameters that were passed to the XSUB from Perl). The typemaps contain the code segments which are used to translate the Perl values to the C parameters. The programmer, however, is allowed to override the typemaps and supply alternate (or additional) initialization code. Initialization code starts with the first =, ; or + on a line in the INPUT: section. The only exception happens if this ; terminates the line, then this ; is quietly ignored.

The following code demonstrates how to supply initialization code for function parameters. The initialization code is eval'd within double quotes by the compiler before it is added to the output so anything which should be interpreted literally [mainly $, @, or \\] must be protected with backslashes. The variables $var, $arg, and $type can be used as in typemaps.

```
bool_t
rpcb_gettime(host,timep)
     char *host = (char *)SvPV($arg,PL_na);
     time_t &timep = 0;
   OUTPUT:
     timep
```

This should not be used to supply default values for parameters. One would normally use this when a function parameter must be processed by another library function before it can be used. Default parameters are covered in the next section.

If the initialization begins with =, then it is output in the declaration for the input variable, replacing the initialization supplied by the typemap. If the initialization begins with `;` or +, then it is performed after all of the input variables have been declared. In the `;` case the initialization normally supplied by the typemap is not performed. For the + case, the declaration for the variable will include the initialization from the typemap. A global variable, `%v`, is available for the truly rare case where information from one initialization is needed in another initialization.

Here's a truly obscure example:

```
bool_t
rpcb_gettime(host,timep)
     time_t &timep ; /* \$v{timep}=@{[$v{timep}=$arg]} */
     char *host + SvOK($v{timep}) ? SvPV($arg,PL_na) : NULL;
   OUTPUT:
     timep
```

The construct `\$v{timep}=@{[$v{timep}=$arg]}` used in the above example has a two-fold purpose: first, when this line is processed by **xsubpp**, the Perl snippet `$v{timep}=$arg` is evaluated. Second, the text of the evaluated snippet is output into the generated C file (inside a C comment)! During the processing of `char *host` line, $arg will evaluate to `ST(0)`, and `$v{timep}` will evaluate to `ST(1)`.

68.1.16 Default Parameter Values

Default values for XSUB arguments can be specified by placing an assignment statement in the parameter list. The default value may be a number, a string or the special string `NO_INIT`. Defaults should always be used on the right-most parameters only.

To allow the XSUB for rpcb_gettime() to have a default host value the parameters to the XSUB could be rearranged. The XSUB will then call the real rpcb_gettime() function with the parameters in the correct order. This XSUB can be called from Perl with either of the following statements:

```
$status = rpcb_gettime( $timep, $host );

$status = rpcb_gettime( $timep );
```

The XSUB will look like the code which follows. A CODE: block is used to call the real rpcb_gettime() function with the parameters in the correct order for that function.

```
bool_t
rpcb_gettime(timep,host="localhost")
     char *host
     time_t timep = NO_INIT
   CODE:
          RETVAL = rpcb_gettime( host, &timep );
   OUTPUT:
     timep
     RETVAL
```

68.1.17 The PREINIT: Keyword

The PREINIT: keyword allows extra variables to be declared immediately before or after the declarations of the parameters from the INPUT: section are emitted.

If a variable is declared inside a CODE: section it will follow any typemap code that is emitted for the input parameters. This may result in the declaration ending up after C code, which is C syntax error. Similar errors may happen with an explicit `;`-type or `+`-type initialization of parameters is used (see §68.1.15). Declaring these variables in an INIT: section will not help.

In such cases, to force an additional variable to be declared together with declarations of other variables, place the declaration into a PREINIT: section. The PREINIT: keyword may be used one or more times within an XSUB.

The following examples are equivalent, but if the code is using complex typemaps then the first example is safer.

```
bool_t
rpcb_gettime(timep)
     time_t timep = NO_INIT
   PREINIT:
     char *host = "localhost";
   CODE:
     RETVAL = rpcb_gettime( host, &timep );
   OUTPUT:
     timep
     RETVAL
```

For this particular case an INIT: keyword would generate the same C code as the PREINIT: keyword. Another correct, but error-prone example:

```
bool_t
rpcb_gettime(timep)
     time_t timep = NO_INIT
   CODE:
     char *host = "localhost";
     RETVAL = rpcb_gettime( host, &timep );
   OUTPUT:
     timep
     RETVAL
```

Another way to declare `host` is to use a C block in the CODE: section:

```
bool_t
rpcb_gettime(timep)
     time_t timep = NO_INIT
   CODE:
     {
       char *host = "localhost";
       RETVAL = rpcb_gettime( host, &timep );
     }
   OUTPUT:
     timep
     RETVAL
```

The ability to put additional declarations before the typemap entries are processed is very handy in the cases when typemap conversions manipulate some global state:

```
MyObject
mutate(o)
    PREINIT:
        MyState st = global_state;
    INPUT:
        MyObject o;
    CLEANUP:
        reset_to(global_state, st);
```

Here we suppose that conversion to `MyObject` in the INPUT: section and from MyObject when processing RETVAL will modify a global variable `global_state`. After these conversions are performed, we restore the old value of `global_state` (to avoid memory leaks, for example).

There is another way to trade clarity for compactness: INPUT sections allow declaration of C variables which do not appear in the parameter list of a subroutine. Thus the above code for mutate() can be rewritten as

```
MyObject
mutate(o)
      MyState st = global_state;
      MyObject o;
    CLEANUP:
      reset_to(global_state, st);
```

and the code for rpcb_gettime() can be rewritten as

```
 bool_t
 rpcb_gettime(timep)
      time_t timep = NO_INIT
      char *host = "localhost";
    C_ARGS:
      host, &timep
    OUTPUT:
      timep
      RETVAL
```

68.1.18 The SCOPE: Keyword

The SCOPE: keyword allows scoping to be enabled for a particular XSUB. If enabled, the XSUB will invoke ENTER and LEAVE automatically.

To support potentially complex type mappings, if a typemap entry used by an XSUB contains a comment like `/*scope*/` then scoping will be automatically enabled for that XSUB.

To enable scoping:

```
SCOPE: ENABLE
```

To disable scoping:

```
SCOPE: DISABLE
```

68.1.19 The INPUT: Keyword

The XSUB's parameters are usually evaluated immediately after entering the XSUB. The INPUT: keyword can be used to force those parameters to be evaluated a little later. The INPUT: keyword can be used multiple times within an XSUB and can be used to list one or more input variables. This keyword is used with the PREINIT: keyword.

The following example shows how the input parameter `timep` can be evaluated late, after a PREINIT.

```
bool_t
rpcb_gettime(host,timep)
      char *host
    PREINIT:
      time_t tt;
    INPUT:
      time_t timep
    CODE:
           RETVAL = rpcb_gettime( host, &tt );
           timep = tt;
    OUTPUT:
      timep
      RETVAL
```

The next example shows each input parameter evaluated late.

```
bool_t
rpcb_gettime(host,timep)
    PREINIT:
      time_t tt;
    INPUT:
      char *host
    PREINIT:
      char *h;
    INPUT:
      time_t timep
    CODE:
           h = host;
           RETVAL = rpcb_gettime( h, &tt );
           timep = tt;
    OUTPUT:
      timep
      RETVAL
```

Since INPUT sections allow declaration of C variables which do not appear in the parameter list of a subroutine, this may be shortened to:

```
bool_t
rpcb_gettime(host,timep)
      time_t tt;
      char *host;
      char *h = host;
      time_t timep;
    CODE:
      RETVAL = rpcb_gettime( h, &tt );
      timep = tt;
    OUTPUT:
      timep
      RETVAL
```

(We used our knowledge that input conversion for `char *` is a "simple" one, thus `host` is initialized on the declaration line, and our assignment `h = host` is not performed too early. Otherwise one would need to have the assignment `h = host` in a CODE: or INIT: section.)

68.1.20 The IN/OUTLIST/IN_OUTLIST/OUT/IN_OUT Keywords

In the list of parameters for an XSUB, one can precede parameter names by the `IN`/`OUTLIST`/`IN_OUTLIST`/`OUT`/`IN_OUT` keywords. `IN` keyword is the default, the other keywords indicate how the Perl interface should differ from the C interface.

Parameters preceded by `OUTLIST`/`IN_OUTLIST`/`OUT`/`IN_OUT` keywords are considered to be used by the C subroutine *via pointers*. `OUTLIST`/`OUT` keywords indicate that the C subroutine does not inspect the memory pointed by this parameter, but will write through this pointer to provide additional return values.

Parameters preceded by `OUTLIST` keyword do not appear in the usage signature of the generated Perl function.

Parameters preceded by `IN_OUTLIST`/`IN_OUT`/`OUT` *do* appear as parameters to the Perl function. With the exception of `OUT`-parameters, these parameters are converted to the corresponding C type, then pointers to these data are given as arguments to the C function. It is expected that the C function will write through these pointers.

The return list of the generated Perl function consists of the C return value from the function (unless the XSUB is of `void` return type or `The NO_OUTPUT Keyword` was used) followed by all the `OUTLIST` and `IN_OUTLIST` parameters (in the order of appearance). On the return from the XSUB the `IN_OUT`/`OUT` Perl parameter will be modified to have the values written by the C function.

For example, an XSUB

```
void
day_month(OUTLIST day, IN unix_time, OUTLIST month)
  int day
  int unix_time
  int month
```

should be used from Perl as

```
my ($day, $month) = day_month(time);
```

The C signature of the corresponding function should be

```
void day_month(int *day, int unix_time, int *month);
```

The `IN`/`OUTLIST`/`IN_OUTLIST`/`IN_OUT`/`OUT` keywords can be mixed with ANSI-style declarations, as in

```
void
day_month(OUTLIST int day, int unix_time, OUTLIST int month)
```

(here the optional `IN` keyword is omitted).

The `IN_OUT` parameters are identical with parameters introduced with The & Unary Operator and put into the `OUTPUT:` section (see The OUTPUT: Keyword). The `IN_OUTLIST` parameters are very similar, the only difference being that the value C function writes through the pointer would not modify the Perl parameter, but is put in the output list.

The `OUTLIST`/`OUT` parameter differ from `IN_OUTLIST`/`IN_OUT` parameters only by the initial value of the Perl parameter not being read (and not being given to the C function - which gets some garbage instead). For example, the same C function as above can be interfaced with as

```
void day_month(OUT int day, int unix_time, OUT int month);
```

or

```
void
day_month(day, unix_time, month)
    int &day = NO_INIT
    int  unix_time
    int &month = NO_INIT
  OUTPUT:
    day
    month
```

However, the generated Perl function is called in very C-ish style:

```
my ($day, $month);
day_month($day, time, $month);
```

68.1.21 The `length(NAME)` Keyword

If one of the input arguments to the C function is the length of a string argument `NAME`, one can substitute the name of the length-argument by `length(NAME)` in the XSUB declaration. This argument must be omited when the generated Perl function is called. E.g.,

```
void
dump_chars(char *s, short l)
{
  short n = 0;
  while (n < l) {
      printf("s[%d] = \"\\%#03o\"\n", n, (int)s[n]);
      n++;
  }
}

MODULE = x            PACKAGE = x

void dump_chars(char *s, short length(s))
```

should be called as `dump_chars($string)`.

This directive is supported with ANSI-type function declarations only.

68.1.22 Variable-length Parameter Lists

XSUBs can have variable-length parameter lists by specifying an ellipsis `(...)` in the parameter list. This use of the ellipsis is similar to that found in ANSI C. The programmer is able to determine the number of arguments passed to the XSUB by examining the `items` variable which the **xsubpp** compiler supplies for all XSUBs. By using this mechanism one can create an XSUB which accepts a list of parameters of unknown length.

The *host* parameter for the rpcb_gettime() XSUB can be optional so the ellipsis can be used to indicate that the XSUB will take a variable number of parameters. Perl should be able to call this XSUB with either of the following statements.

```
   $status = rpcb_gettime( $timep, $host );

   $status = rpcb_gettime( $timep );
```

The XS code, with ellipsis, follows.

```
bool_t
rpcb_gettime(timep, ...)
     time_t timep = NO_INIT
   PREINIT:
     char *host = "localhost";
     STRLEN n_a;
   CODE:
     if( items > 1 )
          host = (char *)SvPV(ST(1), n_a);
     RETVAL = rpcb_gettime( host, &timep );
   OUTPUT:
     timep
     RETVAL
```

68.1.23 The C_ARGS: Keyword

The C_ARGS: keyword allows creating of XSUBS which have different calling sequence from Perl than from C, without a need to write CODE: or PPCODE: section. The contents of the C_ARGS: paragraph is put as the argument to the called C function without any change.

For example, suppose that a C function is declared as

```
symbolic nth_derivative(int n, symbolic function, int flags);
```

and that the default flags are kept in a global C variable `default_flags`. Suppose that you want to create an interface which is called as

```
$second_deriv = $function->nth_derivative(2);
```

To do this, declare the XSUB as

```
symbolic
nth_derivative(function, n)
    symbolic        function
    int             n
  C_ARGS:
    n, function, default_flags
```

68.1.24 The PPCODE: Keyword

The PPCODE: keyword is an alternate form of the CODE: keyword and is used to tell the **xsubpp** compiler that the programmer is supplying the code to control the argument stack for the XSUBs return values. Occasionally one will want an XSUB to return a list of values rather than a single value. In these cases one must use PPCODE: and then explicitly push the list of values on the stack. The PPCODE: and CODE: keywords should not be used together within the same XSUB.

The actual difference between PPCODE: and CODE: sections is in the initialization of `SP` macro (which stands for the *current* Perl stack pointer), and in the handling of data on the stack when returning from an XSUB. In CODE: sections SP preserves the value which was on entry to the XSUB: SP is on the function pointer (which follows the last parameter). In PPCODE: sections SP is moved backward to the beginning of the parameter list, which allows `PUSH*()` macros to place output values in the place Perl expects them to be when the XSUB returns back to Perl.

The generated trailer for a CODE: section ensures that the number of return values Perl will see is either 0 or 1 (depending on the `void`ness of the return value of the C function, and heuristics mentioned in §68.1.5). The trailer generated for a PPCODE: section is based on the number of return values and on the number of times `SP` was updated by `[X]PUSH*()` macros.

Note that macros `ST(i)`, `XST_m*()` and `XSRETURN*()` work equally well in CODE: sections and PPCODE: sections.

The following XSUB will call the C rpcb_gettime() function and will return its two output values, timep and status, to Perl as a single list.

```
void
rpcb_gettime(host)
     char *host
   PREINIT:
     time_t  timep;
     bool_t  status;
   PPCODE:
     status = rpcb_gettime( host, &timep );
     EXTEND(SP, 2);
     PUSHs(sv_2mortal(newSViv(status)));
     PUSHs(sv_2mortal(newSViv(timep)));
```

Notice that the programmer must supply the C code necessary to have the real rpcb_gettime() function called and to have the return values properly placed on the argument stack.

The `void` return type for this function tells the **xsubpp** compiler that the RETVAL variable is not needed or used and that it should not be created. In most scenarios the void return type should be used with the PPCODE: directive.

The EXTEND() macro is used to make room on the argument stack for 2 return values. The PPCODE: directive causes the **xsubpp** compiler to create a stack pointer available as `SP`, and it is this pointer which is being used in the EXTEND() macro. The values are then pushed onto the stack with the PUSHs() macro.

Now the rpcb_gettime() function can be used from Perl with the following statement.

```
($status, $timep) = rpcb_gettime("localhost");
```

When handling output parameters with a PPCODE section, be sure to handle 'set' magic properly. See *perlguts* for details about 'set' magic.

68.1.25 Returning Undef And Empty Lists

Occasionally the programmer will want to return simply `undef` or an empty list if a function fails rather than a separate status value. The rpcb_gettime() function offers just this situation. If the function succeeds we would like to have it return the time and if it fails we would like to have undef returned. In the following Perl code the value of $timep will either be undef or it will be a valid time.

```
$timep = rpcb_gettime( "localhost" );
```

The following XSUB uses the `SV *` return type as a mnemonic only, and uses a CODE: block to indicate to the compiler that the programmer has supplied all the necessary code. The sv_newmortal() call will initialize the return value to undef, making that the default return value.

```
SV *
rpcb_gettime(host)
     char *  host
   PREINIT:
     time_t  timep;
     bool_t x;
   CODE:
     ST(0) = sv_newmortal();
     if( rpcb_gettime( host, &timep ) )
          sv_setnv( ST(0), (double)timep);
```

The next example demonstrates how one would place an explicit undef in the return value, should the need arise.

```
SV *
rpcb_gettime(host)
     char *  host
   PREINIT:
     time_t  timep;
     bool_t x;
   CODE:
     ST(0) = sv_newmortal();
     if( rpcb_gettime( host, &timep ) ){
          sv_setnv( ST(0), (double)timep);
     }
     else{
          ST(0) = &PL_sv_undef;
     }
```

To return an empty list one must use a PPCODE: block and then not push return values on the stack.

```
void
rpcb_gettime(host)
     char *host
   PREINIT:
     time_t  timep;
   PPCODE:
     if( rpcb_gettime( host, &timep ) )
          PUSHs(sv_2mortal(newSViv(timep)));
     else{
         /* Nothing pushed on stack, so an empty
          * list is implicitly returned. */
     }
```

Some people may be inclined to include an explicit `return` in the above XSUB, rather than letting control fall through to the end. In those situations `XSRETURN_EMPTY` should be used, instead. This will ensure that the XSUB stack is properly adjusted. Consult *perlapi* for other `XSRETURN` macros.

Since `XSRETURN_*` macros can be used with CODE blocks as well, one can rewrite this example as:

```
int
rpcb_gettime(host)
     char *host
   PREINIT:
     time_t  timep;
   CODE:
     RETVAL = rpcb_gettime( host, &timep );
     if (RETVAL == 0)
           XSRETURN_UNDEF;
   OUTPUT:
     RETVAL
```

In fact, one can put this check into a POSTCALL: section as well. Together with PREINIT: simplifications, this leads to:

```
int
rpcb_gettime(host)
     char *host
     time_t  timep;
   POSTCALL:
     if (RETVAL == 0)
           XSRETURN_UNDEF;
```

68.1.26 The REQUIRE: Keyword

The REQUIRE: keyword is used to indicate the minimum version of the **xsubpp** compiler needed to compile the XS module. An XS module which contains the following statement will compile with only **xsubpp** version 1.922 or greater:

```
        REQUIRE: 1.922
```

68.1.27 The CLEANUP: Keyword

This keyword can be used when an XSUB requires special cleanup procedures before it terminates. When the CLEANUP: keyword is used it must follow any CODE:, PPCODE:, or OUTPUT: blocks which are present in the XSUB. The code specified for the cleanup block will be added as the last statements in the XSUB.

68.1.28 The POSTCALL: Keyword

This keyword can be used when an XSUB requires special procedures executed after the C subroutine call is performed. When the POSTCALL: keyword is used it must precede OUTPUT: and CLEANUP: blocks which are present in the XSUB.

See examples in §68.1.11 and §68.1.25.

The POSTCALL: block does not make a lot of sense when the C subroutine call is supplied by user by providing either CODE: or PPCODE: section.

68.1.29 The BOOT: Keyword

The BOOT: keyword is used to add code to the extension's bootstrap function. The bootstrap function is generated by the **xsubpp** compiler and normally holds the statements necessary to register any XSUBs with Perl. With the BOOT: keyword the programmer can tell the compiler to add extra statements to the bootstrap function.

This keyword may be used any time after the first MODULE keyword and should appear on a line by itself. The first blank line after the keyword will terminate the code block.

```
     BOOT:
     # The following message will be printed when the
     # bootstrap function executes.
     printf("Hello from the bootstrap!\n");
```

68.1.30 The VERSIONCHECK: Keyword

The VERSIONCHECK: keyword corresponds to **xsubpp**'s `-versioncheck` and `-noversioncheck` options. This keyword overrides the command line options. Version checking is enabled by default. When version checking is enabled the XS module will attempt to verify that its version matches the version of the PM module.

To enable version checking:

```
    VERSIONCHECK: ENABLE
```

To disable version checking:

```
    VERSIONCHECK: DISABLE
```

68.1.31 The PROTOTYPES: Keyword

The PROTOTYPES: keyword corresponds to **xsubpp**'s `-prototypes` and `-noprototypes` options. This keyword overrides the command line options. Prototypes are enabled by default. When prototypes are enabled XSUBs will be given Perl prototypes. This keyword may be used multiple times in an XS module to enable and disable prototypes for different parts of the module.

To enable prototypes:

```
PROTOTYPES: ENABLE
```

To disable prototypes:

```
PROTOTYPES: DISABLE
```

68.1.32 The PROTOTYPE: Keyword

This keyword is similar to the PROTOTYPES: keyword above but can be used to force **xsubpp** to use a specific prototype for the XSUB. This keyword overrides all other prototype options and keywords but affects only the current XSUB. Consult Prototypes in *perlsub* for information about Perl prototypes.

```
bool_t
rpcb_gettime(timep, ...)
      time_t timep = NO_INIT
    PROTOTYPE: $;$
    PREINIT:
      char *host = "localhost";
      STRLEN n_a;
    CODE:
              if( items > 1 )
                   host = (char *)SvPV(ST(1), n_a);
              RETVAL = rpcb_gettime( host, &timep );
    OUTPUT:
      timep
      RETVAL
```

If the prototypes are enabled, you can disable it locally for a given XSUB as in the following example:

```
void
rpcb_gettime_noproto()
    PROTOTYPE: DISABLE
...
```

68.1.33 The ALIAS: Keyword

The ALIAS: keyword allows an XSUB to have two or more unique Perl names and to know which of those names was used when it was invoked. The Perl names may be fully-qualified with package names. Each alias is given an index. The compiler will setup a variable called `ix` which contain the index of the alias which was used. When the XSUB is called with its declared name `ix` will be 0.

The following example will create aliases `FOO::gettime()` and `BAR::getit()` for this function.

```
bool_t
rpcb_gettime(host,timep)
      char *host
      time_t &timep
```

```
        ALIAS:
            FOO::gettime = 1
            BAR::getit = 2
        INIT:
          printf("# ix = %d\n", ix );
        OUTPUT:
          timep
```

68.1.34 The OVERLOAD: Keyword

Instead of writing an overloaded interface using pure Perl, you can also use the OVERLOAD keyword to define additional Perl names for your functions (like the ALIAS: keyword above). However, the overloaded functions must be defined with three parameters (except for the nomethod() function which needs four parameters). If any function has the OVERLOAD: keyword, several additional lines will be defined in the c file generated by xsubpp in order to register with the overload magic.

Since blessed objects are actually stored as RV's, it is useful to use the typemap features to preprocess parameters and extract the actual SV stored within the blessed RV. See the sample for T_PTROBJ_SPECIAL below.

To use the OVERLOAD: keyword, create an XS function which takes three input parameters (or use the c style '...' definition) like this:

```
    SV *
    cmp (lobj, robj, swap)
    My_Module_obj    lobj
    My_Module_obj    robj
    IV               swap
    OVERLOAD: cmp <=>
    { /* function defined here */}
```

In this case, the function will overload both of the three way comparison operators. For all overload operations using non-alpha characters, you must type the parameter without quoting, seperating multiple overloads with whitespace. Note that "" (the stringify overload) should be entered as \"\" (i.e. escaped).

68.1.35 The FALLBACK: Keyword

In addition to the OVERLOAD keyword, if you need to control how Perl autogenerates missing overloaded operators, you can set the FALLBACK keyword in the module header section, like this:

```
    MODULE = RPC  PACKAGE = RPC

    FALLBACK: TRUE
    ...
```

where FALLBACK can take any of the three values TRUE, FALSE, or UNDEF. If you do not set any FALLBACK value when using OVERLOAD, it defaults to UNDEF. FALLBACK is not used except when one or more functions using OVERLOAD have been defined. Please see Fallback in *overload* for more details.

68.1.36 The INTERFACE: Keyword

This keyword declares the current XSUB as a keeper of the given calling signature. If some text follows this keyword, it is considered as a list of functions which have this signature, and should be attached to the current XSUB.

For example, if you have 4 C functions multiply(), divide(), add(), subtract() all having the signature:

```
    symbolic f(symbolic, symbolic);
```

you can make them all to use the same XSUB using this:

```
    symbolic
    interface_s_ss(arg1, arg2)
        symbolic        arg1
        symbolic        arg2
    INTERFACE:
        multiply divide
        add subtract
```

(This is the complete XSUB code for 4 Perl functions!) Four generated Perl function share names with corresponding C functions.

The advantage of this approach comparing to ALIAS: keyword is that there is no need to code a switch statement, each Perl function (which shares the same XSUB) knows which C function it should call. Additionally, one can attach an extra function remainder() at runtime by using

```
    CV *mycv = newXSproto("Symbolic::remainder",
                          XS_Symbolic_interface_s_ss, __FILE__, "$$");
    XSINTERFACE_FUNC_SET(mycv, remainder);
```

say, from another XSUB. (This example supposes that there was no INTERFACE_MACRO: section, otherwise one needs to use something else instead of `XSINTERFACE_FUNC_SET`, see the next section.)

68.1.37 The INTERFACE_MACRO: Keyword

This keyword allows one to define an INTERFACE using a different way to extract a function pointer from an XSUB. The text which follows this keyword should give the name of macros which would extract/set a function pointer. The extractor macro is given return type, `CV*`, and `XSANY.any_dptr` for this `CV*`. The setter macro is given cv, and the function pointer.

The default value is `XSINTERFACE_FUNC` and `XSINTERFACE_FUNC_SET`. An INTERFACE keyword with an empty list of functions can be omitted if INTERFACE_MACRO keyword is used.

Suppose that in the previous example functions pointers for multiply(), divide(), add(), subtract() are kept in a global C array `fp[]` with offsets being `multiply_off`, `divide_off`, `add_off`, `subtract_off`. Then one can use

```
    #define XSINTERFACE_FUNC_BYOFFSET(ret,cv,f) \
        ((XSINTERFACE_CVT(ret,))fp[CvXSUBANY(cv).any_i32])
    #define XSINTERFACE_FUNC_BYOFFSET_set(cv,f) \
        CvXSUBANY(cv).any_i32 = CAT2( f, _off )
```

in C section,

```
    symbolic
    interface_s_ss(arg1, arg2)
        symbolic        arg1
        symbolic        arg2
      INTERFACE_MACRO:
        XSINTERFACE_FUNC_BYOFFSET
        XSINTERFACE_FUNC_BYOFFSET_set
      INTERFACE:
        multiply divide
        add subtract
```

in XSUB section.

68.1.38 The INCLUDE: Keyword

This keyword can be used to pull other files into the XS module. The other files may have XS code. INCLUDE: can also be used to run a command to generate the XS code to be pulled into the module.
The file *Rpcb1.xsh* contains our `rpcb_gettime()` function:

```
bool_t
rpcb_gettime(host,timep)
      char *host
      time_t &timep
    OUTPUT:
      timep
```

The XS module can use INCLUDE: to pull that file into it.

```
INCLUDE: Rpcb1.xsh
```

If the parameters to the INCLUDE: keyword are followed by a pipe (|) then the compiler will interpret the parameters as a command.

```
INCLUDE: cat Rpcb1.xsh |
```

68.1.39 The CASE: Keyword

The CASE: keyword allows an XSUB to have multiple distinct parts with each part acting as a virtual XSUB. CASE: is greedy and if it is used then all other XS keywords must be contained within a CASE:. This means nothing may precede the first CASE: in the XSUB and anything following the last CASE: is included in that case.
A CASE: might switch via a parameter of the XSUB, via the `ix` ALIAS: variable (see §68.1.33), or maybe via the `items` variable (see §68.1.22). The last CASE: becomes the **default** case if it is not associated with a conditional. The following example shows CASE switched via `ix` with a function `rpcb_gettime()` having an alias `x_gettime()`. When the function is called as `rpcb_gettime()` its parameters are the usual `(char *host, time_t *timep)`, but when the function is called as `x_gettime()` its parameters are reversed, `(time_t *timep, char *host)`.

```
long
rpcb_gettime(a,b)
  CASE: ix == 1
    ALIAS:
      x_gettime = 1
    INPUT:
      # 'a' is timep, 'b' is host
      char *b
      time_t a = NO_INIT
    CODE:
           RETVAL = rpcb_gettime( b, &a );
    OUTPUT:
      a
      RETVAL
  CASE:
      # 'a' is host, 'b' is timep
      char *a
      time_t &b = NO_INIT
    OUTPUT:
      b
      RETVAL
```

That function can be called with either of the following statements. Note the different argument lists.

```
$status = rpcb_gettime( $host, $timep );

$status = x_gettime( $timep, $host );
```

68.1.40 The & Unary Operator

The & unary operator in the INPUT: section is used to tell **xsubpp** that it should convert a Perl value to/from C using the C type to the left of &, but provide a pointer to this value when the C function is called.

This is useful to avoid a CODE: block for a C function which takes a parameter by reference. Typically, the parameter should be not a pointer type (an `int` or `long` but not an `int*` or `long*`).

The following XSUB will generate incorrect C code. The **xsubpp** compiler will turn this into code which calls `rpcb_gettime()` with parameters `(char *host, time_t timep)`, but the real `rpcb_gettime()` wants the `timep` parameter to be of type `time_t*` rather than `time_t`.

```
bool_t
rpcb_gettime(host,timep)
      char *host
      time_t timep
    OUTPUT:
      timep
```

That problem is corrected by using the & operator. The **xsubpp** compiler will now turn this into code which calls `rpcb_gettime()` correctly with parameters `(char *host, time_t *timep)`. It does this by carrying the & through, so the function call looks like `rpcb_gettime(host, &timep)`.

```
bool_t
rpcb_gettime(host,timep)
      char *host
      time_t &timep
    OUTPUT:
      timep
```

68.1.41 Inserting POD, Comments and C Preprocessor Directives

C preprocessor directives are allowed within BOOT:, PREINIT: INIT:, CODE:, PPCODE:, POSTCALL:, and CLEANUP: blocks, as well as outside the functions. Comments are allowed anywhere after the MODULE keyword. The compiler will pass the preprocessor directives through untouched and will remove the commented lines. POD documentation is allowed at any point, both in the C and XS language sections. POD must be terminated with a `=cut` command; `xsubpp` will exit with an error if it does not. It is very unlikely that human generated C code will be mistaken for POD, as most indenting styles result in whitespace in front of any line starting with =. Machine generated XS files may fall into this trap unless care is taken to ensure that a space breaks the sequence "\n=".

Comments can be added to XSUBs by placing a # as the first non-whitespace of a line. Care should be taken to avoid making the comment look like a C preprocessor directive, lest it be interpreted as such. The simplest way to prevent this is to put whitespace in front of the #.

If you use preprocessor directives to choose one of two versions of a function, use

```
#if ... version1
#else /* ... version2  */
#endif
```

and not

```
#if ... version1
#endif
#if ... version2
#endif
```

because otherwise **xsubpp** will believe that you made a duplicate definition of the function. Also, put a blank line before the #else/#endif so it will not be seen as part of the function body.

68.1.42 Using XS With C++

If an XSUB name contains `::`, it is considered to be a C++ method. The generated Perl function will assume that its first argument is an object pointer. The object pointer will be stored in a variable called THIS. The object should have been created by C++ with the new() function and should be blessed by Perl with the sv_setref_pv() macro. The blessing of the object by Perl can be handled by a typemap. An example typemap is shown at the end of this section.

If the return type of the XSUB includes `static`, the method is considered to be a static method. It will call the C++ function using the class::method() syntax. If the method is not static the function will be called using the THIS->method() syntax.

The next examples will use the following C++ class.

```
class color {
     public:
     color();
     ~color();
     int blue();
     void set_blue( int );

     private:
     int c_blue;
};
```

The XSUBs for the blue() and set_blue() methods are defined with the class name but the parameter for the object (THIS, or "self") is implicit and is not listed.

```
int
color::blue()

void
color::set_blue( val )
     int val
```

Both Perl functions will expect an object as the first parameter. In the generated C++ code the object is called `THIS`, and the method call will be performed on this object. So in the C++ code the blue() and set_blue() methods will be called as this:

```
RETVAL = THIS->blue();

THIS->set_blue( val );
```

You could also write a single get/set method using an optional argument:

```
int
color::blue( val = NO_INIT )
    int val
    PROTOTYPE $;$
    CODE:
        if (items > 1)
            THIS->set_blue( val );
        RETVAL = THIS->blue();
    OUTPUT:
        RETVAL
```

If the function's name is **DESTROY** then the C++ `delete` function will be called and `THIS` will be given as its parameter. The generated C++ code for

```
void
color::DESTROY()
```

will look like this:

```
color *THIS = ...; // Initialized as in typemap

delete THIS;
```

If the function's name is **new** then the C++ `new` function will be called to create a dynamic C++ object. The XSUB will expect the class name, which will be kept in a variable called `CLASS`, to be given as the first argument.

```
color *
color::new()
```

The generated C++ code will call `new`.

```
RETVAL = new color();
```

The following is an example of a typemap that could be used for this C++ example.

```
TYPEMAP
color *             O_OBJECT

OUTPUT
# The Perl object is blessed into 'CLASS', which should be a
# char* having the name of the package for the blessing.
O_OBJECT
    sv_setref_pv( $arg, CLASS, (void*)$var );

INPUT
O_OBJECT
    if( sv_isobject($arg) && (SvTYPE(SvRV($arg)) == SVt_PVMG) )
            $var = ($type)SvIV((SV*)SvRV( $arg ));
    else{
            warn( \"${Package}::$func_name() -- $var is not a blessed SV reference\" );
            XSRETURN_UNDEF;
    }
```

68.1.43 Interface Strategy

When designing an interface between Perl and a C library a straight translation from C to XS (such as created by `h2xs -x`) is often sufficient. However, sometimes the interface will look very C-like and occasionally nonintuitive, especially when the C function modifies one of its parameters, or returns failure inband (as in "negative return values mean failure"). In cases where the programmer wishes to create a more Perl-like interface the following strategy may help to identify the more critical parts of the interface.

Identify the C functions with input/output or output parameters. The XSUBs for these functions may be able to return lists to Perl.

Identify the C functions which use some inband info as an indication of failure. They may be candidates to return undef or an empty list in case of failure. If the failure may be detected without a call to the C function, you may want to use an INIT: section to report the failure. For failures detectable after the C function returns one may want to use a POSTCALL: section to process the failure. In more complicated cases use CODE: or PPCODE: sections.

If many functions use the same failure indication based on the return value, you may want to create a special typedef to handle this situation. Put

```
  typedef int negative_is_failure;
```

near the beginning of XS file, and create an OUTPUT typemap entry for `negative_is_failure` which converts negative values to `undef`, or maybe croak()s. After this the return value of type `negative_is_failure` will create more Perl-like interface.

Identify which values are used by only the C and XSUB functions themselves, say, when a parameter to a function should be a contents of a global variable. If Perl does not need to access the contents of the value then it may not be necessary to provide a translation for that value from C to Perl.

Identify the pointers in the C function parameter lists and return values. Some pointers may be used to implement input/output or output parameters, they can be handled in XS with the `&` unary operator, and, possibly, using the NO_INIT keyword. Some others will require handling of types like `int *`, and one needs to decide what a useful Perl translation will do in such a case. When the semantic is clear, it is advisable to put the translation into a typemap file.

Identify the structures used by the C functions. In many cases it may be helpful to use the T_PTROBJ typemap for these structures so they can be manipulated by Perl as blessed objects. (This is handled automatically by `h2xs -x`.)

If the same C type is used in several different contexts which require different translations, `typedef` several new types mapped to this C type, and create separate *typemap* entries for these new types. Use these types in declarations of return type and parameters to XSUBs.

68.1.44 Perl Objects And C Structures

When dealing with C structures one should select either **T_PTROBJ** or **T_PTRREF** for the XS type. Both types are designed to handle pointers to complex objects. The T_PTRREF type will allow the Perl object to be unblessed while the T_PTROBJ type requires that the object be blessed. By using T_PTROBJ one can achieve a form of type-checking because the XSUB will attempt to verify that the Perl object is of the expected type.

The following XS code shows the getnetconfigent() function which is used with ONC+ TIRPC. The getnetconfigent() function will return a pointer to a C structure and has the C prototype shown below. The example will demonstrate how the C pointer will become a Perl reference. Perl will consider this reference to be a pointer to a blessed object and will attempt to call a destructor for the object. A destructor will be provided in the XS source to free the memory used by getnetconfigent(). Destructors in XS can be created by specifying an XSUB function whose name ends with the word **DESTROY**. XS destructors can be used to free memory which may have been malloc'd by another XSUB.

```
     struct netconfig *getnetconfigent(const char *netid);
```

A `typedef` will be created for `struct netconfig`. The Perl object will be blessed in a class matching the name of the C type, with the tag `Ptr` appended, and the name should not have embedded spaces if it will be a Perl package name. The destructor will be placed in a class corresponding to the class of the object and the PREFIX keyword will be used to trim the name to the word DESTROY as Perl will expect.

```
     typedef struct netconfig Netconfig;

     MODULE = RPC  PACKAGE = RPC

     Netconfig *
     getnetconfigent(netid)
          char *netid

     MODULE = RPC  PACKAGE = NetconfigPtr  PREFIX = rpcb_

     void
     rpcb_DESTROY(netconf)
          Netconfig *netconf
        CODE:
          printf("Now in NetconfigPtr::DESTROY\n");
          free( netconf );
```

This example requires the following typemap entry. Consult the typemap section for more information about adding new typemaps for an extension.

```
TYPEMAP
Netconfig *  T_PTROBJ
```

This example will be used with the following Perl statements.

```
use RPC;
$netconf = getnetconfigent("udp");
```

When Perl destroys the object referenced by $netconf it will send the object to the supplied XSUB DESTROY function. Perl cannot determine, and does not care, that this object is a C struct and not a Perl object. In this sense, there is no difference between the object created by the getnetconfigent() XSUB and an object created by a normal Perl subroutine.

68.1.45 The Typemap

The typemap is a collection of code fragments which are used by the **xsubpp** compiler to map C function parameters and values to Perl values. The typemap file may consist of three sections labelled `TYPEMAP`, `INPUT`, and `OUTPUT`. An unlabelled initial section is assumed to be a `TYPEMAP` section. The INPUT section tells the compiler how to translate Perl values into variables of certain C types. The OUTPUT section tells the compiler how to translate the values from certain C types into values Perl can understand. The TYPEMAP section tells the compiler which of the INPUT and OUTPUT code fragments should be used to map a given C type to a Perl value. The section labels `TYPEMAP`, `INPUT`, or `OUTPUT` must begin in the first column on a line by themselves, and must be in uppercase.

The default typemap in the `lib/ExtUtils` directory of the Perl source contains many useful types which can be used by Perl extensions. Some extensions define additional typemaps which they keep in their own directory. These additional typemaps may reference INPUT and OUTPUT maps in the main typemap. The **xsubpp** compiler will allow the extension's own typemap to override any mappings which are in the default typemap.

Most extensions which require a custom typemap will need only the TYPEMAP section of the typemap file. The custom typemap used in the getnetconfigent() example shown earlier demonstrates what may be the typical use of extension typemaps. That typemap is used to equate a C structure with the T_PTROBJ typemap. The typemap used by getnetconfigent() is shown here. Note that the C type is separated from the XS type with a tab and that the C unary operator * is considered to be a part of the C type name.

```
TYPEMAP
Netconfig *<tab>T_PTROBJ
```

Here's a more complicated example: suppose that you wanted `struct netconfig` to be blessed into the class `Net::Config`. One way to do this is to use underscores (_) to separate package names, as follows:

```
typedef struct netconfig * Net_Config;
```

And then provide a typemap entry `T_PTROBJ_SPECIAL` that maps underscores to double-colons (::), and declare `Net_Config` to be of that type:

```
TYPEMAP
Net_Config      T_PTROBJ_SPECIAL

INPUT
T_PTROBJ_SPECIAL
        if (sv_derived_from($arg, \"${(my $ntt=$ntype)=~s/_/::/g;\$ntt}\")) {
                IV tmp = SvIV((SV*)SvRV($arg));
        $var = ($type) tmp;
        }
        else
                croak(\"$var is not of type ${(my $ntt=$ntype)=~s/_/::/g;\$ntt}\")
```

```
    OUTPUT
    T_PTROBJ_SPECIAL
            sv_setref_pv($arg, \"${(my $ntt=$ntype)=~s/_/::/g;\$ntt}\",
            (void*)$var);
```

The INPUT and OUTPUT sections substitute underscores for double-colons on the fly, giving the desired effect. This example demonstrates some of the power and versatility of the typemap facility.

68.1.46 Safely Storing Static Data in XS

Starting with Perl 5.8, a macro framework has been defined to allow static data to be safely stored in XS modules that will be accessed from a multi-threaded Perl.

Although primarily designed for use with multi-threaded Perl, the macros have been designed so that they will work with non-threaded Perl as well.

It is therefore strongly recommended that these macros be used by all XS modules that make use of static data.

The easiest way to get a template set of macros to use is by specifying the `-g` (`-global`) option with h2xs (see *h2xs*).

Below is an example module that makes use of the macros.

```
    #include "EXTERN.h"
    #include "perl.h"
    #include "XSUB.h"

    /* Global Data */

    #define MY_CXT_KEY "BlindMice::_guts" XS_VERSION

    typedef struct {
        int count;
        char name[3][100];
    } my_cxt_t;

    START_MY_CXT

    MODULE = BlindMice           PACKAGE = BlindMice

    BOOT:
    {
        MY_CXT_INIT;
        MY_CXT.count = 0;
        strcpy(MY_CXT.name[0], "None");
        strcpy(MY_CXT.name[1], "None");
        strcpy(MY_CXT.name[2], "None");
    }

    int
    newMouse(char * name)
        char * name;
        PREINIT:
          dMY_CXT;
        CODE:
          if (MY_CXT.count >= 3) {
              warn("Already have 3 blind mice") ;
              RETVAL = 0;
          }
          else {
              RETVAL = ++ MY_CXT.count;
              strcpy(MY_CXT.name[MY_CXT.count - 1], name);
          }
```

```
char *
get_mouse_name(index)
  int index
  CODE:
    dMY_CXT;
    RETVAL = MY_CXT.lives ++;
    if (index > MY_CXT.count)
      croak("There are only 3 blind mice.");
    else
      RETVAL = newSVpv(MY_CXT.name[index - 1]);
```

REFERENCE

MY_CXT_KEY

This macro is used to define a unique key to refer to the static data for an XS module. The suggested naming scheme, as used by h2xs, is to use a string that consists of the module name, the string "::_guts" and the module version number.

```
#define MY_CXT_KEY "MyModule::_guts" XS_VERSION
```

typedef my_cxt_t

This struct typedef *must* always be called `my_cxt_t` – the other `CXT*` macros assume the existence of the `my_cxt_t` typedef name.

Declare a typedef named `my_cxt_t` that is a structure that contains all the data that needs to be interpreter-local.

```
typedef struct {
    int some_value;
} my_cxt_t;
```

START_MY_CXT

Always place the START_MY_CXT macro directly after the declaration of `my_cxt_t`.

MY_CXT_INIT

The MY_CXT_INIT macro initialises storage for the `my_cxt_t` struct.

It *must* be called exactly once – typically in a BOOT: section.

dMY_CXT

Use the dMY_CXT macro (a declaration) in all the functions that access MY_CXT.

MY_CXT

Use the MY_CXT macro to access members of the `my_cxt_t` struct. For example, if `my_cxt_t` is

```
typedef struct {
    int index;
} my_cxt_t;
```

then use this to access the `index` member

```
dMY_CXT;
MY_CXT.index = 2;
```

68.2 EXAMPLES

File `RPC.xs`: Interface to some ONC+ RPC bind library functions.

```
#include "EXTERN.h"
#include "perl.h"
#include "XSUB.h"

#include <rpc/rpc.h>

typedef struct netconfig Netconfig;

MODULE = RPC  PACKAGE = RPC

SV *
rpcb_gettime(host="localhost")
     char *host
   PREINIT:
     time_t  timep;
   CODE:
     ST(0) = sv_newmortal();
     if( rpcb_gettime( host, &timep ) )
          sv_setnv( ST(0), (double)timep );

Netconfig *
getnetconfigent(netid="udp")
     char *netid

MODULE = RPC  PACKAGE = NetconfigPtr  PREFIX = rpcb_

void
rpcb_DESTROY(netconf)
     Netconfig *netconf
   CODE:
     printf("NetconfigPtr::DESTROY\n");
     free( netconf );
```

File `typemap`: Custom typemap for RPC.xs.

```
TYPEMAP
Netconfig *  T_PTROBJ
```

File `RPC.pm`: Perl module for the RPC extension.

```
package RPC;

require Exporter;
require DynaLoader;
@ISA = qw(Exporter DynaLoader);
@EXPORT = qw(rpcb_gettime getnetconfigent);

bootstrap RPC;
1;
```

File `rpctest.pl`: Perl test program for the RPC extension.

```
use RPC;

$netconf = getnetconfigent();
$a = rpcb_gettime();
print "time = $a\n";
print "netconf = $netconf\n";

$netconf = getnetconfigent("tcp");
$a = rpcb_gettime("poplar");
print "time = $a\n";
print "netconf = $netconf\n";
```

68.3 XS VERSION

This document covers features supported by `xsubpp` 1.935.

perlclib

Internal replacements for standard C library functions

69.1 DESCRIPTION

One thing Perl porters should note is that *perl* doesn't tend to use that much of the C standard library internally; you'll see very little use of, for example, the *ctype.h* functions in there. This is because Perl tends to reimplement or abstract standard library functions, so that we know exactly how they're going to operate.

This is a reference card for people who are familiar with the C library and who want to do things the Perl way; to tell them which functions they ought to use instead of the more normal C functions.

69.1.1 Conventions

In the following tables:

`t`

is a type.

`p`

is a pointer.

`n`

is a number.

`s`

is a string.

`sv`, `av`, `hv`, etc. represent variables of their respective types.

69.1.2 File Operations

Instead of the *stdio.h* functions, you should use the Perl abstraction layer. Instead of `FILE*` types, you need to be handling `PerlIO*` types. Don't forget that with the new PerlIO layered I/O abstraction `FILE*` types may not even be available. See also the `perlapio` documentation for more information about the following functions:

```
    Instead Of:                 Use:
```

```
    stdin                        PerlIO_stdin()
    stdout                       PerlIO_stdout()
    stderr                       PerlIO_stderr()

    fopen(fn, mode)              PerlIO_open(fn, mode)
    freopen(fn, mode, stream)    PerlIO_reopen(fn, mode, perlio) (Deprecated)
    fflush(stream)               PerlIO_flush(perlio)
    fclose(stream)               PerlIO_close(perlio)
```

69.1.3 File Input and Output

```
    Instead Of:                  Use:

    fprintf(stream, fmt, ...)    PerlIO_printf(perlio, fmt, ...)

    [f]getc(stream)              PerlIO_getc(perlio)
    [f]putc(stream, n)           PerlIO_putc(perlio, n)
    ungetc(n, stream)            PerlIO_ungetc(perlio, n)
```

Note that the PerlIO equivalents of `fread` and `fwrite` are slightly different from their C library counterparts:

```
    fread(p, size, n, stream)    PerlIO_read(perlio, buf, numbytes)
    fwrite(p, size, n, stream)   PerlIO_write(perlio, buf, numbytes)

    fputs(s, stream)             PerlIO_puts(perlio, s)
```

There is no equivalent to `fgets`; one should use `sv_gets` instead:

```
    fgets(s, n, stream)          sv_gets(sv, perlio, append)
```

69.1.4 File Positioning

```
    Instead Of:                  Use:

    feof(stream)                 PerlIO_eof(perlio)
    fseek(stream, n, whence)     PerlIO_seek(perlio, n, whence)
    rewind(stream)               PerlIO_rewind(perlio)

    fgetpos(stream, p)           PerlIO_getpos(perlio, sv)
    fsetpos(stream, p)           PerlIO_setpos(perlio, sv)

    ferror(stream)               PerlIO_error(perlio)
    clearerr(stream)             PerlIO_clearerr(perlio)
```

69.1.5 Memory Management and String Handling

```
    Instead Of:                         Use:

    t* p = malloc(n)                    New(id, p, n, t)
    t* p = calloc(n, s)                 Newz(id, p, n, t)
    p = realloc(p, n)                   Renew(p, n, t)
    memcpy(dst, src, n)                 Copy(src, dst, n, t)
    memmove(dst, src, n)                Move(src, dst, n, t)
    memcpy/*(struct foo *)              StructCopy(src, dst, t)
    memset(dst, 0, n * sizeof(t))       Zero(dst, n, t)
    memzero(dst, 0)                     Zero(dst, n, char)
    free(p)                             Safefree(p)
    strdup(p)                   savepv(p)
    strndup(p, n)               savepvn(p, n) (Hey, strndup doesn't exist!)

    strstr(big, little)         instr(big, little)
    strcmp(s1, s2)              strLE(s1, s2) / strEQ(s1, s2) / strGT(s1,s2)
    strncmp(s1, s2, n)          strnNE(s1, s2, n) / strnEQ(s1, s2, n)
```

Notice the different order of arguments to `Copy` and `Move` than used in `memcpy` and `memmove`.

Most of the time, though, you'll want to be dealing with SVs internally instead of raw `char *` strings:

```
    strlen(s)                   sv_len(sv)
    strcpy(dt, src)             sv_setpv(sv, s)
    strncpy(dt, src, n)         sv_setpvn(sv, s, n)
    strcat(dt, src)             sv_catpv(sv, s)
    strncat(dt, src)            sv_catpvn(sv, s)
    sprintf(s, fmt, ...)        sv_setpvf(sv, fmt, ...)
```

Note also the existence of `sv_catpvf` and `sv_vcatpvfn`, combining concatenation with formatting.

Sometimes instead of zeroing the allocated heap by using Newz() you should consider "poisoning" the data. This means writing a bit pattern into it that should be illegal as pointers (and floating point numbers), and also hopefully surprising enough as integers, so that any code attempting to use the data without forethought will break sooner rather than later. Poisoning can be done using the Poison() macro, which has similar arguments as Zero():

```
    Poison(dst, n, t)
```

69.1.6 Character Class Tests

There are two types of character class tests that Perl implements: one type deals in `char`s and are thus **not** Unicode aware (and hence deprecated unless you **know** you should use them) and the other type deal in `UV`s and know about Unicode properties. In the following table, `c` is a `char`, and `u` is a Unicode codepoint.

```
    Instead Of:                 Use:            But better use:

    isalnum(c)                  isALNUM(c)      isALNUM_uni(u)
    isalpha(c)                  isALPHA(c)      isALPHA_uni(u)
    iscntrl(c)                  isCNTRL(c)      isCNTRL_uni(u)
    isdigit(c)                  isDIGIT(c)      isDIGIT_uni(u)
    isgraph(c)                  isGRAPH(c)      isGRAPH_uni(u)
    islower(c)                  isLOWER(c)      isLOWER_uni(u)
    isprint(c)                  isPRINT(c)      isPRINT_uni(u)
    ispunct(c)                  isPUNCT(c)      isPUNCT_uni(u)
    isspace(c)                  isSPACE(c)      isSPACE_uni(u)
    isupper(c)                  isUPPER(c)      isUPPER_uni(u)
    isxdigit(c)                 isXDIGIT(c)     isXDIGIT_uni(u)

    tolower(c)                  toLOWER(c)      toLOWER_uni(u)
    toupper(c)                  toUPPER(c)      toUPPER_uni(u)
```

69.1.7 *stdlib.h* functions

```
Instead Of:                 Use:

atof(s)                     Atof(s)
atol(s)                     Atol(s)
strtod(s, *p)               Nothing.  Just don't use it.
strtol(s, *p, n)            Strtol(s, *p, n)
strtoul(s, *p, n)           Strtoul(s, *p, n)
```

Notice also the `grok_bin`, `grok_hex`, and `grok_oct` functions in *numeric.c* for converting strings representing numbers in the respective bases into `NV`s.

In theory `Strtol` and `Strtoul` may not be defined if the machine perl is built on doesn't actually have strtol and strtoul. But as those 2 functions are part of the 1989 ANSI C spec we suspect you'll find them everywhere by now.

```
int rand()                  double Drand01()
srand(n)                    { seedDrand01((Rand_seed_t)n);
                              PL_srand_called = TRUE; }

exit(n)                     my_exit(n)
system(s)                   Don't. Look at pp_system or use my_popen

getenv(s)                   PerlEnv_getenv(s)
setenv(s, val)              my_putenv(s, val)
```

69.1.8 Miscellaneous functions

You should not even **want** to use *setjmp.h* functions, but if you think you do, use the `JMPENV` stack in *scope.h* instead.

For `signal`/`sigaction`, use `rsignal(signo, handler)`.

Introduction to the Perl API

70.1 DESCRIPTION

This document attempts to describe how to use the Perl API, as well as to provide some info on the basic workings of the Perl core. It is far from complete and probably contains many errors. Please refer any questions or comments to the author below.

70.2 Variables

70.2.1 Datatypes

Perl has three typedefs that handle Perl's three main data types:

```
    SV  Scalar Value
    AV  Array Value
    HV  Hash Value
```

Each typedef has specific routines that manipulate the various data types.

70.2.2 What is an "IV"?

Perl uses a special typedef IV which is a simple signed integer type that is guaranteed to be large enough to hold a pointer (as well as an integer). Additionally, there is the UV, which is simply an unsigned IV.

Perl also uses two special typedefs, I32 and I16, which will always be at least 32-bits and 16-bits long, respectively. (Again, there are U32 and U16, as well.) They will usually be exactly 32 and 16 bits long, but on Crays they will both be 64 bits.

70.2.3 Working with SVs

An SV can be created and loaded with one command. There are five types of values that can be loaded: an integer value (IV), an unsigned integer value (UV), a double (NV), a string (PV), and another scalar (SV).

The seven routines are:

```
SV*  newSViv(IV);
SV*  newSVuv(UV);
SV*  newSVnv(double);
SV*  newSVpv(const char*, STRLEN);
SV*  newSVpvn(const char*, STRLEN);
SV*  newSVpvf(const char*, ...);
SV*  newSVsv(SV*);
```

`STRLEN` is an integer type (Size_t, usually defined as size_t in *config.h*) guaranteed to be large enough to represent the size of any string that perl can handle.

In the unlikely case of a SV requiring more complex initialisation, you can create an empty SV with newSV(len). If `len` is 0 an empty SV of type NULL is returned, else an SV of type PV is returned with len + 1 (for the NUL) bytes of storage allocated, accessible via SvPVX. In both cases the SV has value undef.

```
SV *sv = newSV(0);   /* no storage allocated  */
SV *sv = newSV(10);  /* 10 (+1) bytes of uninitialised storage allocated  */
```

To change the value of an *already-existing* SV, there are eight routines:

```
void  sv_setiv(SV*, IV);
void  sv_setuv(SV*, UV);
void  sv_setnv(SV*, double);
void  sv_setpv(SV*, const char*);
void  sv_setpvn(SV*, const char*, STRLEN)
void  sv_setpvf(SV*, const char*, ...);
void  sv_vsetpvfn(SV*, const char*, STRLEN, va_list *, SV **, I32, bool *);
void  sv_setsv(SV*, SV*);
```

Notice that you can choose to specify the length of the string to be assigned by using `sv_setpvn`, `newSVpvn`, or `newSVpv`, or you may allow Perl to calculate the length by using `sv_setpv` or by specifying 0 as the second argument to `newSVpv`. Be warned, though, that Perl will determine the string's length by using `strlen`, which depends on the string terminating with a NUL character.

The arguments of `sv_setpvf` are processed like `sprintf`, and the formatted output becomes the value.

`sv_vsetpvfn` is an analogue of `vsprintf`, but it allows you to specify either a pointer to a variable argument list or the address and length of an array of SVs. The last argument points to a boolean; on return, if that boolean is true, then locale-specific information has been used to format the string, and the string's contents are therefore untrustworthy (see *perlsec*). This pointer may be NULL if that information is not important. Note that this function requires you to specify the length of the format.

The `sv_set*()` functions are not generic enough to operate on values that have "magic". See Magic Virtual Tables later in this document.

All SVs that contain strings should be terminated with a NUL character. If it is not NUL-terminated there is a risk of core dumps and corruptions from code which passes the string to C functions or system calls which expect a NUL-terminated string. Perl's own functions typically add a trailing NUL for this reason. Nevertheless, you should be very careful when you pass a string stored in an SV to a C function or system call.

To access the actual value that an SV points to, you can use the macros:

```
SvIV(SV*)
SvUV(SV*)
SvNV(SV*)
SvPV(SV*, STRLEN len)
SvPV_nolen(SV*)
```

which will automatically coerce the actual scalar type into an IV, UV, double, or string.

In the `SvPV` macro, the length of the string returned is placed into the variable `len` (this is a macro, so you do *not* use `&len`). If you do not care what the length of the data is, use the `SvPV_nolen` macro. Historically the `SvPV` macro with the global variable `PL_na` has been used in this case. But that can be quite inefficient because `PL_na` must be accessed in thread-local storage in threaded Perl. In any case, remember that Perl allows arbitrary strings of data that may both contain NULs and might not be terminated by a NUL.

Also remember that C doesn't allow you to safely say `foo(SvPV(s, len), len);`. It might work with your compiler, but it won't work for everyone. Break this sort of statement up into separate assignments:

```
        SV *s;
        STRLEN len;
        char * ptr;
        ptr = SvPV(s, len);
        foo(ptr, len);
```

If you want to know if the scalar value is TRUE, you can use:

```
    SvTRUE(SV*)
```

Although Perl will automatically grow strings for you, if you need to force Perl to allocate more memory for your SV, you can use the macro

```
    SvGROW(SV*, STRLEN newlen)
```

which will determine if more memory needs to be allocated. If so, it will call the function `sv_grow`. Note that `SvGROW` can only increase, not decrease, the allocated memory of an SV and that it does not automatically add a byte for the a trailing NUL (perl's own string functions typically do `SvGROW(sv, len + 1)`).

If you have an SV and want to know what kind of data Perl thinks is stored in it, you can use the following macros to check the type of SV you have.

```
    SvIOK(SV*)
    SvNOK(SV*)
    SvPOK(SV*)
```

You can get and set the current length of the string stored in an SV with the following macros:

```
    SvCUR(SV*)
    SvCUR_set(SV*, I32 val)
```

You can also get a pointer to the end of the string stored in the SV with the macro:

```
    SvEND(SV*)
```

But note that these last three macros are valid only if `SvPOK()` is true.

If you want to append something to the end of string stored in an `SV*`, you can use the following functions:

```
    void  sv_catpv(SV*, const char*);
    void  sv_catpvn(SV*, const char*, STRLEN);
    void  sv_catpvf(SV*, const char*, ...);
    void  sv_vcatpvfn(SV*, const char*, STRLEN, va_list *, SV **, I32, bool);
    void  sv_catsv(SV*, SV*);
```

The first function calculates the length of the string to be appended by using `strlen`. In the second, you specify the length of the string yourself. The third function processes its arguments like `sprintf` and appends the formatted output. The fourth function works like `vsprintf`. You can specify the address and length of an array of SVs instead of the va_list argument. The fifth function extends the string stored in the first SV with the string stored in the second SV. It also forces the second SV to be interpreted as a string.

The `sv_cat*()` functions are not generic enough to operate on values that have "magic". See Magic Virtual Tables later in this document.

If you know the name of a scalar variable, you can get a pointer to its SV by using the following:

```
    SV*  get_sv("package::varname", FALSE);
```

This returns NULL if the variable does not exist.

If you want to know if this variable (or any other SV) is actually `defined`, you can call:

```
    SvOK(SV*)
```

The scalar `undef` value is stored in an SV instance called `PL_sv_undef`.

Its address can be used whenever an `SV*` is needed. Make sure that you don't try to compare a random sv with `&PL_sv_undef`. For example when interfacing Perl code, it'll work correctly for:

```
  foo(undef);
```

But won't work when called as:

```
  $x = undef;
  foo($x);
```

So to repeat always use SvOK() to check whether an sv is defined.

Also you have to be careful when using `&PL_sv_undef` as a value in AVs or HVs (see AVs, HVs and undefined values).

There are also the two values `PL_sv_yes` and `PL_sv_no`, which contain boolean TRUE and FALSE values, respectively. Like `PL_sv_undef`, their addresses can be used whenever an `SV*` is needed.

Do not be fooled into thinking that `(SV *) 0` is the same as `&PL_sv_undef`. Take this code:

```
    SV* sv = (SV*) 0;
    if (I-am-to-return-a-real-value) {
            sv = sv_2mortal(newSViv(42));
    }
    sv_setsv(ST(0), sv);
```

This code tries to return a new SV (which contains the value 42) if it should return a real value, or undef otherwise. Instead it has returned a NULL pointer which, somewhere down the line, will cause a segmentation violation, bus error, or just weird results. Change the zero to `&PL_sv_undef` in the first line and all will be well.

To free an SV that you've created, call `SvREFCNT_dec(SV*)`. Normally this call is not necessary (see Reference Counts and Mortality).

70.2.4 Offsets

Perl provides the function sv_chop to efficiently remove characters from the beginning of a string; you give it an SV and a pointer to somewhere inside the PV, and it discards everything before the pointer. The efficiency comes by means of a little hack: instead of actually removing the characters, sv_chop sets the flag OOK (offset OK) to signal to other functions that the offset hack is in effect, and it puts the number of bytes chopped off into the IV field of the SV. It then moves the PV pointer (called SvPVX) forward that many bytes, and adjusts SvCUR and SvLEN.

Hence, at this point, the start of the buffer that we allocated lives at SvPVX(sv) - SvIV(sv) in memory and the PV pointer is pointing into the middle of this allocated storage.

This is best demonstrated by example:

```
% ./perl -Ilib -MDevel::Peek -le '$a="12345"; $a=~s/.//; Dump($a)'
SV = PVIV(0x8128450) at 0x81340f0
  REFCNT = 1
  FLAGS = (POK,OOK,pPOK)
  IV = 1  (OFFSET)
  PV = 0x8135781 ( "1" . ) "2345"\0
  CUR = 4
  LEN = 5
```

Here the number of bytes chopped off (1) is put into IV, and Devel::Peek::Dump helpfully reminds us that this is an offset. The portion of the string between the "real" and the "fake" beginnings is shown in parentheses, and the values of SvCUR and SvLEN reflect the fake beginning, not the real one.

Something similar to the offset hack is performed on AVs to enable efficient shifting and splicing off the beginning of the array; while AvARRAY points to the first element in the array that is visible from Perl, AvALLOC points to the real start of the C array. These are usually the same, but a shift operation can be carried out by increasing AvARRAY by one and decreasing AvFILL and AvLEN. Again, the location of the real start of the C array only comes into play when freeing the array. See av_shift in *av.c*.

70.2.5 What's Really Stored in an SV?

Recall that the usual method of determining the type of scalar you have is to use Sv*OK macros. Because a scalar can be both a number and a string, usually these macros will always return TRUE and calling the Sv*V macros will do the appropriate conversion of string to integer/double or integer/double to string.

If you *really* need to know if you have an integer, double, or string pointer in an SV, you can use the following three macros instead:

```
    SvIOKp(SV*)
    SvNOKp(SV*)
    SvPOKp(SV*)
```

These will tell you if you truly have an integer, double, or string pointer stored in your SV. The "p" stands for private.

The are various ways in which the private and public flags may differ. For example, a tied SV may have a valid underlying value in the IV slot (so SvIOKp is true), but the data should be accessed via the FETCH routine rather than directly, so SvIOK is false. Another is when numeric conversion has occured and precision has been lost: only the private flag is set on 'lossy' values. So when an NV is converted to an IV with loss, SvIOKp, SvNOKp and SvNOK will be set, while SvIOK wont be.

In general, though, it's best to use the Sv*V macros.

70.2.6 Working with AVs

There are two ways to create and load an AV. The first method creates an empty AV:

```
    AV*  newAV();
```

The second method both creates the AV and initially populates it with SVs:

```
    AV*  av_make(I32 num, SV **ptr);
```

The second argument points to an array containing `num` `SV*`'s. Once the AV has been created, the SVs can be destroyed, if so desired.

Once the AV has been created, the following operations are possible on AVs:

```
    void  av_push(AV*, SV*);
    SV*   av_pop(AV*);
    SV*   av_shift(AV*);
    void  av_unshift(AV*, I32 num);
```

These should be familiar operations, with the exception of `av_unshift`. This routine adds `num` elements at the front of the array with the `undef` value. You must then use `av_store` (described below) to assign values to these new elements.

Here are some other functions:

```
    I32   av_len(AV*);
    SV**  av_fetch(AV*, I32 key, I32 lval);
    SV**  av_store(AV*, I32 key, SV* val);
```

The `av_len` function returns the highest index value in array (just like $#array in Perl). If the array is empty, `-1` is returned. The `av_fetch` function returns the value at index `key`, but if `lval` is non-zero, then `av_fetch` will store an undef value at that index. The `av_store` function stores the value `val` at index `key`, and does not increment the reference count of `val`. Thus the caller is responsible for taking care of that, and if `av_store` returns NULL, the caller will have to decrement the reference count to avoid a memory leak. Note that `av_fetch` and `av_store` both return `SV**`'s, not `SV*`'s as their return value.

```
    void  av_clear(AV*);
    void  av_undef(AV*);
    void  av_extend(AV*, I32 key);
```

The `av_clear` function deletes all the elements in the AV* array, but does not actually delete the array itself. The `av_undef` function will delete all the elements in the array plus the array itself. The `av_extend` function extends the array so that it contains at least `key+1` elements. If `key+1` is less than the currently allocated length of the array, then nothing is done.

If you know the name of an array variable, you can get a pointer to its AV by using the following:

```
    AV*  get_av("package::varname", FALSE);
```

This returns NULL if the variable does not exist.

See Understanding the Magic of Tied Hashes and Arrays for more information on how to use the array access functions on tied arrays.

70.2.7 Working with HVs

To create an HV, you use the following routine:

```
HV*  newHV();
```

Once the HV has been created, the following operations are possible on HVs:

```
SV**  hv_store(HV*, const char* key, U32 klen, SV* val, U32 hash);
SV**  hv_fetch(HV*, const char* key, U32 klen, I32 lval);
```

The `klen` parameter is the length of the key being passed in (Note that you cannot pass 0 in as a value of `klen` to tell Perl to measure the length of the key). The `val` argument contains the SV pointer to the scalar being stored, and `hash` is the precomputed hash value (zero if you want `hv_store` to calculate it for you). The `lval` parameter indicates whether this fetch is actually a part of a store operation, in which case a new undefined value will be added to the HV with the supplied key and `hv_fetch` will return as if the value had already existed.

Remember that `hv_store` and `hv_fetch` return `SV**`'s and not just `SV*`. To access the scalar value, you must first dereference the return value. However, you should check to make sure that the return value is not NULL before dereferencing it.

These two functions check if a hash table entry exists, and deletes it.

```
bool  hv_exists(HV*, const char* key, U32 klen);
SV*   hv_delete(HV*, const char* key, U32 klen, I32 flags);
```

If `flags` does not include the `G_DISCARD` flag then `hv_delete` will create and return a mortal copy of the deleted value.

And more miscellaneous functions:

```
void   hv_clear(HV*);
void   hv_undef(HV*);
```

Like their AV counterparts, `hv_clear` deletes all the entries in the hash table but does not actually delete the hash table. The `hv_undef` deletes both the entries and the hash table itself.

Perl keeps the actual data in linked list of structures with a typedef of HE. These contain the actual key and value pointers (plus extra administrative overhead). The key is a string pointer; the value is an `SV*`. However, once you have an `HE*`, to get the actual key and value, use the routines specified below.

```
I32    hv_iterinit(HV*);
        /* Prepares starting point to traverse hash table */
HE*    hv_iternext(HV*);
        /* Get the next entry, and return a pointer to a
           structure that has both the key and value */
char*  hv_iterkey(HE* entry, I32* retlen);
        /* Get the key from an HE structure and also return
           the length of the key string */
SV*    hv_iterval(HV*, HE* entry);
        /* Return an SV pointer to the value of the HE
           structure */
SV*    hv_iternextsv(HV*, char** key, I32* retlen);
        /* This convenience routine combines hv_iternext,
           hv_iterkey, and hv_iterval.  The key and retlen
           arguments are return values for the key and its
           length.  The value is returned in the SV* argument */
```

If you know the name of a hash variable, you can get a pointer to its HV by using the following:

```
    HV*  get_hv("package::varname", FALSE);
```

This returns NULL if the variable does not exist.

The hash algorithm is defined in the `PERL_HASH(hash, key, klen)` macro:

```
    hash = 0;
    while (klen--)
        hash = (hash * 33) + *key++;
    hash = hash + (hash >> 5);                 /* after 5.6 */
```

The last step was added in version 5.6 to improve distribution of lower bits in the resulting hash value.

See Understanding the Magic of Tied Hashes and Arrays for more information on how to use the hash access functions on tied hashes.

70.2.8 Hash API Extensions

Beginning with version 5.004, the following functions are also supported:

```
    HE*     hv_fetch_ent  (HV* tb, SV* key, I32 lval, U32 hash);
    HE*     hv_store_ent  (HV* tb, SV* key, SV* val, U32 hash);

    bool    hv_exists_ent (HV* tb, SV* key, U32 hash);
    SV*     hv_delete_ent (HV* tb, SV* key, I32 flags, U32 hash);

    SV*     hv_iterkeysv  (HE* entry);
```

Note that these functions take `SV*` keys, which simplifies writing of extension code that deals with hash structures. These functions also allow passing of `SV*` keys to `tie` functions without forcing you to stringify the keys (unlike the previous set of functions).

They also return and accept whole hash entries (`HE*`), making their use more efficient (since the hash number for a particular string doesn't have to be recomputed every time). See *perlapi* for detailed descriptions.

The following macros must always be used to access the contents of hash entries. Note that the arguments to these macros must be simple variables, since they may get evaluated more than once. See *perlapi* for detailed descriptions of these macros.

```
    HePV(HE* he, STRLEN len)
    HeVAL(HE* he)
    HeHASH(HE* he)
    HeSVKEY(HE* he)
    HeSVKEY_force(HE* he)
    HeSVKEY_set(HE* he, SV* sv)
```

These two lower level macros are defined, but must only be used when dealing with keys that are not `SV*`s:

```
    HeKEY(HE* he)
    HeKLEN(HE* he)
```

Note that both `hv_store` and `hv_store_ent` do not increment the reference count of the stored `val`, which is the caller's responsibility. If these functions return a NULL value, the caller will usually have to decrement the reference count of `val` to avoid a memory leak.

70.2.9 AVs, HVs and undefined values

Sometimes you have to store undefined values in AVs or HVs. Although this may be a rare case, it can be tricky. That's because you're used to using `&PL_sv_undef` if you need an undefined SV.

For example, intuition tells you that this XS code:

```
    AV *av = newAV();
    av_store( av, 0, &PL_sv_undef );
```

is equivalent to this Perl code:

```
    my @av;
    $av[0] = undef;
```

Unfortunately, this isn't true. AVs use `&PL_sv_undef` as a marker for indicating that an array element has not yet been initialized. Thus, `exists $av[0]` would be true for the above Perl code, but false for the array generated by the XS code.

Other problems can occur when storing `&PL_sv_undef` in HVs:

```
    hv_store( hv, "key", 3, &PL_sv_undef, 0 );
```

This will indeed make the value `undef`, but if you try to modify the value of `key`, you'll get the following error:

```
    Modification of non-creatable hash value attempted
```

In perl 5.8.0, `&PL_sv_undef` was also used to mark placeholders in restricted hashes. This caused such hash entries not to appear when iterating over the hash or when checking for the keys with the `hv_exists` function.

You can run into similar problems when you store `&PL_sv_true` or `&PL_sv_false` into AVs or HVs. Trying to modify such elements will give you the following error:

```
    Modification of a read-only value attempted
```

To make a long story short, you can use the special variables `&PL_sv_undef`, `&PL_sv_true` and `&PL_sv_false` with AVs and HVs, but you have to make sure you know what you're doing.

Generally, if you want to store an undefined value in an AV or HV, you should not use `&PL_sv_undef`, but rather create a new undefined value using the `newSV` function, for example:

```
    av_store( av, 42, newSV(0) );
    hv_store( hv, "foo", 3, newSV(0), 0 );
```

70.2.10 References

References are a special type of scalar that point to other data types (including references).

To create a reference, use either of the following functions:

```
    SV* newRV_inc((SV*) thing);
    SV* newRV_noinc((SV*) thing);
```

The `thing` argument can be any of an `SV*`, `AV*`, or `HV*`. The functions are identical except that `newRV_inc` increments the reference count of the `thing`, while `newRV_noinc` does not. For historical reasons, `newRV` is a synonym for `newRV_inc`.

Once you have a reference, you can use the following macro to dereference the reference:

```
    SvRV(SV*)
```

then call the appropriate routines, casting the returned `SV*` to either an `AV*` or `HV*`, if required.

To determine if an SV is a reference, you can use the following macro:

```
    SvROK(SV*)
```

To discover what type of value the reference refers to, use the following macro and then check the return value.

```
    SvTYPE(SvRV(SV*))
```

The most useful types that will be returned are:

```
    SVt_IV    Scalar
    SVt_NV    Scalar
    SVt_PV    Scalar
    SVt_RV    Scalar
    SVt_PVAV  Array
    SVt_PVHV  Hash
    SVt_PVCV  Code
    SVt_PVGV  Glob (possible a file handle)
    SVt_PVMG  Blessed or Magical Scalar

    See the sv.h header file for more details.
```

70.2.11 Blessed References and Class Objects

References are also used to support object-oriented programming. In perl's OO lexicon, an object is simply a reference that has been blessed into a package (or class). Once blessed, the programmer may now use the reference to access the various methods in the class.

A reference can be blessed into a package with the following function:

```
    SV* sv_bless(SV* sv, HV* stash);
```

The `sv` argument must be a reference value. The `stash` argument specifies which class the reference will belong to. See Stashes and Globs for information on converting class names into stashes.

/* Still under construction */

Upgrades rv to reference if not already one. Creates new SV for rv to point to. If `classname` is non-null, the SV is blessed into the specified class. SV is returned.

```
        SV* newSVrv(SV* rv, const char* classname);
```

Copies integer, unsigned integer or double into an SV whose reference is `rv`. SV is blessed if `classname` is non-null.

```
        SV* sv_setref_iv(SV* rv, const char* classname, IV iv);
        SV* sv_setref_uv(SV* rv, const char* classname, UV uv);
        SV* sv_setref_nv(SV* rv, const char* classname, NV iv);
```

Copies the pointer value (*the address, not the string!*) into an SV whose reference is rv. SV is blessed if `classname` is non-null.

```
        SV* sv_setref_pv(SV* rv, const char* classname, PV iv);
```

Copies string into an SV whose reference is `rv`. Set length to 0 to let Perl calculate the string length. SV is blessed if `classname` is non-null.

```
        SV* sv_setref_pvn(SV* rv, const char* classname, PV iv, STRLEN length);
```

Tests whether the SV is blessed into the specified class. It does not check inheritance relationships.

```
        int  sv_isa(SV* sv, const char* name);
```

Tests whether the SV is a reference to a blessed object.

```
        int  sv_isobject(SV* sv);
```

Tests whether the SV is derived from the specified class. SV can be either a reference to a blessed object or a string containing a class name. This is the function implementing the `UNIVERSAL::isa` functionality.

```
        bool sv_derived_from(SV* sv, const char* name);
```

To check if you've got an object derived from a specific class you have to write:

```
        if (sv_isobject(sv) && sv_derived_from(sv, class)) { ... }
```

70.2.12 Creating New Variables

To create a new Perl variable with an undef value which can be accessed from your Perl script, use the following routines, depending on the variable type.

```
    SV*  get_sv("package::varname", TRUE);
    AV*  get_av("package::varname", TRUE);
    HV*  get_hv("package::varname", TRUE);
```

Notice the use of TRUE as the second parameter. The new variable can now be set, using the routines appropriate to the data type.

There are additional macros whose values may be bitwise OR'ed with the `TRUE` argument to enable certain extra features. Those bits are:

GV_ADDMULTI

Marks the variable as multiply defined, thus preventing the:

```
  Name <varname> used only once: possible typo
```

warning.

GV_ADDWARN

Issues the warning:

```
  Had to create <varname> unexpectedly
```

if the variable did not exist before the function was called.

If you do not specify a package name, the variable is created in the current package.

70.2.13 Reference Counts and Mortality

Perl uses a reference count-driven garbage collection mechanism. SVs, AVs, or HVs (xV for short in the following) start their life with a reference count of 1. If the reference count of an xV ever drops to 0, then it will be destroyed and its memory made available for reuse.

This normally doesn't happen at the Perl level unless a variable is undef'ed or the last variable holding a reference to it is changed or overwritten. At the internal level, however, reference counts can be manipulated with the following macros:

```
int SvREFCNT(SV* sv);
SV* SvREFCNT_inc(SV* sv);
void SvREFCNT_dec(SV* sv);
```

However, there is one other function which manipulates the reference count of its argument. The `newRV_inc` function, you will recall, creates a reference to the specified argument. As a side effect, it increments the argument's reference count. If this is not what you want, use `newRV_noinc` instead.

For example, imagine you want to return a reference from an XSUB function. Inside the XSUB routine, you create an SV which initially has a reference count of one. Then you call `newRV_inc`, passing it the just-created SV. This returns the reference as a new SV, but the reference count of the SV you passed to `newRV_inc` has been incremented to two. Now you return the reference from the XSUB routine and forget about the SV. But Perl hasn't! Whenever the returned reference is destroyed, the reference count of the original SV is decreased to one and nothing happens. The SV will hang around without any way to access it until Perl itself terminates. This is a memory leak.

The correct procedure, then, is to use `newRV_noinc` instead of `newRV_inc`. Then, if and when the last reference is destroyed, the reference count of the SV will go to zero and it will be destroyed, stopping any memory leak.

There are some convenience functions available that can help with the destruction of xVs. These functions introduce the concept of "mortality". An xV that is mortal has had its reference count marked to be decremented, but not actually decremented, until "a short time later". Generally the term "short time later" means a single Perl statement, such as a call to an XSUB function. The actual determinant for when mortal xVs have their reference count decremented depends on two macros, SAVETMPS and FREETMPS. See *perlcall* and *perlxs* for more details on these macros.

"Mortalization" then is at its simplest a deferred `SvREFCNT_dec`. However, if you mortalize a variable twice, the reference count will later be decremented twice.

"Mortal" SVs are mainly used for SVs that are placed on perl's stack. For example an SV which is created just to pass a number to a called sub is made mortal to have it cleaned up automatically when it's popped off the stack. Similarly, results returned by XSUBs (which are pushed on the stack) are often made mortal.

To create a mortal variable, use the functions:

```
SV*  sv_newmortal()
SV*  sv_2mortal(SV*)
SV*  sv_mortalcopy(SV*)
```

The first call creates a mortal SV (with no value), the second converts an existing SV to a mortal SV (and thus defers a call to `SvREFCNT_dec`), and the third creates a mortal copy of an existing SV. Because `sv_newmortal` gives the new SV no value,it must normally be given one via `sv_setpv`, `sv_setiv`, etc. :

```
SV *tmp = sv_newmortal();
sv_setiv(tmp, an_integer);
```

As that is multiple C statements it is quite common so see this idiom instead:

```
SV *tmp = sv_2mortal(newSViv(an_integer));
```

You should be careful about creating mortal variables. Strange things can happen if you make the same value mortal within multiple contexts, or if you make a variable mortal multiple times. Thinking of "Mortalization" as deferred `SvREFCNT_dec` should help to minimize such problems. For example if you are passing an SV which you *know* has high enough REFCNT to survive its use on the stack you need not do any mortalization. If you are not sure then doing an `SvREFCNT_inc` and `sv_2mortal`, or making a `sv_mortalcopy` is safer.

The mortal routines are not just for SVs – AVs and HVs can be made mortal by passing their address (type-casted to `SV*`) to the `sv_2mortal` or `sv_mortalcopy` routines.

70.2.14 Stashes and Globs

A **stash** is a hash that contains all variables that are defined within a package. Each key of the stash is a symbol name (shared by all the different types of objects that have the same name), and each value in the hash table is a GV (Glob Value). This GV in turn contains references to the various objects of that name, including (but not limited to) the following:

```
    Scalar Value
    Array Value
    Hash Value
    I/O Handle
    Format
    Subroutine
```

There is a single stash called `PL_defstash` that holds the items that exist in the `main` package. To get at the items in other packages, append the string "::" to the package name. The items in the `Foo` package are in the stash `Foo::` in PL_defstash. The items in the `Bar::Baz` package are in the stash `Baz::` in `Bar::`'s stash.

To get the stash pointer for a particular package, use the function:

```
    HV*  gv_stashpv(const char* name, I32 create)
    HV*  gv_stashsv(SV*, I32 create)
```

The first function takes a literal string, the second uses the string stored in the SV. Remember that a stash is just a hash table, so you get back an `HV*`. The `create` flag will create a new package if it is set.

The name that `gv_stash*v` wants is the name of the package whose symbol table you want. The default package is called `main`. If you have multiply nested packages, pass their names to `gv_stash*v`, separated by `::` as in the Perl language itself.

Alternately, if you have an SV that is a blessed reference, you can find out the stash pointer by using:

```
    HV*  SvSTASH(SvRV(SV*));
```

then use the following to get the package name itself:

```
    char*  HvNAME(HV* stash);
```

If you need to bless or re-bless an object you can use the following function:

```
    SV*  sv_bless(SV*, HV* stash)
```

where the first argument, an `SV*`, must be a reference, and the second argument is a stash. The returned `SV*` can now be used in the same way as any other SV.

For more information on references and blessings, consult *perlref*.

70.2.15 Double-Typed SVs

Scalar variables normally contain only one type of value, an integer, double, pointer, or reference. Perl will automatically convert the actual scalar data from the stored type into the requested type.

Some scalar variables contain more than one type of scalar data. For example, the variable `$!` contains either the numeric value of `errno` or its string equivalent from either `strerror` or `sys_errlist[]`.

To force multiple data values into an SV, you must do two things: use the `sv_set*v` routines to add the additional scalar type, then set a flag so that Perl will believe it contains more than one type of data. The four macros to set the flags are:

```
        SvIOK_on
        SvNOK_on
        SvPOK_on
        SvROK_on
```

The particular macro you must use depends on which `sv_set*v` routine you called first. This is because every `sv_set*v` routine turns on only the bit for the particular type of data being set, and turns off all the rest.

For example, to create a new Perl variable called "dberror" that contains both the numeric and descriptive string error values, you could use the following code:

```
    extern int  dberror;
    extern char *dberror_list;

    SV* sv = get_sv("dberror", TRUE);
    sv_setiv(sv, (IV) dberror);
    sv_setpv(sv, dberror_list[dberror]);
    SvIOK_on(sv);
```

If the order of `sv_setiv` and `sv_setpv` had been reversed, then the macro `SvPOK_on` would need to be called instead of `SvIOK_on`.

70.2.16 Magic Variables

[This section still under construction. Ignore everything here. Post no bills. Everything not permitted is forbidden.]

Any SV may be magical, that is, it has special features that a normal SV does not have. These features are stored in the SV structure in a linked list of `struct magic`'s, typedef'ed to `MAGIC`.

```
    struct magic {
        MAGIC*      mg_moremagic;
        MGVTBL*     mg_virtual;
        U16         mg_private;
        char        mg_type;
        U8          mg_flags;
        SV*         mg_obj;
        char*       mg_ptr;
        I32         mg_len;
    };
```

Note this is current as of patchlevel 0, and could change at any time.

70.2.17 Assigning Magic

Perl adds magic to an SV using the sv_magic function:

```
    void sv_magic(SV* sv, SV* obj, int how, const char* name, I32 namlen);
```

The `sv` argument is a pointer to the SV that is to acquire a new magical feature.

If `sv` is not already magical, Perl uses the `SvUPGRADE` macro to convert `sv` to type `SVt_PVMG`. Perl then continues by adding new magic to the beginning of the linked list of magical features. Any prior entry of the same type of magic is deleted. Note that this can be overridden, and multiple instances of the same type of magic can be associated with an SV.

The `name` and `namlen` arguments are used to associate a string with the magic, typically the name of a variable. `namlen` is stored in the `mg_len` field and if `name` is non-null and `namlen` >= 0 a malloc'd copy of the name is stored in `mg_ptr` field.

The sv_magic function uses how to determine which, if any, predefined "Magic Virtual Table" should be assigned to the mg_virtual field. See the Magic Virtual Tables section below. The how argument is also stored in the mg_type field. The value of how should be chosen from the set of macros PERL_MAGIC_foo found in *perl.h*. Note that before these macros were added, Perl internals used to directly use character literals, so you may occasionally come across old code or documentation referring to 'U' magic rather than PERL_MAGIC_uvar for example.

The obj argument is stored in the mg_obj field of the MAGIC structure. If it is not the same as the sv argument, the reference count of the obj object is incremented. If it is the same, or if the how argument is PERL_MAGIC_arylen, or if it is a NULL pointer, then obj is merely stored, without the reference count being incremented.

There is also a function to add magic to an HV:

```
    void hv_magic(HV *hv, GV *gv, int how);
```

This simply calls sv_magic and coerces the gv argument into an SV.

To remove the magic from an SV, call the function sv_unmagic:

```
    void sv_unmagic(SV *sv, int type);
```

The type argument should be equal to the how value when the SV was initially made magical.

70.2.18 Magic Virtual Tables

The mg_virtual field in the MAGIC structure is a pointer to an MGVTBL, which is a structure of function pointers and stands for "Magic Virtual Table" to handle the various operations that might be applied to that variable.

The MGVTBL has five pointers to the following routine types:

```
    int  (*svt_get)(SV* sv, MAGIC* mg);
    int  (*svt_set)(SV* sv, MAGIC* mg);
    U32  (*svt_len)(SV* sv, MAGIC* mg);
    int  (*svt_clear)(SV* sv, MAGIC* mg);
    int  (*svt_free)(SV* sv, MAGIC* mg);
```

This MGVTBL structure is set at compile-time in *perl.h* and there are currently 19 types (or 21 with overloading turned on). These different structures contain pointers to various routines that perform additional actions depending on which function is being called.

```
    Function pointer    Action taken
    ----------------    ------------
    svt_get             Do something before the value of the SV is retrieved.
    svt_set             Do something after the SV is assigned a value.
    svt_len             Report on the SV's length.
    svt_clear           Clear something the SV represents.
    svt_free            Free any extra storage associated with the SV.
```

For instance, the MGVTBL structure called vtbl_sv (which corresponds to an mg_type of PERL_MAGIC_sv) contains:

```
    { magic_get, magic_set, magic_len, 0, 0 }
```

Thus, when an SV is determined to be magical and of type PERL_MAGIC_sv, if a get operation is being performed, the routine magic_get is called. All the various routines for the various magical types begin with magic_. NOTE: the magic routines are not considered part of the Perl API, and may not be exported by the Perl library.

The current kinds of Magic Virtual Tables are:

```
mg_type
(old-style char and macro)   MGVTBL         Type of magic
--------------------------   ------         ----------------------------
\0 PERL_MAGIC_sv             vtbl_sv        Special scalar variable
A  PERL_MAGIC_overload       vtbl_amagic    %OVERLOAD hash
a  PERL_MAGIC_overload_elem  vtbl_amagicelem %OVERLOAD hash element
c  PERL_MAGIC_overload_table (none)         Holds overload table (AMT)
                                            on stash
B  PERL_MAGIC_bm             vtbl_bm        Boyer-Moore (fast string search)
D  PERL_MAGIC_regdata        vtbl_regdata   Regex match position data
                                            (@+ and @- vars)
d  PERL_MAGIC_regdatum       vtbl_regdatum  Regex match position data
                                            element
E  PERL_MAGIC_env            vtbl_env       %ENV hash
e  PERL_MAGIC_envelem        vtbl_envelem   %ENV hash element
f  PERL_MAGIC_fm             vtbl_fm        Formline ('compiled' format)
g  PERL_MAGIC_regex_global   vtbl_mglob     m//g target / study()ed string
I  PERL_MAGIC_isa            vtbl_isa       @ISA array
i  PERL_MAGIC_isaelem        vtbl_isaelem   @ISA array element
k  PERL_MAGIC_nkeys          vtbl_nkeys     scalar(keys()) lvalue
L  PERL_MAGIC_dbfile         (none)         Debugger %_<filename
l  PERL_MAGIC_dbline         vtbl_dbline    Debugger %_<filename element
m  PERL_MAGIC_mutex          vtbl_mutex     ???
o  PERL_MAGIC_collxfrm       vtbl_collxfrm  Locale collate transformation
P  PERL_MAGIC_tied           vtbl_pack      Tied array or hash
p  PERL_MAGIC_tiedelem       vtbl_packelem  Tied array or hash element
q  PERL_MAGIC_tiedscalar     vtbl_packelem  Tied scalar or handle
r  PERL_MAGIC_qr             vtbl_qr        precompiled qr// regex
S  PERL_MAGIC_sig            vtbl_sig       %SIG hash
s  PERL_MAGIC_sigelem        vtbl_sigelem   %SIG hash element
t  PERL_MAGIC_taint          vtbl_taint     Taintedness
U  PERL_MAGIC_uvar           vtbl_uvar      Available for use by extensions
v  PERL_MAGIC_vec            vtbl_vec       vec() lvalue
V  PERL_MAGIC_vstring        (none)         v-string scalars
w  PERL_MAGIC_utf8           vtbl_utf8      UTF-8 length+offset cache
x  PERL_MAGIC_substr         vtbl_substr    substr() lvalue
y  PERL_MAGIC_defelem        vtbl_defelem   Shadow "foreach" iterator
                                            variable / smart parameter
                                            vivification
*  PERL_MAGIC_glob           vtbl_glob      GV (typeglob)
#  PERL_MAGIC_arylen         vtbl_arylen    Array length ($#ary)
.  PERL_MAGIC_pos            vtbl_pos       pos() lvalue
<  PERL_MAGIC_backref        vtbl_backref   ???
~  PERL_MAGIC_ext            (none)         Available for use by extensions
```

When an uppercase and lowercase letter both exist in the table, then the uppercase letter is typically used to represent some kind of composite type (a list or a hash), and the lowercase letter is used to represent an element of that composite type. Some internals code makes use of this case relationship. However, 'v' and 'V' (vec and v-string) are in no way related.

The `PERL_MAGIC_ext` and `PERL_MAGIC_uvar` magic types are defined specifically for use by extensions and will not be used by perl itself. Extensions can use `PERL_MAGIC_ext` magic to 'attach' private information to variables (typically objects). This is especially useful because there is no way for normal perl code to corrupt this private information (unlike using extra elements of a hash object).

Similarly, `PERL_MAGIC_uvar` magic can be used much like tie() to call a C function any time a scalar's value is used or changed. The `MAGIC`'s `mg_ptr` field points to a `ufuncs` structure:

```
    struct ufuncs {
        I32 (*uf_val)(pTHX_ IV, SV*);
        I32 (*uf_set)(pTHX_ IV, SV*);
        IV uf_index;
    };
```

When the SV is read from or written to, the `uf_val` or `uf_set` function will be called with `uf_index` as the first arg and a pointer to the SV as the second. A simple example of how to add `PERL_MAGIC_uvar` magic is shown below. Note that the ufuncs structure is copied by sv_magic, so you can safely allocate it on the stack.

```
    void
    Umagic(sv)
        SV *sv;
    PREINIT:
        struct ufuncs uf;
    CODE:
        uf.uf_val   = &my_get_fn;
        uf.uf_set   = &my_set_fn;
        uf.uf_index = 0;
        sv_magic(sv, 0, PERL_MAGIC_uvar, (char*)&uf, sizeof(uf));
```

Note that because multiple extensions may be using `PERL_MAGIC_ext` or `PERL_MAGIC_uvar` magic, it is important for extensions to take extra care to avoid conflict. Typically only using the magic on objects blessed into the same class as the extension is sufficient. For `PERL_MAGIC_ext` magic, it may also be appropriate to add an I32 'signature' at the top of the private data area and check that.

Also note that the `sv_set*()` and `sv_cat*()` functions described earlier do **not** invoke 'set' magic on their targets. This must be done by the user either by calling the `SvSETMAGIC()` macro after calling these functions, or by using one of the `sv_set*_mg()` or `sv_cat*_mg()` functions. Similarly, generic C code must call the `SvGETMAGIC()` macro to invoke any 'get' magic if they use an SV obtained from external sources in functions that don't handle magic. See *perlapi* for a description of these functions. For example, calls to the `sv_cat*()` functions typically need to be followed by `SvSETMAGIC()`, but they don't need a prior `SvGETMAGIC()` since their implementation handles 'get' magic.

70.2.19 Finding Magic

```
    MAGIC* mg_find(SV*, int type); /* Finds the magic pointer of that type */
```

This routine returns a pointer to the `MAGIC` structure stored in the SV. If the SV does not have that magical feature, `NULL` is returned. Also, if the SV is not of type SVt_PVMG, Perl may core dump.

```
    int mg_copy(SV* sv, SV* nsv, const char* key, STRLEN klen);
```

This routine checks to see what types of magic `sv` has. If the mg_type field is an uppercase letter, then the mg_obj is copied to `nsv`, but the mg_type field is changed to be the lowercase letter.

70.2.20 Understanding the Magic of Tied Hashes and Arrays

Tied hashes and arrays are magical beasts of the `PERL_MAGIC_tied` magic type.

WARNING: As of the 5.004 release, proper usage of the array and hash access functions requires understanding a few caveats. Some of these caveats are actually considered bugs in the API, to be fixed in later releases, and are bracketed with [MAYCHANGE] below. If you find yourself actually applying such information in this section, be aware that the behavior may change in the future, umm, without warning.

The perl tie function associates a variable with an object that implements the various GET, SET, etc methods. To perform the equivalent of the perl tie function from an XSUB, you must mimic this behaviour. The code below carries out the necessary steps - firstly it creates a new hash, and then creates a second hash which it blesses into the class which will implement the tie methods. Lastly it ties the two hashes together, and returns a reference to the new tied hash. Note that the code below does NOT call the TIEHASH method in the MyTie class - see Calling Perl Routines from within C Programs for details on how to do this.

```
    SV*
    mytie()
    PREINIT:
        HV *hash;
        HV *stash;
        SV *tie;
    CODE:
        hash = newHV();
        tie = newRV_noinc((SV*)newHV());
        stash = gv_stashpv("MyTie", TRUE);
        sv_bless(tie, stash);
        hv_magic(hash, (GV*)tie, PERL_MAGIC_tied);
        RETVAL = newRV_noinc(hash);
    OUTPUT:
        RETVAL
```

The `av_store` function, when given a tied array argument, merely copies the magic of the array onto the value to be "stored", using `mg_copy`. It may also return NULL, indicating that the value did not actually need to be stored in the array. [MAYCHANGE] After a call to `av_store` on a tied array, the caller will usually need to call `mg_set(val)` to actually invoke the perl level "STORE" method on the TIEARRAY object. If `av_store` did return NULL, a call to `SvREFCNT_dec(val)` will also be usually necessary to avoid a memory leak. [/MAYCHANGE]

The previous paragraph is applicable verbatim to tied hash access using the `hv_store` and `hv_store_ent` functions as well.

`av_fetch` and the corresponding hash functions `hv_fetch` and `hv_fetch_ent` actually return an undefined mortal value whose magic has been initialized using `mg_copy`. Note the value so returned does not need to be deallocated, as it is already mortal. [MAYCHANGE] But you will need to call `mg_get()` on the returned value in order to actually invoke the perl level "FETCH" method on the underlying TIE object. Similarly, you may also call `mg_set()` on the return value after possibly assigning a suitable value to it using `sv_setsv`, which will invoke the "STORE" method on the TIE object. [/MAYCHANGE]

[MAYCHANGE] In other words, the array or hash fetch/store functions don't really fetch and store actual values in the case of tied arrays and hashes. They merely call `mg_copy` to attach magic to the values that were meant to be "stored" or "fetched". Later calls to `mg_get` and `mg_set` actually do the job of invoking the TIE methods on the underlying objects. Thus the magic mechanism currently implements a kind of lazy access to arrays and hashes.

Currently (as of perl version 5.004), use of the hash and array access functions requires the user to be aware of whether they are operating on "normal" hashes and arrays, or on their tied variants. The API may be changed to provide more transparent access to both tied and normal data types in future versions. [/MAYCHANGE]

You would do well to understand that the TIEARRAY and TIEHASH interfaces are mere sugar to invoke some perl method calls while using the uniform hash and array syntax. The use of this sugar imposes some overhead (typically about two to four extra opcodes per FETCH/STORE operation, in addition to the creation of all the mortal variables required to invoke the methods). This overhead will be comparatively small if the TIE methods are themselves substantial, but if they are only a few statements long, the overhead will not be insignificant.

70.2.21 Localizing changes

Perl has a very handy construction

```
  {
    local $var = 2;
    ...
  }
```

This construction is *approximately* equivalent to

```
{
  my $oldvar = $var;
  $var = 2;
  ...
  $var = $oldvar;
}
```

The biggest difference is that the first construction would reinstate the initial value of $var, irrespective of how control exits the block: `goto`, `return`, `die`/`eval`, etc. It is a little bit more efficient as well.

There is a way to achieve a similar task from C via Perl API: create a *pseudo-block*, and arrange for some changes to be automatically undone at the end of it, either explicit, or via a non-local exit (via die()). A *block*-like construct is created by a pair of `ENTER`/`LEAVE` macros (see Returning a Scalar in *perlcall*). Such a construct may be created specially for some important localized task, or an existing one (like boundaries of enclosing Perl subroutine/block, or an existing pair for freeing TMPs) may be used. (In the second case the overhead of additional localization must be almost negligible.) Note that any XSUB is automatically enclosed in an `ENTER`/`LEAVE` pair.

Inside such a *pseudo-block* the following service is available:

`SAVEINT(int i)`

`SAVEIV(IV i)`

`SAVEI32(I32 i)`

`SAVELONG(long i)`

These macros arrange things to restore the value of integer variable `i` at the end of enclosing *pseudo-block*.

`SAVESPTR(s)`

`SAVEPPTR(p)`

These macros arrange things to restore the value of pointers `s` and `p`. `s` must be a pointer of a type which survives conversion to `SV*` and back, `p` should be able to survive conversion to `char*` and back.

`SAVEFREESV(SV *sv)`

The refcount of `sv` would be decremented at the end of *pseudo-block*. This is similar to `sv_2mortal` in that it is also a mechanism for doing a delayed `SvREFCNT_dec`. However, while `sv_2mortal` extends the lifetime of `sv` until the beginning of the next statement, `SAVEFREESV` extends it until the end of the enclosing scope. These lifetimes can be wildly different.

Also compare `SAVEMORTALIZESV`.

`SAVEMORTALIZESV(SV *sv)`

Just like `SAVEFREESV`, but mortalizes `sv` at the end of the current scope instead of decrementing its reference count. This usually has the effect of keeping `sv` alive until the statement that called the currently live scope has finished executing.

`SAVEFREEOP(OP *op)`

The `OP *` is op_free()ed at the end of *pseudo-block*.

`SAVEFREEPV(p)`

The chunk of memory which is pointed to by `p` is Safefree()ed at the end of *pseudo-block*.

`SAVECLEARSV(SV *sv)`

Clears a slot in the current scratchpad which corresponds to `sv` at the end of *pseudo-block*.

`SAVEDELETE(HV *hv, char *key, I32 length)`

The key `key` of `hv` is deleted at the end of *pseudo-block*. The string pointed to by `key` is Safefree()ed. If one has a *key* in short-lived storage, the corresponding string may be reallocated like this:

```
SAVEDELETE(PL_defstash, savepv(tmpbuf), strlen(tmpbuf));
```

`SAVEDESTRUCTOR(DESTRUCTORFUNC_NOCONTEXT_t f, void *p)`

At the end of *pseudo-block* the function `f` is called with the only argument `p`.

`SAVEDESTRUCTOR_X(DESTRUCTORFUNC_t f, void *p)`

At the end of *pseudo-block* the function `f` is called with the implicit context argument (if any), and `p`.

`SAVESTACK_POS()`

The current offset on the Perl internal stack (cf. `SP`) is restored at the end of *pseudo-block*.

The following API list contains functions, thus one needs to provide pointers to the modifiable data explicitly (either C pointers, or Perlish `GV *`s). Where the above macros take `int`, a similar function takes `int *`.

`SV* save_scalar(GV *gv)`

Equivalent to Perl code `local $gv`.

`AV* save_ary(GV *gv)`

`HV* save_hash(GV *gv)`

Similar to `save_scalar`, but localize `@gv` and `%gv`.

`void save_item(SV *item)`

Duplicates the current value of `SV`, on the exit from the current `ENTER`/`LEAVE` *pseudo-block* will restore the value of `SV` using the stored value.

`void save_list(SV **sarg, I32 maxsarg)`

A variant of `save_item` which takes multiple arguments via an array `sarg` of `SV*` of length `maxsarg`.

`SV* save_svref(SV **sptr)`

Similar to `save_scalar`, but will reinstate an `SV *`.

`void save_aptr(AV **aptr)`

`void save_hptr(HV **hptr)`

Similar to `save_svref`, but localize `AV *` and `HV *`.

The `Alias` module implements localization of the basic types within the *caller's scope*. People who are interested in how to localize things in the containing scope should take a look there too.

70.3 Subroutines

70.3.1 XSUBs and the Argument Stack

The XSUB mechanism is a simple way for Perl programs to access C subroutines. An XSUB routine will have a stack that contains the arguments from the Perl program, and a way to map from the Perl data structures to a C equivalent.

The stack arguments are accessible through the `ST(n)` macro, which returns the `n`'th stack argument. Argument 0 is the first argument passed in the Perl subroutine call. These arguments are `SV*`, and can be used anywhere an `SV*` is used.

Most of the time, output from the C routine can be handled through use of the RETVAL and OUTPUT directives. However, there are some cases where the argument stack is not already long enough to handle all the return values. An example is the POSIX tzname() call, which takes no arguments, but returns two, the local time zone's standard and summer time abbreviations.

To handle this situation, the PPCODE directive is used and the stack is extended using the macro:

```
EXTEND(SP, num);
```

where SP is the macro that represents the local copy of the stack pointer, and num is the number of elements the stack should be extended by.

Now that there is room on the stack, values can be pushed on it using PUSHs macro. The pushed values will often need to be "mortal" (See Reference Counts and Mortality):

```
PUSHs(sv_2mortal(newSViv(an_integer)))
PUSHs(sv_2mortal(newSVuv(an_unsigned_integer)))
PUSHs(sv_2mortal(newSVnv(a_double)))
PUSHs(sv_2mortal(newSVpv("Some String",0)))
```

And now the Perl program calling tzname, the two values will be assigned as in:

```
($standard_abbrev, $summer_abbrev) = POSIX::tzname;
```

An alternate (and possibly simpler) method to pushing values on the stack is to use the macro:

```
XPUSHs(SV*)
```

This macro automatically adjust the stack for you, if needed. Thus, you do not need to call EXTEND to extend the stack.

Despite their suggestions in earlier versions of this document the macros (X)PUSH[iunp] are *not* suited to XSUBs which return multiple results. For that, either stick to the (X)PUSHs macros shown above, or use the new m(X)PUSH[iunp] macros instead; see Putting a C value on Perl stack.

For more information, consult *perlxs* and *perlxstut*.

70.3.2 Calling Perl Routines from within C Programs

There are four routines that can be used to call a Perl subroutine from within a C program. These four are:

```
I32  call_sv(SV*, I32);
I32  call_pv(const char*, I32);
I32  call_method(const char*, I32);
I32  call_argv(const char*, I32, register char**);
```

The routine most often used is call_sv. The SV* argument contains either the name of the Perl subroutine to be called, or a reference to the subroutine. The second argument consists of flags that control the context in which the subroutine is called, whether or not the subroutine is being passed arguments, how errors should be trapped, and how to treat return values.

All four routines return the number of arguments that the subroutine returned on the Perl stack.

These routines used to be called perl_call_sv, etc., before Perl v5.6.0, but those names are now deprecated; macros of the same name are provided for compatibility.

When using any of these routines (except call_argv), the programmer must manipulate the Perl stack. These include the following macros and functions:

```
dSP
SP
PUSHMARK()
PUTBACK
SPAGAIN
ENTER
SAVETMPS
FREETMPS
LEAVE
XPUSH*()
POP*()
```

For a detailed description of calling conventions from C to Perl, consult *perlcall*.

70.3.3 Memory Allocation

Allocation

All memory meant to be used with the Perl API functions should be manipulated using the macros described in this section. The macros provide the necessary transparency between differences in the actual malloc implementation that is used within perl.

It is suggested that you enable the version of malloc that is distributed with Perl. It keeps pools of various sizes of unallocated memory in order to satisfy allocation requests more quickly. However, on some platforms, it may cause spurious malloc or free errors.

The following three macros are used to initially allocate memory :

```
    New(x, pointer, number, type);
    Newc(x, pointer, number, type, cast);
    Newz(x, pointer, number, type);
```

The first argument `x` was a "magic cookie" that was used to keep track of who called the macro, to help when debugging memory problems. However, the current code makes no use of this feature (most Perl developers now use run-time memory checkers), so this argument can be any number.

The second argument `pointer` should be the name of a variable that will point to the newly allocated memory.

The third and fourth arguments `number` and `type` specify how many of the specified type of data structure should be allocated. The argument `type` is passed to `sizeof`. The final argument to `Newc`, `cast`, should be used if the `pointer` argument is different from the `type` argument.

Unlike the `New` and `Newc` macros, the `Newz` macro calls `memzero` to zero out all the newly allocated memory.

Reallocation

```
    Renew(pointer, number, type);
    Renewc(pointer, number, type, cast);
    Safefree(pointer)
```

These three macros are used to change a memory buffer size or to free a piece of memory no longer needed. The arguments to `Renew` and `Renewc` match those of `New` and `Newc` with the exception of not needing the "magic cookie" argument.

Moving

```
    Move(source, dest, number, type);
    Copy(source, dest, number, type);
    Zero(dest, number, type);
```

These three macros are used to move, copy, or zero out previously allocated memory. The `source` and `dest` arguments point to the source and destination starting points. Perl will move, copy, or zero out `number` instances of the size of the `type` data structure (using the `sizeof` function).

70.3.4 PerlIO

The most recent development releases of Perl has been experimenting with removing Perl's dependency on the "normal" standard I/O suite and allowing other stdio implementations to be used. This involves creating a new abstraction layer that then calls whichever implementation of stdio Perl was compiled with. All XSUBs should now use the functions in the PerlIO abstraction layer and not make any assumptions about what kind of stdio is being used.

For a complete description of the PerlIO abstraction, consult *perlapio*.

70.3.5 Putting a C value on Perl stack

A lot of opcodes (this is an elementary operation in the internal perl stack machine) put an SV* on the stack. However, as an optimization the corresponding SV is (usually) not recreated each time. The opcodes reuse specially assigned SVs (*target*s) which are (as a corollary) not constantly freed/created.

Each of the targets is created only once (but see Scratchpads and recursion below), and when an opcode needs to put an integer, a double, or a string on stack, it just sets the corresponding parts of its *target* and puts the *target* on stack.

The macro to put this target on stack is `PUSHTARG`, and it is directly used in some opcodes, as well as indirectly in zillions of others, which use it via `(X)PUSH[iunp]`.

Because the target is reused, you must be careful when pushing multiple values on the stack. The following code will not do what you think:

```
XPUSHi(10);
XPUSHi(20);
```

This translates as "set `TARG` to 10, push a pointer to `TARG` onto the stack; set `TARG` to 20, push a pointer to `TARG` onto the stack". At the end of the operation, the stack does not contain the values 10 and 20, but actually contains two pointers to `TARG`, which we have set to 20.

If you need to push multiple different values then you should either use the `(X)PUSHs` macros, or else use the new `m(X)PUSH[iunp]` macros, none of which make use of `TARG`. The `(X)PUSHs` macros simply push an SV* on the stack, which, as noted under XSUBs and the Argument Stack, will often need to be "mortal". The new `m(X)PUSH[iunp]` macros make this a little easier to achieve by creating a new mortal for you (via `(X)PUSHmortal`), pushing that onto the stack (extending it if necessary in the case of the `mXPUSH[iunp]` macros), and then setting its value. Thus, instead of writing this to "fix" the example above:

```
XPUSHs(sv_2mortal(newSViv(10)))
XPUSHs(sv_2mortal(newSViv(20)))
```

you can simply write:

```
mXPUSHi(10)
mXPUSHi(20)
```

On a related note, if you do use `(X)PUSH[iunp]`, then you're going to need a `dTARG` in your variable declarations so that the `*PUSH*` macros can make use of the local variable `TARG`. See also `dTARGET` and `dXSTARG`.

70.3.6 Scratchpads

The question remains on when the SVs which are *target*s for opcodes are created. The answer is that they are created when the current unit – a subroutine or a file (for opcodes for statements outside of subroutines) – is compiled. During this time a special anonymous Perl array is created, which is called a scratchpad for the current unit.

A scratchpad keeps SVs which are lexicals for the current unit and are targets for opcodes. One can deduce that an SV lives on a scratchpad by looking on its flags: lexicals have `SVs_PADMY` set, and *target*s have `SVs_PADTMP` set.

The correspondence between OPs and *target*s is not 1-to-1. Different OPs in the compile tree of the unit can use the same target, if this would not conflict with the expected life of the temporary.

70.3.7 Scratchpads and recursion

In fact it is not 100% true that a compiled unit contains a pointer to the scratchpad AV. In fact it contains a pointer to an AV of (initially) one element, and this element is the scratchpad AV. Why do we need an extra level of indirection?

The answer is **recursion**, and maybe **threads**. Both these can create several execution pointers going into the same subroutine. For the subroutine-child not write over the temporaries for the subroutine-parent (lifespan of which covers the call to the child), the parent and the child should have different scratchpads. (*And* the lexicals should be separate anyway!)

So each subroutine is born with an array of scratchpads (of length 1). On each entry to the subroutine it is checked that the current depth of the recursion is not more than the length of this array, and if it is, new scratchpad is created and pushed into the array.

The *target*s on this scratchpad are `undef`s, but they are already marked with correct flags.

70.4 Compiled code

70.4.1 Code tree

Here we describe the internal form your code is converted to by Perl. Start with a simple example:

```
  $a = $b + $c;
```

This is converted to a tree similar to this one:

```
             assign-to
           /           \
          +             $a
        /   \
      $b     $c
```

(but slightly more complicated). This tree reflects the way Perl parsed your code, but has nothing to do with the execution order. There is an additional "thread" going through the nodes of the tree which shows the order of execution of the nodes. In our simplified example above it looks like:

```
     $b ---> $c ---> + ---> $a ---> assign-to
```

But with the actual compile tree for `$a = $b + $c` it is different: some nodes *optimized away*. As a corollary, though the actual tree contains more nodes than our simplified example, the execution order is the same as in our example.

70.4.2 Examining the tree

If you have your perl compiled for debugging (usually done with `-DDEBUGGING` on the `Configure` command line), you may examine the compiled tree by specifying `-Dx` on the Perl command line. The output takes several lines per node, and for `$b+$c` it looks like this:

```
    5           TYPE = add  ===> 6
                TARG = 1
                FLAGS = (SCALAR,KIDS)
                {
                    TYPE = null  ===> (4)
                      (was rv2sv)
                    FLAGS = (SCALAR,KIDS)
                    {
    3                   TYPE = gvsv  ===> 4
                        FLAGS = (SCALAR)
                        GV = main::b
                    }
                }
                {
                    TYPE = null  ===> (5)
                      (was rv2sv)
                    FLAGS = (SCALAR,KIDS)
                    {
    4                   TYPE = gvsv  ===> 5
                        FLAGS = (SCALAR)
                        GV = main::c
                    }
                }
```

This tree has 5 nodes (one per `TYPE` specifier), only 3 of them are not optimized away (one per number in the left column). The immediate children of the given node correspond to `{}` pairs on the same level of indentation, thus this listing corresponds to the tree:

```
           add
         /     \
       null    null
        |        |
       gvsv    gvsv
```

The execution order is indicated by ===> marks, thus it is `3 4 5 6` (node `6` is not included into above listing), i.e., `gvsv gvsv add whatever`.

Each of these nodes represents an op, a fundamental operation inside the Perl core. The code which implements each operation can be found in the *pp*.c* files; the function which implements the op with type `gvsv` is `pp_gvsv`, and so on. As the tree above shows, different ops have different numbers of children: `add` is a binary operator, as one would expect, and so has two children. To accommodate the various different numbers of children, there are various types of op data structure, and they link together in different ways.

The simplest type of op structure is `OP`: this has no children. Unary operators, `UNOP`s, have one child, and this is pointed to by the `op_first` field. Binary operators (`BINOP`s) have not only an `op_first` field but also an `op_last` field. The most complex type of op is a `LISTOP`, which has any number of children. In this case, the first child is pointed to by `op_first` and the last child by `op_last`. The children in between can be found by iteratively following the `op_sibling` pointer from the first child to the last.

There are also two other op types: a `PMOP` holds a regular expression, and has no children, and a `LOOP` may or may not have children. If the `op_children` field is non-zero, it behaves like a `LISTOP`. To complicate matters, if a `UNOP` is actually a `null` op after optimization (see Compile pass 2: context propagation) it will still have children in accordance with its former type.

Another way to examine the tree is to use a compiler back-end module, such as *B::Concise*.

70.4.3 Compile pass 1: check routines

The tree is created by the compiler while *yacc* code feeds it the constructions it recognizes. Since *yacc* works bottom-up, so does the first pass of perl compilation.

What makes this pass interesting for perl developers is that some optimization may be performed on this pass. This is optimization by so-called "check routines". The correspondence between node names and corresponding check routines is described in *opcode.pl* (do not forget to run `make regen_headers` if you modify this file).

A check routine is called when the node is fully constructed except for the execution-order thread. Since at this time there are no back-links to the currently constructed node, one can do most any operation to the top-level node, including freeing it and/or creating new nodes above/below it.

The check routine returns the node which should be inserted into the tree (if the top-level node was not modified, check routine returns its argument).

By convention, check routines have names `ck_*`. They are usually called from `new*OP` subroutines (or `convert`) (which in turn are called from *perly.y*).

70.4.4 Compile pass 1a: constant folding

Immediately after the check routine is called the returned node is checked for being compile-time executable. If it is (the value is judged to be constant) it is immediately executed, and a *constant* node with the "return value" of the corresponding subtree is substituted instead. The subtree is deleted.

If constant folding was not performed, the execution-order thread is created.

70.4.5 Compile pass 2: context propagation

When a context for a part of compile tree is known, it is propagated down through the tree. At this time the context can have 5 values (instead of 2 for runtime context): void, boolean, scalar, list, and lvalue. In contrast with the pass 1 this pass is processed from top to bottom: a node's context determines the context for its children.

Additional context-dependent optimizations are performed at this time. Since at this moment the compile tree contains back-references (via "thread" pointers), nodes cannot be free()d now. To allow optimized-away nodes at this stage, such nodes are null()ified instead of free()ing (i.e. their type is changed to OP_NULL).

70.4.6 Compile pass 3: peephole optimization

After the compile tree for a subroutine (or for an `eval` or a file) is created, an additional pass over the code is performed. This pass is neither top-down or bottom-up, but in the execution order (with additional complications for conditionals). These optimizations are done in the subroutine peep(). Optimizations performed at this stage are subject to the same restrictions as in the pass 2.

70.4.7 Pluggable runops

The compile tree is executed in a runops function. There are two runops functions, in *run.c* and in *dump.c*. `Perl_runops_debug` is used with DEBUGGING and `Perl_runops_standard` is used otherwise. For fine control over the execution of the compile tree it is possible to provide your own runops function.

It's probably best to copy one of the existing runops functions and change it to suit your needs. Then, in the BOOT section of your XS file, add the line:

```
  PL_runops = my_runops;
```

This function should be as efficient as possible to keep your programs running as fast as possible.

70.5 Examining internal data structures with the `dump` functions

To aid debugging, the source file *dump.c* contains a number of functions which produce formatted output of internal data structures.

The most commonly used of these functions is `Perl_sv_dump`; it's used for dumping SVs, AVs, HVs, and CVs. The `Devel::Peek` module calls `sv_dump` to produce debugging output from Perl-space, so users of that module should already be familiar with its format.

`Perl_op_dump` can be used to dump an `OP` structure or any of its derivatives, and produces output similar to `perl -Dx`; in fact, `Perl_dump_eval` will dump the main root of the code being evaluated, exactly like `-Dx`.

Other useful functions are `Perl_dump_sub`, which turns a `GV` into an op tree, `Perl_dump_packsubs` which calls `Perl_dump_sub` on all the subroutines in a package like so: (Thankfully, these are all xsubs, so there is no op tree)

```
    (gdb) print Perl_dump_packsubs(PL_defstash)

    SUB attributes::bootstrap = (xsub 0x811fedc 0)

    SUB UNIVERSAL::can = (xsub 0x811f50c 0)

    SUB UNIVERSAL::isa = (xsub 0x811f304 0)

    SUB UNIVERSAL::VERSION = (xsub 0x811f7ac 0)

    SUB DynaLoader::boot_DynaLoader = (xsub 0x805b188 0)
```

and `Perl_dump_all`, which dumps all the subroutines in the stash and the op tree of the main root.

70.6 How multiple interpreters and concurrency are supported

70.6.1 Background and PERL_IMPLICIT_CONTEXT

The Perl interpreter can be regarded as a closed box: it has an API for feeding it code or otherwise making it do things, but it also has functions for its own use. This smells a lot like an object, and there are ways for you to build Perl so that you can have multiple interpreters, with one interpreter represented either as a C structure, or inside a thread-specific structure. These structures contain all the context, the state of that interpreter.

Two macros control the major Perl build flavors: MULTIPLICITY and USE_5005THREADS. The MULTIPLICITY build has a C structure that packages all the interpreter state, and there is a similar thread-specific data structure under USE_5005THREADS. In both cases, PERL_IMPLICIT_CONTEXT is also normally defined, and enables the support for passing in a "hidden" first argument that represents all three data structures.

All this obviously requires a way for the Perl internal functions to be either subroutines taking some kind of structure as the first argument, or subroutines taking nothing as the first argument. To enable these two very different ways of building the interpreter, the Perl source (as it does in so many other situations) makes heavy use of macros and subroutine naming conventions.

First problem: deciding which functions will be public API functions and which will be private. All functions whose names begin `S_` are private (think "S" for "secret" or "static"). All other functions begin with "Perl_", but just because a function begins with "Perl_" does not mean it is part of the API. (See Internal Functions.) The easiest way to be **sure** a function is part of the API is to find its entry in *perlapi*. If it exists in *perlapi*, it's part of the API. If it doesn't, and you think it should be (i.e., you need it for your extension), send mail via *perlbug* explaining why you think it should be.

Second problem: there must be a syntax so that the same subroutine declarations and calls can pass a structure as their first argument, or pass nothing. To solve this, the subroutines are named and declared in a particular way. Here's a typical start of a static function used within the Perl guts:

```
  STATIC void
  S_incline(pTHX_ char *s)
```

STATIC becomes "static" in C, and may be #define'd to nothing in some configurations in future.

A public function (i.e. part of the internal API, but not necessarily sanctioned for use in extensions) begins like this:

```
  void
  Perl_sv_setiv(pTHX_ SV* dsv, IV num)
```

`pTHX_` is one of a number of macros (in perl.h) that hide the details of the interpreter's context. THX stands for "thread", "this", or "thingy", as the case may be. (And no, George Lucas is not involved. :-) The first character could be 'p' for a **p**rototype, 'a' for **a**rgument, or 'd' for **d**eclaration, so we have `pTHX`, `aTHX` and `dTHX`, and their variants.

When Perl is built without options that set PERL_IMPLICIT_CONTEXT, there is no first argument containing the interpreter's context. The trailing underscore in the pTHX_ macro indicates that the macro expansion needs a comma after the context argument because other arguments follow it. If PERL_IMPLICIT_CONTEXT is not defined, pTHX_ will be ignored, and the subroutine is not prototyped to take the extra argument. The form of the macro without the trailing underscore is used when there are no additional explicit arguments.

When a core function calls another, it must pass the context. This is normally hidden via macros. Consider `sv_setiv`. It expands into something like this:

```
    #ifdef PERL_IMPLICIT_CONTEXT
      #define sv_setiv(a,b)      Perl_sv_setiv(aTHX_ a, b)
      /* can't do this for vararg functions, see below */
    #else
      #define sv_setiv           Perl_sv_setiv
    #endif
```

This works well, and means that XS authors can gleefully write:

```
    sv_setiv(foo, bar);
```

and still have it work under all the modes Perl could have been compiled with.

This doesn't work so cleanly for varargs functions, though, as macros imply that the number of arguments is known in advance. Instead we either need to spell them out fully, passing `aTHX_` as the first argument (the Perl core tends to do this with functions like Perl_warner), or use a context-free version.

The context-free version of Perl_warner is called Perl_warner_nocontext, and does not take the extra argument. Instead it does dTHX; to get the context from thread-local storage. We `#define warner Perl_warner_nocontext` so that extensions get source compatibility at the expense of performance. (Passing an arg is cheaper than grabbing it from thread-local storage.)

You can ignore [pad]THXx when browsing the Perl headers/sources. Those are strictly for use within the core. Extensions and embedders need only be aware of [pad]THX.

70.6.2 So what happened to dTHR?

`dTHR` was introduced in perl 5.005 to support the older thread model. The older thread model now uses the `THX` mechanism to pass context pointers around, so `dTHR` is not useful any more. Perl 5.6.0 and later still have it for backward source compatibility, but it is defined to be a no-op.

70.6.3 How do I use all this in extensions?

When Perl is built with PERL_IMPLICIT_CONTEXT, extensions that call any functions in the Perl API will need to pass the initial context argument somehow. The kicker is that you will need to write it in such a way that the extension still compiles when Perl hasn't been built with PERL_IMPLICIT_CONTEXT enabled.

There are three ways to do this. First, the easy but inefficient way, which is also the default, in order to maintain source compatibility with extensions: whenever XSUB.h is #included, it redefines the aTHX and aTHX_ macros to call a function that will return the context. Thus, something like:

```
        sv_setiv(sv, num);
```

in your extension will translate to this when PERL_IMPLICIT_CONTEXT is in effect:

```
        Perl_sv_setiv(Perl_get_context(), sv, num);
```

or to this otherwise:

```
        Perl_sv_setiv(sv, num);
```

You have to do nothing new in your extension to get this; since the Perl library provides Perl_get_context(), it will all just work.

The second, more efficient way is to use the following template for your Foo.xs:

```
        #define PERL_NO_GET_CONTEXT     /* we want efficiency */
        #include "EXTERN.h"
        #include "perl.h"
        #include "XSUB.h"

        static my_private_function(int arg1, int arg2);

        static SV *
        my_private_function(int arg1, int arg2)
        {
            dTHX;       /* fetch context */
            ... call many Perl API functions ...
        }
        [... etc ...]

        MODULE = Foo            PACKAGE = Foo

        /* typical XSUB */

        void
        my_xsub(arg)
                int arg
            CODE:
                my_private_function(arg, 10);
```

Note that the only two changes from the normal way of writing an extension is the addition of a `#define PERL_NO_GET_CONTEXT` before including the Perl headers, followed by a `dTHX;` declaration at the start of every function that will call the Perl API. (You'll know which functions need this, because the C compiler will complain that there's an undeclared identifier in those functions.) No changes are needed for the XSUBs themselves, because the XS() macro is correctly defined to pass in the implicit context if needed.

The third, even more efficient way is to ape how it is done within the Perl guts:

```
        #define PERL_NO_GET_CONTEXT     /* we want efficiency */
        #include "EXTERN.h"
        #include "perl.h"
        #include "XSUB.h"

        /* pTHX_ only needed for functions that call Perl API */
        static my_private_function(pTHX_ int arg1, int arg2);

        static SV *
        my_private_function(pTHX_ int arg1, int arg2)
        {
            /* dTHX; not needed here, because THX is an argument */
            ... call Perl API functions ...
        }

        [... etc ...]

        MODULE = Foo            PACKAGE = Foo

        /* typical XSUB */

        void
        my_xsub(arg)
                int arg
            CODE:
                my_private_function(aTHX_ arg, 10);
```

This implementation never has to fetch the context using a function call, since it is always passed as an extra argument. Depending on your needs for simplicity or efficiency, you may mix the previous two approaches freely.

Never add a comma after `pTHX` yourself–always use the form of the macro with the underscore for functions that take explicit arguments, or the form without the argument for functions with no explicit arguments.

70.6.4 Should I do anything special if I call perl from multiple threads?

If you create interpreters in one thread and then proceed to call them in another, you need to make sure perl's own Thread Local Storage (TLS) slot is initialized correctly in each of those threads.

The `perl_alloc` and `perl_clone` API functions will automatically set the TLS slot to the interpreter they created, so that there is no need to do anything special if the interpreter is always accessed in the same thread that created it, and that thread did not create or call any other interpreters afterwards. If that is not the case, you have to set the TLS slot of the thread before calling any functions in the Perl API on that particular interpreter. This is done by calling the `PERL_SET_CONTEXT` macro in that thread as the first thing you do:

```
        /* do this before doing anything else with some_perl */
        PERL_SET_CONTEXT(some_perl);

        ... other Perl API calls on some_perl go here ...
```

70.6.5 Future Plans and PERL_IMPLICIT_SYS

Just as PERL_IMPLICIT_CONTEXT provides a way to bundle up everything that the interpreter knows about itself and pass it around, so too are there plans to allow the interpreter to bundle up everything it knows about the environment it's running on. This is enabled with the PERL_IMPLICIT_SYS macro. Currently it only works with USE_ITHREADS and USE_5005THREADS on Windows (see inside iperlsys.h).

This allows the ability to provide an extra pointer (called the "host" environment) for all the system calls. This makes it possible for all the system stuff to maintain their own state, broken down into seven C structures. These are thin wrappers around the usual system calls (see win32/perllib.c) for the default perl executable, but for a more ambitious host (like the one that would do fork() emulation) all the extra work needed to pretend that different interpreters are actually different "processes", would be done here.

The Perl engine/interpreter and the host are orthogonal entities. There could be one or more interpreters in a process, and one or more "hosts", with free association between them.

70.7 Internal Functions

All of Perl's internal functions which will be exposed to the outside world are prefixed by `Perl_` so that they will not conflict with XS functions or functions used in a program in which Perl is embedded. Similarly, all global variables begin with `PL_`. (By convention, static functions start with `S_`.)

Inside the Perl core, you can get at the functions either with or without the `Perl_` prefix, thanks to a bunch of defines that live in *embed.h*. This header file is generated automatically from *embed.pl* and *embed.fnc*. *embed.pl* also creates the prototyping header files for the internal functions, generates the documentation and a lot of other bits and pieces. It's important that when you add a new function to the core or change an existing one, you change the data in the table in *embed.fnc* as well. Here's a sample entry from that table:

```
    Apd |SV**   |av_fetch   |AV* ar|I32 key|I32 lval
```

The second column is the return type, the third column the name. Columns after that are the arguments. The first column is a set of flags:

A

This function is a part of the public API.

p

This function has a `Perl_` prefix; ie, it is defined as `Perl_av_fetch`

d

This function has documentation using the `apidoc` feature which we'll look at in a second.

Other available flags are:

s

This is a static function and is defined as `S_whatever`, and usually called within the sources as `whatever(...)`.

n

This does not use `aTHX_` and `pTHX` to pass interpreter context. (See Background and PERL_IMPLICIT_CONTEXT in *perlguts*.)

r

This function never returns; `croak`, `exit` and friends.

f

This function takes a variable number of arguments, `printf` style. The argument list should end with `...`, like this:

```
    Afprd   |void   |croak          |const char* pat|...
```

M

This function is part of the experimental development API, and may change or disappear without notice.

o

This function should not have a compatibility macro to define, say, `Perl_parse` to `parse`. It must be called as `Perl_parse`.

x

This function isn't exported out of the Perl core.

m

This is implemented as a macro.

X

This function is explicitly exported.

E

This function is visible to extensions included in the Perl core.

b

Binary backward compatibility; this function is a macro but also has a `Perl_` implementation (which is exported).

If you edit *embed.pl* or *embed.fnc*, you will need to run `make regen_headers` to force a rebuild of *embed.h* and other auto-generated files.

70.7.1 Formatted Printing of IVs, UVs, and NVs

If you are printing IVs, UVs, or NVS instead of the stdio(3) style formatting codes like `%d`, `%ld`, `%f`, you should use the following macros for portability

```
        IVdf            IV in decimal
        UVuf            UV in decimal
        UVof            UV in octal
        UVxf            UV in hexadecimal
        NVef            NV %e-like
        NVff            NV %f-like
        NVgf            NV %g-like
```

These will take care of 64-bit integers and long doubles. For example:

```
        printf("IV is %"IVdf"\n", iv);
```

The IVdf will expand to whatever is the correct format for the IVs.

If you are printing addresses of pointers, use UVxf combined with PTR2UV(), do not use %lx or %p.

70.7.2 Pointer-To-Integer and Integer-To-Pointer

Because pointer size does not necessarily equal integer size, use the follow macros to do it right.

```
        PTR2UV(pointer)
        PTR2IV(pointer)
        PTR2NV(pointer)
        INT2PTR(pointertotype, integer)
```

For example:

```
        IV  iv = ...;
        SV *sv = INT2PTR(SV*, iv);
```

and

```
        AV *av = ...;
        UV  uv = PTR2UV(av);
```

70.7.3 Source Documentation

There's an effort going on to document the internal functions and automatically produce reference manuals from them - *perlapi* is one such manual which details all the functions which are available to XS writers. *perlintern* is the autogenerated manual for the functions which are not part of the API and are supposedly for internal use only.

Source documentation is created by putting POD comments into the C source, like this:

```
 /*
 =for apidoc sv_setiv

 Copies an integer into the given SV.  Does not handle 'set' magic.  See
 C<sv_setiv_mg>.

 =cut
 */
```

Please try and supply some documentation if you add functions to the Perl core.

70.8 Unicode Support

Perl 5.6.0 introduced Unicode support. It's important for porters and XS writers to understand this support and make sure that the code they write does not corrupt Unicode data.

70.8.1 What is Unicode, anyway?

In the olden, less enlightened times, we all used to use ASCII. Most of us did, anyway. The big problem with ASCII is that it's American. Well, no, that's not actually the problem; the problem is that it's not particularly useful for people who don't use the Roman alphabet. What used to happen was that particular languages would stick their own alphabet in the upper range of the sequence, between 128 and 255. Of course, we then ended up with plenty of variants that weren't quite ASCII, and the whole point of it being a standard was lost.

Worse still, if you've got a language like Chinese or Japanese that has hundreds or thousands of characters, then you really can't fit them into a mere 256, so they had to forget about ASCII altogether, and build their own systems using pairs of numbers to refer to one character.

To fix this, some people formed Unicode, Inc. and produced a new character set containing all the characters you can possibly think of and more. There are several ways of representing these characters, and the one Perl uses is called UTF-8. UTF-8 uses a variable number of bytes to represent a character, instead of just one. You can learn more about Unicode at http://www.unicode.org/

70.8.2 How can I recognise a UTF-8 string?

You can't. This is because UTF-8 data is stored in bytes just like non-UTF-8 data. The Unicode character 200, (`0xC8` for you hex types) capital E with a grave accent, is represented by the two bytes `v196.172`. Unfortunately, the non-Unicode string `chr(196).chr(172)` has that byte sequence as well. So you can't tell just by looking - this is what makes Unicode input an interesting problem.

The API function `is_utf8_string` can help; it'll tell you if a string contains only valid UTF-8 characters. However, it can't do the work for you. On a character-by-character basis, `is_utf8_char` will tell you whether the current character in a string is valid UTF-8.

70.8.3 How does UTF-8 represent Unicode characters?

As mentioned above, UTF-8 uses a variable number of bytes to store a character. Characters with values 1...128 are stored in one byte, just like good ol' ASCII. Character 129 is stored as `v194.129`; this continues up to character 191, which is `v194.191`. Now we've run out of bits (191 is binary `10111111`) so we move on; 192 is `v195.128`. And so it goes on, moving to three bytes at character 2048.

Assuming you know you're dealing with a UTF-8 string, you can find out how long the first character in it is with the `UTF8SKIP` macro:

```
char *utf = "\305\233\340\240\201";
I32 len;

len = UTF8SKIP(utf); /* len is 2 here */
utf += len;
len = UTF8SKIP(utf); /* len is 3 here */
```

Another way to skip over characters in a UTF-8 string is to use `utf8_hop`, which takes a string and a number of characters to skip over. You're on your own about bounds checking, though, so don't use it lightly.

All bytes in a multi-byte UTF-8 character will have the high bit set, so you can test if you need to do something special with this character like this (the UTF8_IS_INVARIANT() is a macro that tests whether the byte can be encoded as a single byte even in UTF-8):

```
U8 *utf;
UV uv;      /* Note: a UV, not a U8, not a char */

if (!UTF8_IS_INVARIANT(*utf))
    /* Must treat this as UTF-8 */
    uv = utf8_to_uv(utf);
else
    /* OK to treat this character as a byte */
    uv = *utf;
```

You can also see in that example that we use `utf8_to_uv` to get the value of the character; the inverse function `uv_to_utf8` is available for putting a UV into UTF-8:

```
    if (!UTF8_IS_INVARIANT(uv))
        /* Must treat this as UTF8 */
        utf8 = uv_to_utf8(utf8, uv);
    else
        /* OK to treat this character as a byte */
        *utf8++ = uv;
```

You **must** convert characters to UVs using the above functions if you're ever in a situation where you have to match UTF-8 and non-UTF-8 characters. You may not skip over UTF-8 characters in this case. If you do this, you'll lose the ability to match hi-bit non-UTF-8 characters; for instance, if your UTF-8 string contains `v196.172`, and you skip that character, you can never match a `chr(200)` in a non-UTF-8 string. So don't do that!

70.8.4 How does Perl store UTF-8 strings?

Currently, Perl deals with Unicode strings and non-Unicode strings slightly differently. If a string has been identified as being UTF-8 encoded, Perl will set a flag in the SV, `SVf_UTF8`. You can check and manipulate this flag with the following macros:

```
    SvUTF8(sv)
    SvUTF8_on(sv)
    SvUTF8_off(sv)
```

This flag has an important effect on Perl's treatment of the string: if Unicode data is not properly distinguished, regular expressions, `length`, `substr` and other string handling operations will have undesirable results.

The problem comes when you have, for instance, a string that isn't flagged is UTF-8, and contains a byte sequence that could be UTF-8 - especially when combining non-UTF-8 and UTF-8 strings.

Never forget that the `SVf_UTF8` flag is separate to the PV value; you need be sure you don't accidentally knock it off while you're manipulating SVs. More specifically, you cannot expect to do this:

```
    SV *sv;
    SV *nsv;
    STRLEN len;
    char *p;

    p = SvPV(sv, len);
    frobnicate(p);
    nsv = newSVpvn(p, len);
```

The `char*` string does not tell you the whole story, and you can't copy or reconstruct an SV just by copying the string value. Check if the old SV has the UTF-8 flag set, and act accordingly:

```
    p = SvPV(sv, len);
    frobnicate(p);
    nsv = newSVpvn(p, len);
    if (SvUTF8(sv))
        SvUTF8_on(nsv);
```

In fact, your `frobnicate` function should be made aware of whether or not it's dealing with UTF-8 data, so that it can handle the string appropriately.

Since just passing an SV to an XS function and copying the data of the SV is not enough to copy the UTF-8 flags, even less right is just passing a `char *` to an XS function.

70.8.5 How do I convert a string to UTF-8?

If you're mixing UTF-8 and non-UTF-8 strings, you might find it necessary to upgrade one of the strings to UTF-8. If you've got an SV, the easiest way to do this is:

```
    sv_utf8_upgrade(sv);
```

However, you must not do this, for example:

```
    if (!SvUTF8(left))
        sv_utf8_upgrade(left);
```

If you do this in a binary operator, you will actually change one of the strings that came into the operator, and, while it shouldn't be noticeable by the end user, it can cause problems.

Instead, `bytes_to_utf8` will give you a UTF-8-encoded **copy** of its string argument. This is useful for having the data available for comparisons and so on, without harming the original SV. There's also `utf8_to_bytes` to go the other way, but naturally, this will fail if the string contains any characters above 255 that can't be represented in a single byte.

70.8.6 Is there anything else I need to know?

Not really. Just remember these things:

- There's no way to tell if a string is UTF-8 or not. You can tell if an SV is UTF-8 by looking at is `SvUTF8` flag. Don't forget to set the flag if something should be UTF-8. Treat the flag as part of the PV, even though it's not - if you pass on the PV to somewhere, pass on the flag too.
- If a string is UTF-8, **always** use `utf8_to_uv` to get at the value, unless `UTF8_IS_INVARIANT(*s)` in which case you can use `*s`.
- When writing a character `uv` to a UTF-8 string, **always** use `uv_to_utf8`, unless `UTF8_IS_INVARIANT(uv))` in which case you can use `*s = uv`.
- Mixing UTF-8 and non-UTF-8 strings is tricky. Use `bytes_to_utf8` to get a new string which is UTF-8 encoded. There are tricks you can use to delay deciding whether you need to use a UTF-8 string until you get to a high character - `HALF_UPGRADE` is one of those.

70.9 Custom Operators

Custom operator support is a new experimental feature that allows you to define your own ops. This is primarily to allow the building of interpreters for other languages in the Perl core, but it also allows optimizations through the creation of "macro-ops" (ops which perform the functions of multiple ops which are usually executed together, such as `gvsv, gvsv, add`.)

This feature is implemented as a new op type, `OP_CUSTOM`. The Perl core does not "know" anything special about this op type, and so it will not be involved in any optimizations. This also means that you can define your custom ops to be any op structure - unary, binary, list and so on - you like.

It's important to know what custom operators won't do for you. They won't let you add new syntax to Perl, directly. They won't even let you add new keywords, directly. In fact, they won't change the way Perl compiles a program at all. You have to do those changes yourself, after Perl has compiled the program. You do this either by manipulating the op tree using a `CHECK` block and the `B::Generate` module, or by adding a custom peephole optimizer with the `optimize` module.

When you do this, you replace ordinary Perl ops with custom ops by creating ops with the type `OP_CUSTOM` and the `pp_addr` of your own PP function. This should be defined in XS code, and should look like the PP ops in `pp_*.c`. You are responsible for ensuring that your op takes the appropriate number of values from the stack, and you are responsible for adding stack marks if necessary.

You should also "register" your op with the Perl interpreter so that it can produce sensible error and warning messages. Since it is possible to have multiple custom ops within the one "logical" op type `OP_CUSTOM`, Perl uses the value of `o->op_ppaddr` as a key into the `PL_custom_op_descs` and `PL_custom_op_names` hashes. This means you need to enter a name and description for your op at the appropriate place in the `PL_custom_op_names` and `PL_custom_op_descs` hashes.

Forthcoming versions of `B::Generate` (version 1.0 and above) should directly support the creation of custom ops by name; `Opcodes::Custom` will provide functions which make it trivial to "register" custom ops to the Perl interpreter.

Chapter 71

perlcall

Perl calling conventions from C

71.1 DESCRIPTION

The purpose of this document is to show you how to call Perl subroutines directly from C, i.e., how to write *callbacks*.

Apart from discussing the C interface provided by Perl for writing callbacks the document uses a series of examples to show how the interface actually works in practice. In addition some techniques for coding callbacks are covered.

Examples where callbacks are necessary include

- An Error Handler

  You have created an XSUB interface to an application's C API.

  A fairly common feature in applications is to allow you to define a C function that will be called whenever something nasty occurs. What we would like is to be able to specify a Perl subroutine that will be called instead.

- An Event Driven Program

  The classic example of where callbacks are used is when writing an event driven program like for an X windows application. In this case you register functions to be called whenever specific events occur, e.g., a mouse button is pressed, the cursor moves into a window or a menu item is selected.

Although the techniques described here are applicable when embedding Perl in a C program, this is not the primary goal of this document. There are other details that must be considered and are specific to embedding Perl. For details on embedding Perl in C refer to *perlembed*.

Before you launch yourself head first into the rest of this document, it would be a good idea to have read the following two documents - *perlxs* and *perlguts*.

71.2 THE CALL_ FUNCTIONS

Although this stuff is easier to explain using examples, you first need be aware of a few important definitions.

Perl has a number of C functions that allow you to call Perl subroutines. They are

```
    I32 call_sv(SV* sv, I32 flags) ;
    I32 call_pv(char *subname, I32 flags) ;
    I32 call_method(char *methname, I32 flags) ;
    I32 call_argv(char *subname, I32 flags, register char **argv) ;
```

The key function is *call_sv*. All the other functions are fairly simple wrappers which make it easier to call Perl subroutines in special cases. At the end of the day they will all call *call_sv* to invoke the Perl subroutine.

All the *call_** functions have a `flags` parameter which is used to pass a bit mask of options to Perl. This bit mask operates identically for each of the functions. The settings available in the bit mask are discussed in FLAG VALUES.

Each of the functions will now be discussed in turn.

call_sv

call_sv takes two parameters, the first, `sv`, is an SV*. This allows you to specify the Perl subroutine to be called either as a C string (which has first been converted to an SV) or a reference to a subroutine. The section, *Using call_sv*, shows how you can make use of *call_sv*.

call_pv

The function, *call_pv*, is similar to *call_sv* except it expects its first parameter to be a C char* which identifies the Perl subroutine you want to call, e.g., `call_pv("fred", 0)`. If the subroutine you want to call is in another package, just include the package name in the string, e.g., `"pkg::fred"`.

call_method

The function *call_method* is used to call a method from a Perl class. The parameter `methname` corresponds to the name of the method to be called. Note that the class that the method belongs to is passed on the Perl stack rather than in the parameter list. This class can be either the name of the class (for a static method) or a reference to an object (for a virtual method). See *perlobj* for more information on static and virtual methods and Using call_method for an example of using *call_method*.

call_argv

call_argv calls the Perl subroutine specified by the C string stored in the `subname` parameter. It also takes the usual `flags` parameter. The final parameter, `argv`, consists of a NULL terminated list of C strings to be passed as parameters to the Perl subroutine. See *Using call_argv*.

All the functions return an integer. This is a count of the number of items returned by the Perl subroutine. The actual items returned by the subroutine are stored on the Perl stack.

As a general rule you should *always* check the return value from these functions. Even if you are expecting only a particular number of values to be returned from the Perl subroutine, there is nothing to stop someone from doing something unexpected–don't say you haven't been warned.

71.3 FLAG VALUES

The `flags` parameter in all the *call_** functions is a bit mask which can consist of any combination of the symbols defined below, OR'ed together.

71.3.1 G_VOID

Calls the Perl subroutine in a void context.

This flag has 2 effects:

1. It indicates to the subroutine being called that it is executing in a void context (if it executes *wantarray* the result will be the undefined value).
2. It ensures that nothing is actually returned from the subroutine.

The value returned by the *call_** function indicates how many items have been returned by the Perl subroutine - in this case it will be 0.

71.3.2 G_SCALAR

Calls the Perl subroutine in a scalar context. This is the default context flag setting for all the *call_** functions.

This flag has 2 effects:

1. It indicates to the subroutine being called that it is executing in a scalar context (if it executes *wantarray* the result will be false).
2. It ensures that only a scalar is actually returned from the subroutine. The subroutine can, of course, ignore the *wantarray* and return a list anyway. If so, then only the last element of the list will be returned.

The value returned by the *call_** function indicates how many items have been returned by the Perl subroutine - in this case it will be either 0 or 1.

If 0, then you have specified the G_DISCARD flag.

If 1, then the item actually returned by the Perl subroutine will be stored on the Perl stack - the section *Returning a Scalar* shows how to access this value on the stack. Remember that regardless of how many items the Perl subroutine returns, only the last one will be accessible from the stack - think of the case where only one value is returned as being a list with only one element. Any other items that were returned will not exist by the time control returns from the *call_** function. The section *Returning a list in a scalar context* shows an example of this behavior.

71.3.3 G_ARRAY

Calls the Perl subroutine in a list context.

As with G_SCALAR, this flag has 2 effects:

1. It indicates to the subroutine being called that it is executing in a list context (if it executes *wantarray* the result will be true).
2. It ensures that all items returned from the subroutine will be accessible when control returns from the *call_** function.

The value returned by the *call_** function indicates how many items have been returned by the Perl subroutine.

If 0, then you have specified the G_DISCARD flag.

If not 0, then it will be a count of the number of items returned by the subroutine. These items will be stored on the Perl stack. The section *Returning a list of values* gives an example of using the G_ARRAY flag and the mechanics of accessing the returned items from the Perl stack.

71.3.4 G_DISCARD

By default, the *call_** functions place the items returned from by the Perl subroutine on the stack. If you are not interested in these items, then setting this flag will make Perl get rid of them automatically for you. Note that it is still possible to indicate a context to the Perl subroutine by using either G_SCALAR or G_ARRAY.

If you do not set this flag then it is *very* important that you make sure that any temporaries (i.e., parameters passed to the Perl subroutine and values returned from the subroutine) are disposed of yourself. The section *Returning a Scalar* gives details of how to dispose of these temporaries explicitly and the section *Using Perl to dispose of temporaries* discusses the specific circumstances where you can ignore the problem and let Perl deal with it for you.

71.3.5 G_NOARGS

Whenever a Perl subroutine is called using one of the *call_** functions, it is assumed by default that parameters are to be passed to the subroutine. If you are not passing any parameters to the Perl subroutine, you can save a bit of time by setting this flag. It has the effect of not creating the `@_` array for the Perl subroutine.

Although the functionality provided by this flag may seem straightforward, it should be used only if there is a good reason to do so. The reason for being cautious is that even if you have specified the G_NOARGS flag, it is still possible for the Perl subroutine that has been called to think that you have passed it parameters.

In fact, what can happen is that the Perl subroutine you have called can access the `@_` array from a previous Perl subroutine. This will occur when the code that is executing the *call_** function has itself been called from another Perl subroutine. The code below illustrates this

```
    sub fred
      { print "@_\n"  }

    sub joe
      { &fred }

    &joe(1,2,3) ;
```

This will print

```
    1 2 3
```

What has happened is that `fred` accesses the `@_` array which belongs to `joe`.

71.3.6 G_EVAL

It is possible for the Perl subroutine you are calling to terminate abnormally, e.g., by calling *die* explicitly or by not actually existing. By default, when either of these events occurs, the process will terminate immediately. If you want to trap this type of event, specify the G_EVAL flag. It will put an *eval { }* around the subroutine call.

Whenever control returns from the *call_** function you need to check the `$@` variable as you would in a normal Perl script.

The value returned from the *call_** function is dependent on what other flags have been specified and whether an error has occurred. Here are all the different cases that can occur:

- If the *call_** function returns normally, then the value returned is as specified in the previous sections.
- If G_DISCARD is specified, the return value will always be 0.
- If G_ARRAY is specified *and* an error has occurred, the return value will always be 0.
- If G_SCALAR is specified *and* an error has occurred, the return value will be 1 and the value on the top of the stack will be *undef*. This means that if you have already detected the error by checking `$@` and you want the program to continue, you must remember to pop the *undef* from the stack.

See *Using G_EVAL* for details on using G_EVAL.

71.3.7 G_KEEPERR

You may have noticed that using the G_EVAL flag described above will **always** clear the `$@` variable and set it to a string describing the error iff there was an error in the called code. This unqualified resetting of `$@` can be problematic in the reliable identification of errors using the `eval {}` mechanism, because the possibility exists that perl will call other code (end of block processing code, for example) between the time the error causes `$@` to be set within `eval {}`, and the subsequent statement which checks for the value of `$@` gets executed in the user's script.

This scenario will mostly be applicable to code that is meant to be called from within destructors, asynchronous callbacks, signal handlers, `__DIE__` or `__WARN__` hooks, and `tie` functions. In such situations, you will not want to clear `$@` at all, but simply to append any new errors to any existing value of `$@`.

The G_KEEPERR flag is meant to be used in conjunction with G_EVAL in *call_** functions that are used to implement such code. This flag has no effect when G_EVAL is not used.

When G_KEEPERR is used, any errors in the called code will be prefixed with the string "\t(in cleanup)", and appended to the current value of `$@`.

The G_KEEPERR flag was introduced in Perl version 5.002.

See *Using G_KEEPERR* for an example of a situation that warrants the use of this flag.

71.3.8 Determining the Context

As mentioned above, you can determine the context of the currently executing subroutine in Perl with *wantarray*. The equivalent test can be made in C by using the `GIMME_V` macro, which returns `G_ARRAY` if you have been called in a list context, `G_SCALAR` if in a scalar context, or `G_VOID` if in a void context (i.e. the return value will not be used). An older version of this macro is called `GIMME`; in a void context it returns `G_SCALAR` instead of `G_VOID`. An example of using the `GIMME_V` macro is shown in section *Using GIMME_V*.

71.4 KNOWN PROBLEMS

This section outlines all known problems that exist in the *call_** functions.

1. If you are intending to make use of both the G_EVAL and G_SCALAR flags in your code, use a version of Perl greater than 5.000. There is a bug in version 5.000 of Perl which means that the combination of these two flags will not work as described in the section *FLAG VALUES*.

   Specifically, if the two flags are used when calling a subroutine and that subroutine does not call *die*, the value returned by *call_** will be wrong.

2. In Perl 5.000 and 5.001 there is a problem with using *call_** if the Perl sub you are calling attempts to trap a *die*.

   The symptom of this problem is that the called Perl sub will continue to completion, but whenever it attempts to pass control back to the XSUB, the program will immediately terminate.

   For example, say you want to call this Perl sub

   ```
   sub fred
   {
       eval { die "Fatal Error" ; }
       print "Trapped error: $@\n"
           if $@ ;
   }
   ```

   via this XSUB

   ```
   void
   Call_fred()
       CODE:
       PUSHMARK(SP) ;
       call_pv("fred", G_DISCARD|G_NOARGS) ;
       fprintf(stderr, "back in Call_fred\n") ;
   ```

When `Call_fred` is executed it will print

```
Trapped error: Fatal Error
```

As control never returns to `Call_fred`, the `"back in Call_fred"` string will not get printed.

To work around this problem, you can either upgrade to Perl 5.002 or higher, or use the G_EVAL flag with *call_** as shown below

```
void
Call_fred()
    CODE:
    PUSHMARK(SP) ;
    call_pv("fred", G_EVAL|G_DISCARD|G_NOARGS) ;
    fprintf(stderr, "back in Call_fred\n") ;
```

71.5 EXAMPLES

Enough of the definition talk, let's have a few examples.

Perl provides many macros to assist in accessing the Perl stack. Wherever possible, these macros should always be used when interfacing to Perl internals. We hope this should make the code less vulnerable to any changes made to Perl in the future.

Another point worth noting is that in the first series of examples I have made use of only the *call_pv* function. This has been done to keep the code simpler and ease you into the topic. Wherever possible, if the choice is between using *call_pv* and *call_sv*, you should always try to use *call_sv*. See *Using call_sv* for details.

71.5.1 No Parameters, Nothing returned

This first trivial example will call a Perl subroutine, *PrintUID*, to print out the UID of the process.

```
sub PrintUID
{
    print "UID is $<\n" ;
}
```

and here is a C function to call it

```
static void
call_PrintUID()
{
    dSP ;

    PUSHMARK(SP) ;
    call_pv("PrintUID", G_DISCARD|G_NOARGS) ;
}
```

Simple, eh.

A few points to note about this example.

1. Ignore `dSP` and `PUSHMARK(SP)` for now. They will be discussed in the next example.
2. We aren't passing any parameters to *PrintUID* so G_NOARGS can be specified.
3. We aren't interested in anything returned from *PrintUID*, so G_DISCARD is specified. Even if *PrintUID* was changed to return some value(s), having specified G_DISCARD will mean that they will be wiped by the time control returns from *call_pv*.
4. As *call_pv* is being used, the Perl subroutine is specified as a C string. In this case the subroutine name has been 'hard-wired' into the code.
5. Because we specified G_DISCARD, it is not necessary to check the value returned from *call_pv*. It will always be 0.

71.5.2 Passing Parameters

Now let's make a slightly more complex example. This time we want to call a Perl subroutine, `LeftString`, which will take 2 parameters–a string ($s) and an integer ($n). The subroutine will simply print the first $n characters of the string.

So the Perl subroutine would look like this

```
sub LeftString
{
    my($s, $n) = @_ ;
    print substr($s, 0, $n), "\n" ;
}
```

The C function required to call *LeftString* would look like this.

```
static void
call_LeftString(a, b)
char * a ;
int b ;
{
    dSP ;

    ENTER ;
    SAVETMPS ;

    PUSHMARK(SP) ;
    XPUSHs(sv_2mortal(newSVpv(a, 0)));
    XPUSHs(sv_2mortal(newSViv(b)));
    PUTBACK ;

    call_pv("LeftString", G_DISCARD);

    FREETMPS ;
    LEAVE ;
}
```

Here are a few notes on the C function *call_LeftString*.

1. Parameters are passed to the Perl subroutine using the Perl stack. This is the purpose of the code beginning with the line `dSP` and ending with the line `PUTBACK`. The `dSP` declares a local copy of the stack pointer. This local copy should **always** be accessed as `SP`.

2. If you are going to put something onto the Perl stack, you need to know where to put it. This is the purpose of the macro `dSP`–it declares and initializes a *local* copy of the Perl stack pointer.

   All the other macros which will be used in this example require you to have used this macro.

   The exception to this rule is if you are calling a Perl subroutine directly from an XSUB function. In this case it is not necessary to use the `dSP` macro explicitly–it will be declared for you automatically.

3. Any parameters to be pushed onto the stack should be bracketed by the `PUSHMARK` and `PUTBACK` macros. The purpose of these two macros, in this context, is to count the number of parameters you are pushing automatically. Then whenever Perl is creating the `@_` array for the subroutine, it knows how big to make it.

   The `PUSHMARK` macro tells Perl to make a mental note of the current stack pointer. Even if you aren't passing any parameters (like the example shown in the section *No Parameters, Nothing returned*) you must still call the `PUSHMARK` macro before you can call any of the *call_** functions–Perl still needs to know that there are no parameters.

   The `PUTBACK` macro sets the global copy of the stack pointer to be the same as our local copy. If we didn't do this *call_pv* wouldn't know where the two parameters we pushed were–remember that up to now all the stack pointer manipulation we have done is with our local copy, *not* the global copy.

4. Next, we come to XPUSHs. This is where the parameters actually get pushed onto the stack. In this case we are pushing a string and an integer.

   See XSUBs and the Argument Stack in *perlguts* for details on how the XPUSH macros work.

5. Because we created temporary values (by means of sv_2mortal() calls) we will have to tidy up the Perl stack and dispose of mortal SVs.

   This is the purpose of

   ```
   ENTER ;
   SAVETMPS ;
   ```

   at the start of the function, and

   ```
   FREETMPS ;
   LEAVE ;
   ```

   at the end. The `ENTER`/`SAVETMPS` pair creates a boundary for any temporaries we create. This means that the temporaries we get rid of will be limited to those which were created after these calls.

   The `FREETMPS`/`LEAVE` pair will get rid of any values returned by the Perl subroutine (see next example), plus it will also dump the mortal SVs we have created. Having `ENTER`/`SAVETMPS` at the beginning of the code makes sure that no other mortals are destroyed.

   Think of these macros as working a bit like using `{` and `}` in Perl to limit the scope of local variables.

   See the section *Using Perl to dispose of temporaries* for details of an alternative to using these macros.

6. Finally, *LeftString* can now be called via the *call_pv* function. The only flag specified this time is G_DISCARD. Because we are passing 2 parameters to the Perl subroutine this time, we have not specified G_NOARGS.

71.5.3 Returning a Scalar

Now for an example of dealing with the items returned from a Perl subroutine.

Here is a Perl subroutine, *Adder*, that takes 2 integer parameters and simply returns their sum.

```
sub Adder
{
    my($a, $b) = @_ ;
    $a + $b ;
}
```

Because we are now concerned with the return value from *Adder*, the C function required to call it is now a bit more complex.

```
static void
call_Adder(a, b)
int a ;
int b ;
{
    dSP ;
    int count ;

    ENTER ;
    SAVETMPS;
```

```
        PUSHMARK(SP) ;
        XPUSHs(sv_2mortal(newSViv(a)));
        XPUSHs(sv_2mortal(newSViv(b)));
        PUTBACK ;

        count = call_pv("Adder", G_SCALAR);

        SPAGAIN ;

        if (count != 1)
            croak("Big trouble\n") ;

        printf ("The sum of %d and %d is %d\n", a, b, POPi) ;

        PUTBACK ;
        FREETMPS ;
        LEAVE ;
    }
```

Points to note this time are

1. The only flag specified this time was G_SCALAR. That means the `@_` array will be created and that the value returned by *Adder* will still exist after the call to *call_pv*.
2. The purpose of the macro `SPAGAIN` is to refresh the local copy of the stack pointer. This is necessary because it is possible that the memory allocated to the Perl stack has been reallocated whilst in the *call_pv* call.

   If you are making use of the Perl stack pointer in your code you must always refresh the local copy using SPAGAIN whenever you make use of the *call_** functions or any other Perl internal function.
3. Although only a single value was expected to be returned from *Adder*, it is still good practice to check the return code from *call_pv* anyway.

   Expecting a single value is not quite the same as knowing that there will be one. If someone modified *Adder* to return a list and we didn't check for that possibility and take appropriate action the Perl stack would end up in an inconsistent state. That is something you *really* don't want to happen ever.
4. The `POPi` macro is used here to pop the return value from the stack. In this case we wanted an integer, so `POPi` was used.

   Here is the complete list of POP macros available, along with the types they return.

   ```
   POPs        SV
   POPp        pointer
   POPn        double
   POPi        integer
   POPl        long
   ```
5. The final `PUTBACK` is used to leave the Perl stack in a consistent state before exiting the function. This is necessary because when we popped the return value from the stack with `POPi` it updated only our local copy of the stack pointer. Remember, `PUTBACK` sets the global stack pointer to be the same as our local copy.

71.5.4 Returning a list of values

Now, let's extend the previous example to return both the sum of the parameters and the difference.
Here is the Perl subroutine

```
sub AddSubtract
{
   my($a, $b) = @_ ;
   ($a+$b, $a-$b) ;
}
```

and this is the C function

```
static void
call_AddSubtract(a, b)
int a ;
int b ;
{
    dSP ;
    int count ;

    ENTER ;
    SAVETMPS;

    PUSHMARK(SP) ;
    XPUSHs(sv_2mortal(newSViv(a)));
    XPUSHs(sv_2mortal(newSViv(b)));
    PUTBACK ;

    count = call_pv("AddSubtract", G_ARRAY);

    SPAGAIN ;

    if (count != 2)
        croak("Big trouble\n") ;

    printf ("%d - %d = %d\n", a, b, POPi) ;
    printf ("%d + %d = %d\n", a, b, POPi) ;

    PUTBACK ;
    FREETMPS ;
    LEAVE ;
}
```

If *call_AddSubtract* is called like this

```
call_AddSubtract(7, 4) ;
```

then here is the output

```
7 - 4 = 3
7 + 4 = 11
```

Notes

1. We wanted list context, so G_ARRAY was used.
2. Not surprisingly `POPi` is used twice this time because we were retrieving 2 values from the stack. The important thing to note is that when using the `POP*` macros they come off the stack in *reverse* order.

71.5.5 Returning a list in a scalar context

Say the Perl subroutine in the previous section was called in a scalar context, like this

```
static void
call_AddSubScalar(a, b)
int a ;
int b ;
{
    dSP ;
    int count ;
    int i ;

    ENTER ;
    SAVETMPS;

    PUSHMARK(SP) ;
    XPUSHs(sv_2mortal(newSViv(a)));
    XPUSHs(sv_2mortal(newSViv(b)));
    PUTBACK ;

    count = call_pv("AddSubtract", G_SCALAR);

    SPAGAIN ;

    printf ("Items Returned = %d\n", count) ;

    for (i = 1 ; i <= count ; ++i)
        printf ("Value %d = %d\n", i, POPi) ;

    PUTBACK ;
    FREETMPS ;
    LEAVE ;
}
```

The other modification made is that *call_AddSubScalar* will print the number of items returned from the Perl subroutine and their value (for simplicity it assumes that they are integer). So if *call_AddSubScalar* is called

```
call_AddSubScalar(7, 4) ;
```

then the output will be

```
Items Returned = 1
Value 1 = 3
```

In this case the main point to note is that only the last item in the list is returned from the subroutine, *AddSubtract* actually made it back to *call_AddSubScalar*.

71.5.6 Returning Data from Perl via the parameter list

It is also possible to return values directly via the parameter list - whether it is actually desirable to do it is another matter entirely.

The Perl subroutine, *Inc*, below takes 2 parameters and increments each directly.

```
sub Inc
{
    ++ $_[0] ;
    ++ $_[1] ;
}
```

and here is a C function to call it.

```
static void
call_Inc(a, b)
int a ;
int b ;
{
    dSP ;
    int count ;
    SV * sva ;
    SV * svb ;

    ENTER ;
    SAVETMPS;

    sva = sv_2mortal(newSViv(a)) ;
    svb = sv_2mortal(newSViv(b)) ;

    PUSHMARK(SP) ;
    XPUSHs(sva);
    XPUSHs(svb);
    PUTBACK ;

    count = call_pv("Inc", G_DISCARD);

    if (count != 0)
        croak ("call_Inc: expected 0 values from 'Inc', got %d\n",
               count) ;

    printf ("%d + 1 = %d\n", a, SvIV(sva)) ;
    printf ("%d + 1 = %d\n", b, SvIV(svb)) ;

    FREETMPS ;
    LEAVE ;
}
```

To be able to access the two parameters that were pushed onto the stack after they return from *call_pv* it is necessary to make a note of their addresses–thus the two variables `sva` and `svb`.

The reason this is necessary is that the area of the Perl stack which held them will very likely have been overwritten by something else by the time control returns from *call_pv*.

71.5.7 Using G_EVAL

Now an example using G_EVAL. Below is a Perl subroutine which computes the difference of its 2 parameters. If this would result in a negative result, the subroutine calls *die*.

```
    sub Subtract
    {
        my ($a, $b) = @_ ;

        die "death can be fatal\n" if $a < $b ;

        $a - $b ;
    }
```

and some C to call it

```
    static void
    call_Subtract(a, b)
    int a ;
    int b ;
    {
        dSP ;
        int count ;

        ENTER ;
        SAVETMPS;

        PUSHMARK(SP) ;
        XPUSHs(sv_2mortal(newSViv(a)));
        XPUSHs(sv_2mortal(newSViv(b)));
        PUTBACK ;

        count = call_pv("Subtract", G_EVAL|G_SCALAR);

        SPAGAIN ;

        /* Check the eval first */
        if (SvTRUE(ERRSV))
        {
            STRLEN n_a;
            printf ("Uh oh - %s\n", SvPV(ERRSV, n_a)) ;
            POPs ;
        }
        else
        {
            if (count != 1)
               croak("call_Subtract: wanted 1 value from 'Subtract', got %d\n",
                        count) ;

            printf ("%d - %d = %d\n", a, b, POPi) ;
        }

        PUTBACK ;
        FREETMPS ;
        LEAVE ;
    }
```

If *call_Subtract* is called thus

```
call_Subtract(4, 5)
```

the following will be printed

```
Uh oh - death can be fatal
```

Notes

1. We want to be able to catch the *die* so we have used the G_EVAL flag. Not specifying this flag would mean that the program would terminate immediately at the *die* statement in the subroutine *Subtract*.
2. The code

   ```
   if (SvTRUE(ERRSV))
   {
       STRLEN n_a;
       printf ("Uh oh - %s\n", SvPV(ERRSV, n_a)) ;
       POPs ;
   }
   ```

   is the direct equivalent of this bit of Perl

   ```
   print "Uh oh - $@\n" if $@ ;
   ```

   `PL_errgv` is a perl global of type `GV *` that points to the symbol table entry containing the error. `ERRSV` therefore refers to the C equivalent of `$@`.
3. Note that the stack is popped using `POPs` in the block where `SvTRUE(ERRSV)` is true. This is necessary because whenever a *call_** function invoked with G_EVAL|G_SCALAR returns an error, the top of the stack holds the value *undef*. Because we want the program to continue after detecting this error, it is essential that the stack is tidied up by removing the *undef*.

71.5.8 Using G_KEEPERR

Consider this rather facetious example, where we have used an XS version of the call_Subtract example above inside a destructor:

```
package Foo;
sub new { bless {}, $_[0] }
sub Subtract {
    my($a,$b) = @_;
    die "death can be fatal" if $a < $b ;
    $a - $b;
}
sub DESTROY { call_Subtract(5, 4); }
sub foo { die "foo dies"; }

package main;
eval { Foo->new->foo };
print "Saw: $@" if $@;             # should be, but isn't
```

This example will fail to recognize that an error occurred inside the `eval {}`. Here's why: the call_Subtract code got executed while perl was cleaning up temporaries when exiting the eval block, and because call_Subtract is implemented with *call_pv* using the G_EVAL flag, it promptly reset `$@`. This results in the failure of the outermost test for `$@`, and thereby the failure of the error trap.

Appending the G_KEEPERR flag, so that the *call_pv* call in call_Subtract reads:

```
    count = call_pv("Subtract", G_EVAL|G_SCALAR|G_KEEPERR);
```

will preserve the error and restore reliable error handling.

71.5.9 Using call_sv

In all the previous examples I have 'hard-wired' the name of the Perl subroutine to be called from C. Most of the time though, it is more convenient to be able to specify the name of the Perl subroutine from within the Perl script.

Consider the Perl code below

```
sub fred
{
    print "Hello there\n" ;
}

CallSubPV("fred") ;
```

Here is a snippet of XSUB which defines *CallSubPV*.

```
void
CallSubPV(name)
    char *  name
    CODE:
    PUSHMARK(SP) ;
    call_pv(name, G_DISCARD|G_NOARGS) ;
```

That is fine as far as it goes. The thing is, the Perl subroutine can be specified as only a string. For Perl 4 this was adequate, but Perl 5 allows references to subroutines and anonymous subroutines. This is where *call_sv* is useful.

The code below for *CallSubSV* is identical to *CallSubPV* except that the `name` parameter is now defined as an SV* and we use *call_sv* instead of *call_pv*.

```
void
CallSubSV(name)
    SV *    name
    CODE:
    PUSHMARK(SP) ;
    call_sv(name, G_DISCARD|G_NOARGS) ;
```

Because we are using an SV to call *fred* the following can all be used

```
CallSubSV("fred") ;
CallSubSV(\&fred) ;
$ref = \&fred ;
CallSubSV($ref) ;
CallSubSV( sub { print "Hello there\n" } ) ;
```

As you can see, *call_sv* gives you much greater flexibility in how you can specify the Perl subroutine.

You should note that if it is necessary to store the SV (`name` in the example above) which corresponds to the Perl subroutine so that it can be used later in the program, it not enough just to store a copy of the pointer to the SV. Say the code above had been like this

```
static SV * rememberSub ;

void
SaveSub1(name)
    SV *    name
    CODE:
    rememberSub = name ;
void
CallSavedSub1()
    CODE:
    PUSHMARK(SP) ;
    call_sv(rememberSub, G_DISCARD|G_NOARGS) ;
```

The reason this is wrong is that by the time you come to use the pointer `rememberSub` in `CallSavedSub1`, it may or may not still refer to the Perl subroutine that was recorded in `SaveSub1`. This is particularly true for these cases

```
    SaveSub1(\&fred) ;
    CallSavedSub1() ;

    SaveSub1( sub { print "Hello there\n" } ) ;
    CallSavedSub1() ;
```

By the time each of the `SaveSub1` statements above have been executed, the SV*s which corresponded to the parameters will no longer exist. Expect an error message from Perl of the form

```
    Can't use an undefined value as a subroutine reference at ...
```

for each of the `CallSavedSub1` lines.

Similarly, with this code

```
    $ref = \&fred ;
    SaveSub1($ref) ;
    $ref = 47 ;
    CallSavedSub1() ;
```

you can expect one of these messages (which you actually get is dependent on the version of Perl you are using)

```
    Not a CODE reference at ...
    Undefined subroutine &main::47 called ...
```

The variable $ref may have referred to the subroutine `fred` whenever the call to `SaveSub1` was made but by the time `CallSavedSub1` gets called it now holds the number `47`. Because we saved only a pointer to the original SV in `SaveSub1`, any changes to $ref will be tracked by the pointer `rememberSub`. This means that whenever `CallSavedSub1` gets called, it will attempt to execute the code which is referenced by the SV* `rememberSub`. In this case though, it now refers to the integer `47`, so expect Perl to complain loudly.

A similar but more subtle problem is illustrated with this code

```
    $ref = \&fred ;
    SaveSub1($ref) ;
    $ref = \&joe ;
    CallSavedSub1() ;
```

This time whenever `CallSavedSub1` get called it will execute the Perl subroutine `joe` (assuming it exists) rather than `fred` as was originally requested in the call to `SaveSub1`.

To get around these problems it is necessary to take a full copy of the SV. The code below shows `SaveSub2` modified to do that

```
    static SV * keepSub = (SV*)NULL ;
    void
    SaveSub2(name)
        SV *    name
        CODE:
        /* Take a copy of the callback */
        if (keepSub == (SV*)NULL)
            /* First time, so create a new SV */
            keepSub = newSVsv(name) ;
        else
            /* Been here before, so overwrite */
            SvSetSV(keepSub, name) ;

    void
    CallSavedSub2()
        CODE:
        PUSHMARK(SP) ;
        call_sv(keepSub, G_DISCARD|G_NOARGS) ;
```

To avoid creating a new SV every time `SaveSub2` is called, the function first checks to see if it has been called before. If not, then space for a new SV is allocated and the reference to the Perl subroutine, `name` is copied to the variable `keepSub` in one operation using `newSVsv`. Thereafter, whenever `SaveSub2` is called the existing SV, `keepSub`, is overwritten with the new value using `SvSetSV`.

71.5.10 Using call_argv

Here is a Perl subroutine which prints whatever parameters are passed to it.

```
    sub PrintList
    {
        my(@list) = @_ ;

        foreach (@list) { print "$_\n" }
    }
```

and here is an example of *call_argv* which will call *PrintList*.

```
    static char * words[] = {"alpha", "beta", "gamma", "delta", NULL} ;

    static void
    call_PrintList()
    {
        dSP ;

        call_argv("PrintList", G_DISCARD, words) ;
    }
```

Note that it is not necessary to call `PUSHMARK` in this instance. This is because *call_argv* will do it for you.

71.5.11 Using call_method

Consider the following Perl code

```
    {
        package Mine ;

        sub new
        {
            my($type) = shift ;
            bless [@_]
        }

        sub Display
        {
            my ($self, $index) = @_ ;
            print "$index: $$self[$index]\n" ;
        }

        sub PrintID
        {
            my($class) = @_ ;
            print "This is Class $class version 1.0\n" ;
        }
    }
```

It implements just a very simple class to manage an array. Apart from the constructor, `new`, it declares methods, one static and one virtual. The static method, `PrintID`, prints out simply the class name and a version number. The virtual method, `Display`, prints out a single element of the array. Here is an all Perl example of using it.

```
    $a = new Mine ('red', 'green', 'blue') ;
    $a->Display(1) ;
    PrintID Mine;
```

will print

```
    1: green
    This is Class Mine version 1.0
```

Calling a Perl method from C is fairly straightforward. The following things are required

- a reference to the object for a virtual method or the name of the class for a static method.
- the name of the method.
- any other parameters specific to the method.

Here is a simple XSUB which illustrates the mechanics of calling both the `PrintID` and `Display` methods from C.

```
    void
    call_Method(ref, method, index)
        SV *    ref
        char *  method
        int             index
        CODE:
        PUSHMARK(SP);
        XPUSHs(ref);
        XPUSHs(sv_2mortal(newSViv(index))) ;
        PUTBACK;
        call_method(method, G_DISCARD) ;

    void
    call_PrintID(class, method)
        char *  class
        char *  method
        CODE:
        PUSHMARK(SP);
        XPUSHs(sv_2mortal(newSVpv(class, 0))) ;
        PUTBACK;

        call_method(method, G_DISCARD) ;
```

So the methods `PrintID` and `Display` can be invoked like this

```
    $a = new Mine ('red', 'green', 'blue') ;
    call_Method($a, 'Display', 1) ;
    call_PrintID('Mine', 'PrintID') ;
```

The only thing to note is that in both the static and virtual methods, the method name is not passed via the stack–it is used as the first parameter to *call_method*.

71.5.12 Using GIMME_V

Here is a trivial XSUB which prints the context in which it is currently executing.

```
    void
    PrintContext()
        CODE:
        I32 gimme = GIMME_V;
        if (gimme == G_VOID)
            printf ("Context is Void\n") ;
        else if (gimme == G_SCALAR)
            printf ("Context is Scalar\n") ;
        else
            printf ("Context is Array\n") ;
```

and here is some Perl to test it

```
    PrintContext ;
    $a = PrintContext ;
    @a = PrintContext ;
```

The output from that will be

```
    Context is Void
    Context is Scalar
    Context is Array
```

71.5.13 Using Perl to dispose of temporaries

In the examples given to date, any temporaries created in the callback (i.e., parameters passed on the stack to the *call_** function or values returned via the stack) have been freed by one of these methods

- specifying the G_DISCARD flag with *call_**.
- explicitly disposed of using the `ENTER`/`SAVETMPS` - `FREETMPS`/`LEAVE` pairing.

There is another method which can be used, namely letting Perl do it for you automatically whenever it regains control after the callback has terminated. This is done by simply not using the

```
    ENTER ;
    SAVETMPS ;
    ...
    FREETMPS ;
    LEAVE ;
```

sequence in the callback (and not, of course, specifying the G_DISCARD flag).

If you are going to use this method you have to be aware of a possible memory leak which can arise under very specific circumstances. To explain these circumstances you need to know a bit about the flow of control between Perl and the callback routine.

The examples given at the start of the document (an error handler and an event driven program) are typical of the two main sorts of flow control that you are likely to encounter with callbacks. There is a very important distinction between them, so pay attention.

In the first example, an error handler, the flow of control could be as follows. You have created an interface to an external library. Control can reach the external library like this

```
    perl --> XSUB --> external library
```

Whilst control is in the library, an error condition occurs. You have previously set up a Perl callback to handle this situation, so it will get executed. Once the callback has finished, control will drop back to Perl again. Here is what the flow of control will be like in that situation

```
    perl --> XSUB --> external library
                      ...
                      error occurs
                      ...
                      external library --> call_* --> perl
                                                          |
    perl <-- XSUB <-- external library <-- call_* <----+
```

After processing of the error using *call_** is completed, control reverts back to Perl more or less immediately.

In the diagram, the further right you go the more deeply nested the scope is. It is only when control is back with perl on the extreme left of the diagram that you will have dropped back to the enclosing scope and any temporaries you have left hanging around will be freed.

In the second example, an event driven program, the flow of control will be more like this

```
    perl --> XSUB --> event handler
                      ...
                      event handler --> call_* --> perl
                                                       |
                      event handler <-- call_* <----+
                      ...
                      event handler --> call_* --> perl
```

```
                                        |
                    event handler <-- call_* <----+
                    ...
                    event handler --> call_* --> perl
                                                  |
                    event handler <-- call_* <----+
```

In this case the flow of control can consist of only the repeated sequence

```
    event handler --> call_* --> perl
```

for practically the complete duration of the program. This means that control may *never* drop back to the surrounding scope in Perl at the extreme left.

So what is the big problem? Well, if you are expecting Perl to tidy up those temporaries for you, you might be in for a long wait. For Perl to dispose of your temporaries, control must drop back to the enclosing scope at some stage. In the event driven scenario that may never happen. This means that as time goes on, your program will create more and more temporaries, none of which will ever be freed. As each of these temporaries consumes some memory your program will eventually consume all the available memory in your system–kapow!

So here is the bottom line–if you are sure that control will revert back to the enclosing Perl scope fairly quickly after the end of your callback, then it isn't absolutely necessary to dispose explicitly of any temporaries you may have created. Mind you, if you are at all uncertain about what to do, it doesn't do any harm to tidy up anyway.

71.5.14 Strategies for storing Callback Context Information

Potentially one of the trickiest problems to overcome when designing a callback interface can be figuring out how to store the mapping between the C callback function and the Perl equivalent.

To help understand why this can be a real problem first consider how a callback is set up in an all C environment. Typically a C API will provide a function to register a callback. This will expect a pointer to a function as one of its parameters. Below is a call to a hypothetical function `register_fatal` which registers the C function to get called when a fatal error occurs.

```
    register_fatal(cb1) ;
```

The single parameter `cb1` is a pointer to a function, so you must have defined `cb1` in your code, say something like this

```
    static void
    cb1()
    {
        printf ("Fatal Error\n") ;
        exit(1) ;
    }
```

Now change that to call a Perl subroutine instead

```
    static SV * callback = (SV*)NULL;

    static void
    cb1()
    {
        dSP ;

        PUSHMARK(SP) ;
        /* Call the Perl sub to process the callback */
        call_sv(callback, G_DISCARD) ;
    }

    void
    register_fatal(fn)
        SV *    fn
        CODE:
        /* Remember the Perl sub */
        if (callback == (SV*)NULL)
            callback = newSVsv(fn) ;
        else
            SvSetSV(callback, fn) ;

        /* register the callback with the external library */
        register_fatal(cb1) ;
```

where the Perl equivalent of `register_fatal` and the callback it registers, `pcb1`, might look like this

```
    # Register the sub pcb1
    register_fatal(\&pcb1) ;

    sub pcb1
    {
        die "I'm dying...\n" ;
    }
```

The mapping between the C callback and the Perl equivalent is stored in the global variable `callback`.

This will be adequate if you ever need to have only one callback registered at any time. An example could be an error handler like the code sketched out above. Remember though, repeated calls to `register_fatal` will replace the previously registered callback function with the new one.

Say for example you want to interface to a library which allows asynchronous file i/o. In this case you may be able to register a callback whenever a read operation has completed. To be of any use we want to be able to call separate Perl subroutines for each file that is opened. As it stands, the error handler example above would not be adequate as it allows only a single callback to be defined at any time. What we require is a means of storing the mapping between the opened file and the Perl subroutine we want to be called for that file.

Say the i/o library has a function `asynch_read` which associates a C function `ProcessRead` with a file handle `fh`–this assumes that it has also provided some routine to open the file and so obtain the file handle.

```
    asynch_read(fh, ProcessRead)
```

This may expect the C *ProcessRead* function of this form

```
    void
    ProcessRead(fh, buffer)
    int fh ;
    char *      buffer ;
    {
         ...
    }
```

To provide a Perl interface to this library we need to be able to map between the `fh` parameter and the Perl subroutine we want called. A hash is a convenient mechanism for storing this mapping. The code below shows a possible implementation

```
    static HV * Mapping = (HV*)NULL ;

    void
    asynch_read(fh, callback)
        int     fh
        SV *    callback
        CODE:
        /* If the hash doesn't already exist, create it */
        if (Mapping == (HV*)NULL)
            Mapping = newHV() ;

        /* Save the fh -> callback mapping */
        hv_store(Mapping, (char*)&fh, sizeof(fh), newSVsv(callback), 0) ;

        /* Register with the C Library */
        asynch_read(fh, asynch_read_if) ;
```

and `asynch_read_if` could look like this

```
    static void
    asynch_read_if(fh, buffer)
    int fh ;
    char *      buffer ;
    {
        dSP ;
        SV ** sv ;

        /* Get the callback associated with fh */
        sv =  hv_fetch(Mapping, (char*)&fh , sizeof(fh), FALSE) ;
        if (sv == (SV**)NULL)
            croak("Internal error...\n") ;

        PUSHMARK(SP) ;
        XPUSHs(sv_2mortal(newSViv(fh))) ;
        XPUSHs(sv_2mortal(newSVpv(buffer, 0))) ;
        PUTBACK ;

        /* Call the Perl sub */
        call_sv(*sv, G_DISCARD) ;
    }
```

For completeness, here is `asynch_close`. This shows how to remove the entry from the hash `Mapping`.

```
    void
    asynch_close(fh)
        int     fh
        CODE:
        /* Remove the entry from the hash */
        (void) hv_delete(Mapping, (char*)&fh, sizeof(fh), G_DISCARD) ;

        /* Now call the real asynch_close */
        asynch_close(fh) ;
```

So the Perl interface would look like this

```
    sub callback1
    {
        my($handle, $buffer) = @_ ;
    }

    # Register the Perl callback
    asynch_read($fh, \&callback1) ;

    asynch_close($fh) ;
```

The mapping between the C callback and Perl is stored in the global hash `Mapping` this time. Using a hash has the distinct advantage that it allows an unlimited number of callbacks to be registered.

What if the interface provided by the C callback doesn't contain a parameter which allows the file handle to Perl subroutine mapping? Say in the asynchronous i/o package, the callback function gets passed only the `buffer` parameter like this

```
    void
    ProcessRead(buffer)
    char *      buffer ;
    {
        ...
    }
```

Without the file handle there is no straightforward way to map from the C callback to the Perl subroutine.

In this case a possible way around this problem is to predefine a series of C functions to act as the interface to Perl, thus

```
    #define MAX_CB              3
    #define NULL_HANDLE -1
    typedef void (*FnMap)() ;

    struct MapStruct {
        FnMap    Function ;
        SV *     PerlSub ;
        int      Handle ;
      } ;

    static void  fn1() ;
    static void  fn2() ;
    static void  fn3() ;

    static struct MapStruct Map [MAX_CB] =
        {
            { fn1, NULL, NULL_HANDLE },
            { fn2, NULL, NULL_HANDLE },
            { fn3, NULL, NULL_HANDLE }
        } ;

    static void
    Pcb(index, buffer)
    int index ;
    char * buffer ;
    {
        dSP ;
        PUSHMARK(SP) ;
        XPUSHs(sv_2mortal(newSVpv(buffer, 0))) ;
        PUTBACK ;

        /* Call the Perl sub */
        call_sv(Map[index].PerlSub, G_DISCARD) ;
    }

    static void
    fn1(buffer)
    char * buffer ;
    {
        Pcb(0, buffer) ;
    }

    static void
    fn2(buffer)
    char * buffer ;
    {
        Pcb(1, buffer) ;
    }

    static void
    fn3(buffer)
    char * buffer ;
    {
        Pcb(2, buffer) ;
    }

    void
    array_asynch_read(fh, callback)
        int             fh
        SV *    callback
        CODE:
        int index ;
        int null_index = MAX_CB ;

        /* Find the same handle or an empty entry */
        for (index = 0 ; index < MAX_CB ; ++index)
        {
            if (Map[index].Handle == fh)
                break ;

            if (Map[index].Handle == NULL_HANDLE)
                null_index = index ;
        }

        if (index == MAX_CB && null_index == MAX_CB)
            croak ("Too many callback functions registered\n") ;

        if (index == MAX_CB)
            index = null_index ;

        /* Save the file handle */
        Map[index].Handle = fh ;
        /* Remember the Perl sub */
        if (Map[index].PerlSub == (SV*)NULL)
            Map[index].PerlSub = newSVsv(callback) ;
        else
            SvSetSV(Map[index].PerlSub, callback) ;

        asynch_read(fh, Map[index].Function) ;

    void
    array_asynch_close(fh)
        int     fh
        CODE:
        int index ;

        /* Find the file handle */
        for (index = 0; index < MAX_CB ; ++ index)
            if (Map[index].Handle == fh)
                break ;

        if (index == MAX_CB)
            croak ("could not close fh %d\n", fh) ;

        Map[index].Handle = NULL_HANDLE ;
        SvREFCNT_dec(Map[index].PerlSub) ;
        Map[index].PerlSub = (SV*)NULL ;

        asynch_close(fh) ;
```

In this case the functions `fn1`, `fn2`, and `fn3` are used to remember the Perl subroutine to be called. Each of the functions holds a separate hard-wired index which is used in the function `Pcb` to access the `Map` array and actually call the Perl subroutine.

There are some obvious disadvantages with this technique.

Firstly, the code is considerably more complex than with the previous example.

Secondly, there is a hard-wired limit (in this case 3) to the number of callbacks that can exist simultaneously. The only way to increase the limit is by modifying the code to add more functions and then recompiling. None the less, as long as the number of functions is chosen with some care, it is still a workable solution and in some cases is the only one available.

To summarize, here are a number of possible methods for you to consider for storing the mapping between C and the Perl callback

1. Ignore the problem - Allow only 1 callback

   For a lot of situations, like interfacing to an error handler, this may be a perfectly adequate solution.

2. Create a sequence of callbacks - hard wired limit

   If it is impossible to tell from the parameters passed back from the C callback what the context is, then you may need to create a sequence of C callback interface functions, and store pointers to each in an array.

3. Use a parameter to map to the Perl callback

   A hash is an ideal mechanism to store the mapping between C and Perl.

71.5.15 Alternate Stack Manipulation

Although I have made use of only the POP* macros to access values returned from Perl subroutines, it is also possible to bypass these macros and read the stack using the ST macro (See *perlxs* for a full description of the ST macro).

Most of the time the POP* macros should be adequate, the main problem with them is that they force you to process the returned values in sequence. This may not be the most suitable way to process the values in some cases. What we want is to be able to access the stack in a random order. The ST macro as used when coding an XSUB is ideal for this purpose.

The code below is the example given in the section *Returning a list of values* recoded to use ST instead of POP*.

```
static void
call_AddSubtract2(a, b)
int a ;
int b ;
{
    dSP ;
    I32 ax ;
    int count ;

    ENTER ;
    SAVETMPS;

    PUSHMARK(SP) ;
    XPUSHs(sv_2mortal(newSViv(a)));
    XPUSHs(sv_2mortal(newSViv(b)));
    PUTBACK ;

    count = call_pv("AddSubtract", G_ARRAY);

    SPAGAIN ;
    SP -= count ;
    ax = (SP - PL_stack_base) + 1 ;

    if (count != 2)
        croak("Big trouble\n") ;

    printf ("%d + %d = %d\n", a, b, SvIV(ST(0))) ;
    printf ("%d - %d = %d\n", a, b, SvIV(ST(1))) ;

    PUTBACK ;
    FREETMPS ;
    LEAVE ;
}
```

Notes

1. Notice that it was necessary to define the variable ax. This is because the ST macro expects it to exist. If we were in an XSUB it would not be necessary to define ax as it is already defined for you.

2. The code

   ```
   SPAGAIN ;
   SP -= count ;
   ax = (SP - PL_stack_base) + 1 ;
   ```

   sets the stack up so that we can use the ST macro.

3. Unlike the original coding of this example, the returned values are not accessed in reverse order. So ST(0) refers to the first value returned by the Perl subroutine and ST(count-1) refers to the last.

71.5.16 Creating and calling an anonymous subroutine in C

As we’ve already shown, `call_sv` can be used to invoke an anonymous subroutine. However, our example showed a Perl script invoking an XSUB to perform this operation. Let’s see how it can be done inside our C code:

```
...

SV *cvrv = eval_pv("sub { print 'You will not find me cluttering any namespace!' }", TRUE);

...

call_sv(cvrv, G_VOID|G_NOARGS);
```

`eval_pv` is used to compile the anonymous subroutine, which will be the return value as well (read more about `eval_pv` in eval_pv in *perlapi*). Once this code reference is in hand, it can be mixed in with all the previous examples we’ve shown.

Chapter 72

perlapi

Autogenerated documentation for the perl public API

72.1 DESCRIPTION

This file contains the documentation of the perl public API generated by embed.pl, specifically a listing of functions, macros, flags, and variables that may be used by extension writers. The interfaces of any functions that are not listed here are subject to change without notice. For this reason, blindly using functions listed in proto.h is to be avoided when writing extensions.

Note that all Perl API global variables must be referenced with the `PL_` prefix. Some macros are provided for compatibility with the older, unadorned names, but this support may be disabled in a future release.

The listing is alphabetical, case insensitive.

72.2 "Gimme" Values

GIMME

A backward-compatible version of `GIMME_V` which can only return `G_SCALAR` or `G_ARRAY`; in a void context, it returns `G_SCALAR`. Deprecated. Use `GIMME_V` instead.

```
        U32     GIMME
```

GIMME_V

The XSUB-writer's equivalent to Perl's `wantarray`. Returns `G_VOID`, `G_SCALAR` or `G_ARRAY` for void, scalar or list context, respectively.

```
        U32     GIMME_V
```

G_ARRAY

Used to indicate list context. See `GIMME_V`, `GIMME` and *perlcall*.

G_DISCARD

Indicates that arguments returned from a callback should be discarded. See *perlcall*.

G_EVAL

Used to force a Perl `eval` wrapper around a callback. See *perlcall*.

G_NOARGS

Indicates that no arguments are being sent to a callback. See *perlcall*.

G_SCALAR

Used to indicate scalar context. See `GIMME_V`, `GIMME`, and *perlcall*.

G_VOID

Used to indicate void context. See `GIMME_V` and *perlcall*.

72.3 Array Manipulation Functions

AvFILL

Same as `av_len()`. Deprecated, use `av_len()` instead.

```
        int     AvFILL(AV* av)
```

av_clear

Clears an array, making it empty. Does not free the memory used by the array itself.

```
        void    av_clear(AV* ar)
```

av_delete

Deletes the element indexed by `key` from the array. Returns the deleted element. `flags` is currently ignored.

```
        SV*     av_delete(AV* ar, I32 key, I32 flags)
```

av_exists

Returns true if the element indexed by `key` has been initialized.

This relies on the fact that uninitialized array elements are set to `&PL_sv_undef`.

```
        bool    av_exists(AV* ar, I32 key)
```

av_extend

Pre-extend an array. The `key` is the index to which the array should be extended.

```
        void    av_extend(AV* ar, I32 key)
```

av_fetch

Returns the SV at the specified index in the array. The `key` is the index. If `lval` is set then the fetch will be part of a store. Check that the return value is non-null before dereferencing it to a `SV*`.

See Understanding the Magic of Tied Hashes and Arrays in *perlguts* for more information on how to use this function on tied arrays.

```
        SV**    av_fetch(AV* ar, I32 key, I32 lval)
```

av_fill

Ensure than an array has a given number of elements, equivalent to Perl's `$#array = $fill;`.

```
        void    av_fill(AV* ar, I32 fill)
```

av_len

Returns the highest index in the array. Returns -1 if the array is empty.

```
        I32     av_len(AV* ar)
```

av_make

Creates a new AV and populates it with a list of SVs. The SVs are copied into the array, so they may be freed after the call to av_make. The new AV will have a reference count of 1.

```
        AV*     av_make(I32 size, SV** svp)
```

av_pop

Pops an SV off the end of the array. Returns `&PL_sv_undef` if the array is empty.

```
        SV*     av_pop(AV* ar)
```

av_push

Pushes an SV onto the end of the array. The array will grow automatically to accommodate the addition.

```
        void    av_push(AV* ar, SV* val)
```

av_shift

Shifts an SV off the beginning of the array.

```
        SV*     av_shift(AV* ar)
```

av_store

Stores an SV in an array. The array index is specified as `key`. The return value will be NULL if the operation failed or if the value did not need to be actually stored within the array (as in the case of tied arrays). Otherwise it can be dereferenced to get the original `SV*`. Note that the caller is responsible for suitably incrementing the reference count of `val` before the call, and decrementing it if the function returned NULL.

See Understanding the Magic of Tied Hashes and Arrays in *perlguts* for more information on how to use this function on tied arrays.

```
        SV**    av_store(AV* ar, I32 key, SV* val)
```

av_undef

Undefines the array. Frees the memory used by the array itself.

```
        void    av_undef(AV* ar)
```

av_unshift

Unshift the given number of `undef` values onto the beginning of the array. The array will grow automatically to accommodate the addition. You must then use `av_store` to assign values to these new elements.

```
        void    av_unshift(AV* ar, I32 num)
```

get_av

Returns the AV of the specified Perl array. If `create` is set and the Perl variable does not exist then it will be created. If `create` is not set and the variable does not exist then NULL is returned.

NOTE: the perl_ form of this function is deprecated.

```
        AV*     get_av(const char* name, I32 create)
```

newAV

Creates a new AV. The reference count is set to 1.

```
        AV*     newAV()
```

sortsv

Sort an array. Here is an example:

```
    sortsv(AvARRAY(av), av_len(av)+1, Perl_sv_cmp_locale);
```

See lib/sort.pm for details about controlling the sorting algorithm.

```
        void    sortsv(SV ** array, size_t num_elts, SVCOMPARE_t cmp)
```

72.4 Callback Functions

call_argv

Performs a callback to the specified Perl sub. See *perlcall*.

NOTE: the perl_ form of this function is deprecated.

```
        I32     call_argv(const char* sub_name, I32 flags, char** argv)
```

call_method

Performs a callback to the specified Perl method. The blessed object must be on the stack. See *perlcall*.

NOTE: the perl_ form of this function is deprecated.

```
        I32     call_method(const char* methname, I32 flags)
```

call_pv

Performs a callback to the specified Perl sub. See *perlcall*.

NOTE: the perl_ form of this function is deprecated.

```
        I32     call_pv(const char* sub_name, I32 flags)
```

call_sv

Performs a callback to the Perl sub whose name is in the SV. See *perlcall*.

NOTE: the perl_ form of this function is deprecated.

```
        I32     call_sv(SV* sv, I32 flags)
```

ENTER

Opening bracket on a callback. See `LEAVE` and *perlcall*.

```
                ENTER;
```

eval_pv

Tells Perl to `eval` the given string and return an SV* result.

NOTE: the perl_ form of this function is deprecated.

```
        SV*     eval_pv(const char* p, I32 croak_on_error)
```

eval_sv

Tells Perl to `eval` the string in the SV.

NOTE: the perl_ form of this function is deprecated.

```
        I32     eval_sv(SV* sv, I32 flags)
```

FREETMPS

Closing bracket for temporaries on a callback. See `SAVETMPS` and *perlcall*.

```
                FREETMPS;
```

LEAVE

Closing bracket on a callback. See `ENTER` and *perlcall*.

```
                LEAVE;
```

SAVETMPS

Opening bracket for temporaries on a callback. See `FREETMPS` and *perlcall*.

```
                SAVETMPS;
```

72.5 Character classes

isALNUM

Returns a boolean indicating whether the C `char` is an ASCII alphanumeric character (including underscore) or digit.

```
        bool    isALNUM(char ch)
```

isALPHA

Returns a boolean indicating whether the C `char` is an ASCII alphabetic character.

```
        bool    isALPHA(char ch)
```

isDIGIT

Returns a boolean indicating whether the C `char` is an ASCII digit.

```
        bool    isDIGIT(char ch)
```

isLOWER

Returns a boolean indicating whether the C `char` is a lowercase character.

```
        bool    isLOWER(char ch)
```

isSPACE

Returns a boolean indicating whether the C `char` is whitespace.

```
        bool    isSPACE(char ch)
```

isUPPER

Returns a boolean indicating whether the C `char` is an uppercase character.

```
        bool    isUPPER(char ch)
```

toLOWER

Converts the specified character to lowercase.

```
        char    toLOWER(char ch)
```

toUPPER

Converts the specified character to uppercase.

```
        char    toUPPER(char ch)
```

72.6 Cloning an interpreter

perl_clone

Create and return a new interpreter by cloning the current one.

perl_clone takes these flags as parameters:

CLONEf_COPY_STACKS - is used to, well, copy the stacks also, without it we only clone the data and zero the stacks, with it we copy the stacks and the new perl interpreter is ready to run at the exact same point as the previous one. The pseudo-fork code uses COPY_STACKS while the threads->new doesn't.

CLONEf_KEEP_PTR_TABLE perl_clone keeps a ptr_table with the pointer of the old variable as a key and the new variable as a value, this allows it to check if something has been cloned and not clone it again but rather just use the value and increase the refcount. If KEEP_PTR_TABLE is not set then perl_clone will kill the ptr_table using the function `ptr_table_free(PL_ptr_table); PL_ptr_table = NULL;`, reason to keep it around is if you want to dup some of your own variable who are outside the graph perl scans, example of this code is in threads.xs create

CLONEf_CLONE_HOST This is a win32 thing, it is ignored on unix, it tells perls win32host code (which is c++) to clone itself, this is needed on win32 if you want to run two threads at the same time, if you just want to do some stuff in a separate perl interpreter and then throw it away and return to the original one, you don't need to do anything.

```
        PerlInterpreter*        perl_clone(PerlInterpreter* interp, UV flags)
```

72.7 CV Manipulation Functions

CvSTASH

Returns the stash of the CV.

```
        HV*     CvSTASH(CV* cv)
```

get_cv

Returns the CV of the specified Perl subroutine. If `create` is set and the Perl subroutine does not exist then it will be declared (which has the same effect as saying `sub name;`). If `create` is not set and the subroutine does not exist then NULL is returned.

NOTE: the perl_ form of this function is deprecated.

```
        CV*     get_cv(const char* name, I32 create)
```

72.8 Embedding Functions

cv_undef

Clear out all the active components of a CV. This can happen either by an explicit `undef &foo`, or by the reference count going to zero. In the former case, we keep the CvOUTSIDE pointer, so that any anonymous children can still follow the full lexical scope chain.

```
        void    cv_undef(CV* cv)
```

load_module

Loads the module whose name is pointed to by the string part of name. Note that the actual module name, not its filename, should be given. Eg, "Foo::Bar" instead of "Foo/Bar.pm". flags can be any of PERL_LOADMOD_DENY, PERL_LOADMOD_NOIMPORT, or PERL_LOADMOD_IMPORT_OPS (or 0 for no flags). ver, if specified, provides version semantics similar to `use Foo::Bar VERSION`. The optional trailing SV* arguments can be used to specify arguments to the module's import() method, similar to `use Foo::Bar VERSION LIST`.

```
        void    load_module(U32 flags, SV* name, SV* ver, ...)
```

nothreadhook

Stub that provides thread hook for perl_destruct when there are no threads.

```
        int     nothreadhook()
```

perl_alloc

Allocates a new Perl interpreter. See *perlembed*.

```
        PerlInterpreter*        perl_alloc()
```

perl_construct

Initializes a new Perl interpreter. See *perlembed*.

```
        void    perl_construct(PerlInterpreter* interp)
```

perl_destruct

Shuts down a Perl interpreter. See *perlembed*.

```
        int     perl_destruct(PerlInterpreter* interp)
```

perl_free

Releases a Perl interpreter. See *perlembed*.

```
        void    perl_free(PerlInterpreter* interp)
```

perl_parse

Tells a Perl interpreter to parse a Perl script. See *perlembed*.

```
        int     perl_parse(PerlInterpreter* interp, XSINIT_t xsinit, int argc, char** argv, char**
```

perl_run

Tells a Perl interpreter to run. See *perlembed*.

```
        int     perl_run(PerlInterpreter* interp)
```

require_pv

Tells Perl to `require` the file named by the string argument. It is analogous to the Perl code `eval "require '$file'"`. It's even implemented that way; consider using load_module instead.

NOTE: the perl_ form of this function is deprecated.

```
        void    require_pv(const char* pv)
```

72.9 Functions in file pp_pack.c

packlist

The engine implementing pack() Perl function.

```
        void    packlist(SV *cat, char *pat, char *patend, SV **beglist, SV **endlist)
```

pack_cat

The engine implementing pack() Perl function. Note: parameters next_in_list and flags are not used. This call should not be used; use packlist instead.

```
        void    pack_cat(SV *cat, char *pat, char *patend, SV **beglist, SV **endlist, SV ***next_
```

unpackstring

The engine implementing unpack() Perl function. `unpackstring` puts the extracted list items on the stack and returns the number of elements. Issue `PUTBACK` before and `SPAGAIN` after the call to this function.

```
        I32     unpackstring(char *pat, char *patend, char *s, char *strend, U32 flags)
```

unpack_str

The engine implementing unpack() Perl function. Note: parameters strbeg, new_s and ocnt are not used. This call should not be used, use unpackstring instead.

```
        I32     unpack_str(char *pat, char *patend, char *s, char *strbeg, char *strend, char **ne
```

72.10 Global Variables

PL_modglobal

`PL_modglobal` is a general purpose, interpreter global HV for use by extensions that need to keep information on a per-interpreter basis. In a pinch, it can also be used as a symbol table for extensions to share data among each other. It is a good idea to use keys prefixed by the package name of the extension that owns the data.

```
        HV*     PL_modglobal
```

PL_na

A convenience variable which is typically used with `SvPV` when one doesn't care about the length of the string. It is usually more efficient to either declare a local variable and use that instead or to use the `SvPV_nolen` macro.

```
        STRLEN  PL_na
```

PL_sv_no

This is the `false` SV. See `PL_sv_yes`. Always refer to this as `&PL_sv_no`.

```
SV      PL_sv_no
```

PL_sv_undef

This is the `undef` SV. Always refer to this as `&PL_sv_undef`.

```
SV      PL_sv_undef
```

PL_sv_yes

This is the `true` SV. See `PL_sv_no`. Always refer to this as `&PL_sv_yes`.

```
SV      PL_sv_yes
```

72.11 GV Functions

GvSV

Return the SV from the GV.

```
SV*     GvSV(GV* gv)
```

gv_fetchmeth

Returns the glob with the given `name` and a defined subroutine or `NULL`. The glob lives in the given `stash`, or in the stashes accessible via @ISA and UNIVERSAL::.

The argument `level` should be either 0 or -1. If `level==0`, as a side-effect creates a glob with the given `name` in the given `stash` which in the case of success contains an alias for the subroutine, and sets up caching info for this glob. Similarly for all the searched stashes.

This function grants `"SUPER"` token as a postfix of the stash name. The GV returned from `gv_fetchmeth` may be a method cache entry, which is not visible to Perl code. So when calling `call_sv`, you should not use the GV directly; instead, you should use the method's CV, which can be obtained from the GV with the `GvCV` macro.

```
GV*     gv_fetchmeth(HV* stash, const char* name, STRLEN len, I32 level)
```

gv_fetchmethod

See gv_fetchmethod_autoload.

```
GV*     gv_fetchmethod(HV* stash, const char* name)
```

gv_fetchmethod_autoload

Returns the glob which contains the subroutine to call to invoke the method on the `stash`. In fact in the presence of autoloading this may be the glob for "AUTOLOAD". In this case the corresponding variable $AUTOLOAD is already setup.

The third parameter of `gv_fetchmethod_autoload` determines whether AUTOLOAD lookup is performed if the given method is not present: non-zero means yes, look for AUTOLOAD; zero means no, don't look for AUTOLOAD. Calling `gv_fetchmethod` is equivalent to calling `gv_fetchmethod_autoload` with a non-zero `autoload` parameter.

These functions grant `"SUPER"` token as a prefix of the method name. Note that if you want to keep the returned glob for a long time, you need to check for it being "AUTOLOAD", since at the later time the call may load a different subroutine due to $AUTOLOAD changing its value. Use the glob created via a side effect to do this.

These functions have the same side-effects and as `gv_fetchmeth` with `level==0`. `name` should be writable if contains `':'` or `' '`. The warning against passing the GV returned by `gv_fetchmeth` to `call_sv` apply equally to these functions.

```
        GV*     gv_fetchmethod_autoload(HV* stash, const char* name, I32 autoload)
```

gv_fetchmeth_autoload

Same as gv_fetchmeth(), but looks for autoloaded subroutines too. Returns a glob for the subroutine.

For an autoloaded subroutine without a GV, will create a GV even if `level < 0`. For an autoloaded subroutine without a stub, GvCV() of the result may be zero.

```
        GV*     gv_fetchmeth_autoload(HV* stash, const char* name, STRLEN len, I32 level)
```

gv_stashpv

Returns a pointer to the stash for a specified package. `name` should be a valid UTF-8 string. If `create` is set then the package will be created if it does not already exist. If `create` is not set and the package does not exist then NULL is returned.

```
        HV*     gv_stashpv(const char* name, I32 create)
```

gv_stashsv

Returns a pointer to the stash for a specified package, which must be a valid UTF-8 string. See `gv_stashpv`.

```
        HV*     gv_stashsv(SV* sv, I32 create)
```

72.12 Handy Values

Nullav

Null AV pointer.

Nullch

Null character pointer.

Nullcv

Null CV pointer.

Nullhv

Null HV pointer.

Nullsv

Null SV pointer.

72.13 Hash Manipulation Functions

get_hv

Returns the HV of the specified Perl hash. If `create` is set and the Perl variable does not exist then it will be created. If `create` is not set and the variable does not exist then NULL is returned.

NOTE: the perl_ form of this function is deprecated.

```
        HV*     get_hv(const char* name, I32 create)
```

HEf_SVKEY

This flag, used in the length slot of hash entries and magic structures, specifies the structure contains an `SV*` pointer where a `char*` pointer is to be expected. (For information only–not to be used).

HeHASH

Returns the computed hash stored in the hash entry.

```
U32     HeHASH(HE* he)
```

HeKEY

Returns the actual pointer stored in the key slot of the hash entry. The pointer may be either `char*` or `SV*`, depending on the value of `HeKLEN()`. Can be assigned to. The `HePV()` or `HeSVKEY()` macros are usually preferable for finding the value of a key.

```
void*   HeKEY(HE* he)
```

HeKLEN

If this is negative, and amounts to `HEf_SVKEY`, it indicates the entry holds an `SV*` key. Otherwise, holds the actual length of the key. Can be assigned to. The `HePV()` macro is usually preferable for finding key lengths.

```
STRLEN  HeKLEN(HE* he)
```

HePV

Returns the key slot of the hash entry as a `char*` value, doing any necessary dereferencing of possibly `SV*` keys. The length of the string is placed in `len` (this is a macro, so do *not* use `&len`). If you do not care about what the length of the key is, you may use the global variable `PL_na`, though this is rather less efficient than using a local variable. Remember though, that hash keys in perl are free to contain embedded nulls, so using `strlen()` or similar is not a good way to find the length of hash keys. This is very similar to the `SvPV()` macro described elsewhere in this document.

```
char*   HePV(HE* he, STRLEN len)
```

HeSVKEY

Returns the key as an `SV*`, or `Nullsv` if the hash entry does not contain an `SV*` key.

```
SV*     HeSVKEY(HE* he)
```

HeSVKEY_force

Returns the key as an `SV*`. Will create and return a temporary mortal `SV*` if the hash entry contains only a `char*` key.

```
SV*     HeSVKEY_force(HE* he)
```

HeSVKEY_set

Sets the key to a given `SV*`, taking care to set the appropriate flags to indicate the presence of an `SV*` key, and returns the same `SV*`.

```
SV*     HeSVKEY_set(HE* he, SV* sv)
```

HeVAL

Returns the value slot (type `SV*`) stored in the hash entry.

```
SV*     HeVAL(HE* he)
```

HvNAME

Returns the package name of a stash. See `SvSTASH`, `CvSTASH`.

```
        char*   HvNAME(HV* stash)
```

hv_clear

Clears a hash, making it empty.

```
        void    hv_clear(HV* tb)
```

hv_clear_placeholders

Clears any placeholders from a hash. If a restricted hash has any of its keys marked as readonly and the key is subsequently deleted, the key is not actually deleted but is marked by assigning it a value of &PL_sv_placeholder. This tags it so it will be ignored by future operations such as iterating over the hash, but will still allow the hash to have a value reaasigned to the key at some future point. This function clears any such placeholder keys from the hash. See Hash::Util::lock_keys() for an example of its use.

```
        void    hv_clear_placeholders(HV* hb)
```

hv_delete

Deletes a key/value pair in the hash. The value SV is removed from the hash and returned to the caller. The `klen` is the length of the key. The `flags` value will normally be zero; if set to G_DISCARD then NULL will be returned.

```
        SV*     hv_delete(HV* tb, const char* key, I32 klen, I32 flags)
```

hv_delete_ent

Deletes a key/value pair in the hash. The value SV is removed from the hash and returned to the caller. The `flags` value will normally be zero; if set to G_DISCARD then NULL will be returned. `hash` can be a valid precomputed hash value, or 0 to ask for it to be computed.

```
        SV*     hv_delete_ent(HV* tb, SV* key, I32 flags, U32 hash)
```

hv_exists

Returns a boolean indicating whether the specified hash key exists. The `klen` is the length of the key.

```
        bool    hv_exists(HV* tb, const char* key, I32 klen)
```

hv_exists_ent

Returns a boolean indicating whether the specified hash key exists. `hash` can be a valid precomputed hash value, or 0 to ask for it to be computed.

```
        bool    hv_exists_ent(HV* tb, SV* key, U32 hash)
```

hv_fetch

Returns the SV which corresponds to the specified key in the hash. The `klen` is the length of the key. If `lval` is set then the fetch will be part of a store. Check that the return value is non-null before dereferencing it to an `SV*`.

See Understanding the Magic of Tied Hashes and Arrays in *perlguts* for more information on how to use this function on tied hashes.

```
        SV**    hv_fetch(HV* tb, const char* key, I32 klen, I32 lval)
```

hv_fetch_ent

Returns the hash entry which corresponds to the specified key in the hash. `hash` must be a valid precomputed hash number for the given `key`, or 0 if you want the function to compute it. IF `lval` is set then the fetch will be part of a store. Make sure the return value is non-null before accessing it. The return value when `tb` is a tied hash is a pointer to a static location, so be sure to make a copy of the structure if you need to store it somewhere.

See Understanding the Magic of Tied Hashes and Arrays in *perlguts* for more information on how to use this function on tied hashes.

```
HE*     hv_fetch_ent(HV* tb, SV* key, I32 lval, U32 hash)
```

hv_iterinit

Prepares a starting point to traverse a hash table. Returns the number of keys in the hash (i.e. the same as `HvKEYS(tb)`). The return value is currently only meaningful for hashes without tie magic.

NOTE: Before version 5.004_65, `hv_iterinit` used to return the number of hash buckets that happen to be in use. If you still need that esoteric value, you can get it through the macro `HvFILL(tb)`.

```
I32     hv_iterinit(HV* tb)
```

hv_iterkey

Returns the key from the current position of the hash iterator. See `hv_iterinit`.

```
char*   hv_iterkey(HE* entry, I32* retlen)
```

hv_iterkeysv

Returns the key as an `SV*` from the current position of the hash iterator. The return value will always be a mortal copy of the key. Also see `hv_iterinit`.

```
SV*     hv_iterkeysv(HE* entry)
```

hv_iternext

Returns entries from a hash iterator. See `hv_iterinit`.

You may call `hv_delete` or `hv_delete_ent` on the hash entry that the iterator currently points to, without losing your place or invalidating your iterator. Note that in this case the current entry is deleted from the hash with your iterator holding the last reference to it. Your iterator is flagged to free the entry on the next call to `hv_iternext`, so you must not discard your iterator immediately else the entry will leak - call `hv_iternext` to trigger the resource deallocation.

```
HE*     hv_iternext(HV* tb)
```

hv_iternextsv

Performs an `hv_iternext`, `hv_iterkey`, and `hv_iterval` in one operation.

```
SV*     hv_iternextsv(HV* hv, char** key, I32* retlen)
```

hv_iternext_flags

Returns entries from a hash iterator. See `hv_iterinit` and `hv_iternext`. The `flags` value will normally be zero; if HV_ITERNEXT_WANTPLACEHOLDERS is set the placeholders keys (for restricted hashes) will be returned in addition to normal keys. By default placeholders are automatically skipped over. Currently a placeholder is implemented with a value that is `&Perl_sv_placeholder`. Note that the implementation of placeholders and restricted hashes may change, and the implementation currently is insufficiently abstracted for any change to be tidy.

NOTE: this function is experimental and may change or be removed without notice.

```
HE*     hv_iternext_flags(HV* tb, I32 flags)
```

hv_iterval

Returns the value from the current position of the hash iterator. See `hv_iterkey`.

```
SV*     hv_iterval(HV* tb, HE* entry)
```

hv_magic

Adds magic to a hash. See `sv_magic`.

```
        void    hv_magic(HV* hv, GV* gv, int how)
```

hv_scalar

Evaluates the hash in scalar context and returns the result. Handles magic when the hash is tied.

```
        SV*     hv_scalar(HV* hv)
```

hv_store

Stores an SV in a hash. The hash key is specified as `key` and `klen` is the length of the key. The `hash` parameter is the precomputed hash value; if it is zero then Perl will compute it. The return value will be NULL if the operation failed or if the value did not need to be actually stored within the hash (as in the case of tied hashes). Otherwise it can be dereferenced to get the original `SV*`. Note that the caller is responsible for suitably incrementing the reference count of `val` before the call, and decrementing it if the function returned NULL. Effectively a successful hv_store takes ownership of one reference to `val`. This is usually what you want; a newly created SV has a reference count of one, so if all your code does is create SVs then store them in a hash, hv_store will own the only reference to the new SV, and your code doesn't need to do anything further to tidy up. hv_store is not implemented as a call to hv_store_ent, and does not create a temporary SV for the key, so if your key data is not already in SV form then use hv_store in preference to hv_store_ent.

See Understanding the Magic of Tied Hashes and Arrays in *perlguts* for more information on how to use this function on tied hashes.

```
        SV**    hv_store(HV* tb, const char* key, I32 klen, SV* val, U32 hash)
```

hv_store_ent

Stores `val` in a hash. The hash key is specified as `key`. The `hash` parameter is the precomputed hash value; if it is zero then Perl will compute it. The return value is the new hash entry so created. It will be NULL if the operation failed or if the value did not need to be actually stored within the hash (as in the case of tied hashes). Otherwise the contents of the return value can be accessed using the `He?` macros described here. Note that the caller is responsible for suitably incrementing the reference count of `val` before the call, and decrementing it if the function returned NULL. Effectively a successful hv_store_ent takes ownership of one reference to `val`. This is usually what you want; a newly created SV has a reference count of one, so if all your code does is create SVs then store them in a hash, hv_store will own the only reference to the new SV, and your code doesn't need to do anything further to tidy up. Note that hv_store_ent only reads the `key`; unlike `val` it does not take ownership of it, so maintaining the correct reference count on `key` is entirely the caller's responsibility. hv_store is not implemented as a call to hv_store_ent, and does not create a temporary SV for the key, so if your key data is not already in SV form then use hv_store in preference to hv_store_ent.

See Understanding the Magic of Tied Hashes and Arrays in *perlguts* for more information on how to use this function on tied hashes.

```
        HE*     hv_store_ent(HV* tb, SV* key, SV* val, U32 hash)
```

hv_undef

Undefines the hash.

```
        void    hv_undef(HV* tb)
```

newHV

Creates a new HV. The reference count is set to 1.

```
        HV*     newHV()
```

72.14 Magical Functions

mg_clear

Clear something magical that the SV represents. See `sv_magic`.

```
        int     mg_clear(SV* sv)
```

mg_copy

Copies the magic from one SV to another. See `sv_magic`.

```
        int     mg_copy(SV* sv, SV* nsv, const char* key, I32 klen)
```

mg_find

Finds the magic pointer for type matching the SV. See `sv_magic`.

```
        MAGIC*  mg_find(SV* sv, int type)
```

mg_free

Free any magic storage used by the SV. See `sv_magic`.

```
        int     mg_free(SV* sv)
```

mg_get

Do magic after a value is retrieved from the SV. See `sv_magic`.

```
        int     mg_get(SV* sv)
```

mg_length

Report on the SV's length. See `sv_magic`.

```
        U32     mg_length(SV* sv)
```

mg_magical

Turns on the magical status of an SV. See `sv_magic`.

```
        void    mg_magical(SV* sv)
```

mg_set

Do magic after a value is assigned to the SV. See `sv_magic`.

```
        int     mg_set(SV* sv)
```

SvGETMAGIC

Invokes `mg_get` on an SV if it has 'get' magic. This macro evaluates its argument more than once.

```
        void    SvGETMAGIC(SV* sv)
```

SvLOCK

Arranges for a mutual exclusion lock to be obtained on sv if a suitable module has been loaded.

```
        void    SvLOCK(SV* sv)
```

SvSETMAGIC

Invokes `mg_set` on an SV if it has 'set' magic. This macro evaluates its argument more than once.

```
        void    SvSETMAGIC(SV* sv)
```

SvSetMagicSV

Like `SvSetSV`, but does any set magic required afterwards.

```
        void    SvSetMagicSV(SV* dsb, SV* ssv)
```

SvSetMagicSV_nosteal

Like `SvSetMagicSV`, but does any set magic required afterwards.

```
        void    SvSetMagicSV_nosteal(SV* dsv, SV* ssv)
```

SvSetSV

Calls `sv_setsv` if dsv is not the same as ssv. May evaluate arguments more than once.

```
        void    SvSetSV(SV* dsb, SV* ssv)
```

SvSetSV_nosteal

Calls a non-destructive version of `sv_setsv` if dsv is not the same as ssv. May evaluate arguments more than once.

```
        void    SvSetSV_nosteal(SV* dsv, SV* ssv)
```

SvSHARE

Arranges for sv to be shared between threads if a suitable module has been loaded.

```
        void    SvSHARE(SV* sv)
```

SvUNLOCK

Releases a mutual exclusion lock on sv if a suitable module has been loaded.

```
        void    SvUNLOCK(SV* sv)
```

72.15 Memory Management

Copy

The XSUB-writer's interface to the C `memcpy` function. The `src` is the source, `dest` is the destination, `nitems` is the number of items, and `type` is the type. May fail on overlapping copies. See also `Move`.

```
        void    Copy(void* src, void* dest, int nitems, type)
```

Move

The XSUB-writer's interface to the C `memmove` function. The `src` is the source, `dest` is the destination, `nitems` is the number of items, and `type` is the type. Can do overlapping moves. See also `Copy`.

```
        void    Move(void* src, void* dest, int nitems, type)
```

New

The XSUB-writer's interface to the C `malloc` function.

```
        void    New(int id, void* ptr, int nitems, type)
```

Newc

The XSUB-writer's interface to the C `malloc` function, with cast.

```
        void    Newc(int id, void* ptr, int nitems, type, cast)
```

Newz

The XSUB-writer's interface to the C `malloc` function. The allocated memory is zeroed with `memzero`.

```
        void    Newz(int id, void* ptr, int nitems, type)
```

Poison

Fill up memory with a pattern (byte 0xAB over and over again) that hopefully catches attempts to access uninitialized memory.

```
        void    Poison(void* dest, int nitems, type)
```

Renew

The XSUB-writer's interface to the C `realloc` function.

```
        void    Renew(void* ptr, int nitems, type)
```

Renewc

The XSUB-writer's interface to the C `realloc` function, with cast.

```
        void    Renewc(void* ptr, int nitems, type, cast)
```

Safefree

The XSUB-writer's interface to the C `free` function.

```
        void    Safefree(void* ptr)
```

savepv

Perl's version of `strdup()`. Returns a pointer to a newly allocated string which is a duplicate of `pv`. The size of the string is determined by `strlen()`. The memory allocated for the new string can be freed with the `Safefree()` function.

```
        char*   savepv(const char* pv)
```

savepvn

Perl's version of what `strndup()` would be if it existed. Returns a pointer to a newly allocated string which is a duplicate of the first `len` bytes from `pv`. The memory allocated for the new string can be freed with the `Safefree()` function.

```
        char*   savepvn(const char* pv, I32 len)
```

savesharedpv

A version of `savepv()` which allocates the duplicate string in memory which is shared between threads.

```
        char*   savesharedpv(const char* pv)
```

StructCopy

This is an architecture-independent macro to copy one structure to another.

```
        void    StructCopy(type src, type dest, type)
```

Zero

The XSUB-writer's interface to the C `memzero` function. The `dest` is the destination, `nitems` is the number of items, and `type` is the type.

```
        void    Zero(void* dest, int nitems, type)
```

72.16 Miscellaneous Functions

fbm_compile

Analyses the string in order to make fast searches on it using fbm_instr() – the Boyer-Moore algorithm.

```
        void    fbm_compile(SV* sv, U32 flags)
```

fbm_instr

Returns the location of the SV in the string delimited by `str` and `strend`. It returns `Nullch` if the string can't be found. The `sv` does not have to be fbm_compiled, but the search will not be as fast then.

```
        char*   fbm_instr(unsigned char* big, unsigned char* bigend, SV* littlesv, U32 flags)
```

form

Takes a sprintf-style format pattern and conventional (non-SV) arguments and returns the formatted string.

```
    (char *) Perl_form(pTHX_ const char* pat, ...)
```

can be used any place a string (char *) is required:

```
    char * s = Perl_form("%d.%d",major,minor);
```

Uses a single private buffer so if you want to format several strings you must explicitly copy the earlier strings away (and free the copies when you are done).

```
        char*   form(const char* pat, ...)
```

getcwd_sv

Fill the sv with current working directory

```
        int     getcwd_sv(SV* sv)
```

strEQ

Test two strings to see if they are equal. Returns true or false.

```
        bool    strEQ(char* s1, char* s2)
```

strGE

Test two strings to see if the first, `s1`, is greater than or equal to the second, `s2`. Returns true or false.

```
        bool    strGE(char* s1, char* s2)
```

strGT

Test two strings to see if the first, `s1`, is greater than the second, `s2`. Returns true or false.

```
        bool    strGT(char* s1, char* s2)
```

strLE

Test two strings to see if the first, `s1`, is less than or equal to the second, `s2`. Returns true or false.

```
        bool    strLE(char* s1, char* s2)
```

strLT

Test two strings to see if the first, `s1`, is less than the second, `s2`. Returns true or false.

```
        bool    strLT(char* s1, char* s2)
```

strNE

Test two strings to see if they are different. Returns true or false.

```
        bool    strNE(char* s1, char* s2)
```

strnEQ

Test two strings to see if they are equal. The `len` parameter indicates the number of bytes to compare. Returns true or false. (A wrapper for `strncmp`).

```
        bool    strnEQ(char* s1, char* s2, STRLEN len)
```

strnNE

Test two strings to see if they are different. The `len` parameter indicates the number of bytes to compare. Returns true or false. (A wrapper for `strncmp`).

```
        bool    strnNE(char* s1, char* s2, STRLEN len)
```

sv_nolocking

Dummy routine which "locks" an SV when there is no locking module present. Exists to avoid test for a NULL function pointer and because it could potentially warn under some level of strict-ness.

```
        void    sv_nolocking(SV *)
```

sv_nosharing

Dummy routine which "shares" an SV when there is no sharing module present. Exists to avoid test for a NULL function pointer and because it could potentially warn under some level of strict-ness.

```
        void    sv_nosharing(SV *)
```

sv_nounlocking

Dummy routine which "unlocks" an SV when there is no locking module present. Exists to avoid test for a NULL function pointer and because it could potentially warn under some level of strict-ness.

```
        void    sv_nounlocking(SV *)
```

72.17 Numeric functions

grok_bin

converts a string representing a binary number to numeric form.

On entry *start* and **len* give the string to scan, **flags* gives conversion flags, and *result* should be NULL or a pointer to an NV. The scan stops at the end of the string, or the first invalid character. On return **len* is set to the length scanned string, and **flags* gives output flags.

If the value is <= UV_MAX it is returned as a UV, the output flags are clear, and nothing is written to **result*. If the value is > UV_MAX `grok_bin` returns UV_MAX, sets `PERL_SCAN_GREATER_THAN_UV_MAX` in the output flags, and writes the value to **result* (or the value is discarded if *result* is NULL).

The hex number may optionally be prefixed with "0b" or "b" unless `PERL_SCAN_DISALLOW_PREFIX` is set in **flags* on entry. If `PERL_SCAN_ALLOW_UNDERSCORES` is set in **flags* then the binary number may use '_' characters to separate digits.

```
        UV      grok_bin(char* start, STRLEN* len, I32* flags, NV *result)
```

grok_hex

converts a string representing a hex number to numeric form.

On entry *start* and **len* give the string to scan, **flags* gives conversion flags, and *result* should be NULL or a pointer to an NV. The scan stops at the end of the string, or the first non-hex-digit character. On return **len* is set to the length scanned string, and **flags* gives output flags.

If the value is <= UV_MAX it is returned as a UV, the output flags are clear, and nothing is written to **result*. If the value is > UV_MAX `grok_hex` returns UV_MAX, sets `PERL_SCAN_GREATER_THAN_UV_MAX` in the output flags, and writes the value to **result* (or the value is discarded if *result* is NULL).

The hex number may optionally be prefixed with "0x" or "x" unless `PERL_SCAN_DISALLOW_PREFIX` is set in **flags* on entry. If `PERL_SCAN_ALLOW_UNDERSCORES` is set in **flags* then the hex number may use '_' characters to separate digits.

```
        UV      grok_hex(char* start, STRLEN* len, I32* flags, NV *result)
```

grok_number

Recognise (or not) a number. The type of the number is returned (0 if unrecognised), otherwise it is a bit-ORed combination of IS_NUMBER_IN_UV, IS_NUMBER_GREATER_THAN_UV_MAX, IS_NUMBER_NOT_INT, IS_NUMBER_NEG, IS_NUMBER_INFINITY, IS_NUMBER_NAN (defined in perl.h).

If the value of the number can fit an in UV, it is returned in the *valuep IS_NUMBER_IN_UV will be set to indicate that *valuep is valid, IS_NUMBER_IN_UV will never be set unless *valuep is valid, but *valuep may have been assigned to during processing even though IS_NUMBER_IN_UV is not set on return. If valuep is NULL, IS_NUMBER_IN_UV will be set for the same cases as when valuep is non-NULL, but no actual assignment (or SEGV) will occur.

IS_NUMBER_NOT_INT will be set with IS_NUMBER_IN_UV if trailing decimals were seen (in which case *valuep gives the true value truncated to an integer), and IS_NUMBER_NEG if the number is negative (in which case *valuep holds the absolute value). IS_NUMBER_IN_UV is not set if e notation was used or the number is larger than a UV.

```
        int     grok_number(const char *pv, STRLEN len, UV *valuep)
```

grok_numeric_radix

Scan and skip for a numeric decimal separator (radix).

```
        bool    grok_numeric_radix(const char **sp, const char *send)
```

grok_oct

```
        UV      grok_oct(char* start, STRLEN* len, I32* flags, NV *result)
```

scan_bin

For backwards compatibility. Use `grok_bin` instead.

```
        NV      scan_bin(char* start, STRLEN len, STRLEN* retlen)
```

scan_hex

For backwards compatibility. Use `grok_hex` instead.

```
        NV      scan_hex(char* start, STRLEN len, STRLEN* retlen)
```

scan_oct

For backwards compatibility. Use `grok_oct` instead.

```
        NV      scan_oct(char* start, STRLEN len, STRLEN* retlen)
```

72.18 Optree Manipulation Functions

cv_const_sv

If `cv` is a constant sub eligible for inlining. returns the constant value returned by the sub. Otherwise, returns NULL.

Constant subs can be created with `newCONSTSUB` or as described in Constant Functions in *perlsub*.

```
        SV*     cv_const_sv(CV* cv)
```

newCONSTSUB

Creates a constant sub equivalent to Perl `sub FOO () { 123 }` which is eligible for inlining at compile-time.

```
        CV*     newCONSTSUB(HV* stash, char* name, SV* sv)
```

newXS

Used by `xsubpp` to hook up XSUBs as Perl subs.

72.19 Pad Data Structures

pad_sv

Get the value at offset po in the current pad. Use macro PAD_SV instead of calling this function directly.

```
        SV*     pad_sv(PADOFFSET po)
```

72.20 Stack Manipulation Macros

dMARK

Declare a stack marker variable, `mark`, for the XSUB. See `MARK` and `dORIGMARK`.

```
                dMARK;
```

dORIGMARK

Saves the original stack mark for the XSUB. See `ORIGMARK`.

```
                dORIGMARK;
```

dSP

Declares a local copy of perl's stack pointer for the XSUB, available via the `SP` macro. See `SP`.

```
                dSP;
```

EXTEND

Used to extend the argument stack for an XSUB's return values. Once used, guarantees that there is room for at least `nitems` to be pushed onto the stack.

```
        void    EXTEND(SP, int nitems)
```

MARK

Stack marker variable for the XSUB. See `dMARK`.

mPUSHi

Push an integer onto the stack. The stack must have room for this element. Handles 'set' magic. Does not use `TARG`. See also `PUSHi`, `mXPUSHi` and `XPUSHi`.

```
        void    mPUSHi(IV iv)
```

mPUSHn

Push a double onto the stack. The stack must have room for this element. Handles 'set' magic. Does not use `TARG`. See also `PUSHn`, `mXPUSHn` and `XPUSHn`.

```
        void    mPUSHn(NV nv)
```

mPUSHp

Push a string onto the stack. The stack must have room for this element. The `len` indicates the length of the string. Handles 'set' magic. Does not use `TARG`. See also `PUSHp`, `mXPUSHp` and `XPUSHp`.

```
        void    mPUSHp(char* str, STRLEN len)
```

mPUSHu

Push an unsigned integer onto the stack. The stack must have room for this element. Handles 'set' magic. Does not use `TARG`. See also `PUSHu`, `mXPUSHu` and `XPUSHu`.

```
        void    mPUSHu(UV uv)
```

mXPUSHi

Push an integer onto the stack, extending the stack if necessary. Handles 'set' magic. Does not use `TARG`. See also `XPUSHi`, `mPUSHi` and `PUSHi`.

```
        void    mXPUSHi(IV iv)
```

mXPUSHn

Push a double onto the stack, extending the stack if necessary. Handles 'set' magic. Does not use `TARG`. See also `XPUSHn`, `mPUSHn` and `PUSHn`.

```
        void    mXPUSHn(NV nv)
```

mXPUSHp

Push a string onto the stack, extending the stack if necessary. The `len` indicates the length of the string. Handles 'set' magic. Does not use `TARG`. See also `XPUSHp`, `mPUSHp` and `PUSHp`.

```
        void    mXPUSHp(char* str, STRLEN len)
```

mXPUSHu

Push an unsigned integer onto the stack, extending the stack if necessary. Handles 'set' magic. Does not use `TARG`. See also `XPUSHu`, `mPUSHu` and `PUSHu`.

```
        void    mXPUSHu(UV uv)
```

ORIGMARK

The original stack mark for the XSUB. See `dORIGMARK`.

POPi

Pops an integer off the stack.

```
        IV      POPi
```

POPl

Pops a long off the stack.

```
        long    POPl
```

POPn

Pops a double off the stack.

```
        NV      POPn
```

POPp

Pops a string off the stack. Deprecated. New code should provide a STRLEN n_a and use POPpx.

```
        char*   POPp
```

POPpbytex

Pops a string off the stack which must consist of bytes i.e. characters < 256. Requires a variable STRLEN n_a in scope.

```
        char*   POPpbytex
```

POPpx

Pops a string off the stack. Requires a variable STRLEN n_a in scope.

```
char*   POPpx
```

POPs

Pops an SV off the stack.

```
SV*     POPs
```

PUSHi

Push an integer onto the stack. The stack must have room for this element. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mPUSHi` instead. See also `XPUSHi` and `mXPUSHi`.

```
void    PUSHi(IV iv)
```

PUSHMARK

Opening bracket for arguments on a callback. See `PUTBACK` and *perlcall*.

```
void    PUSHMARK(SP)
```

PUSHmortal

Push a new mortal SV onto the stack. The stack must have room for this element. Does not handle 'set' magic. Does not use `TARG`. See also `PUSHs`, `XPUSHmortal` and `XPUSHs`.

```
void    PUSHmortal()
```

PUSHn

Push a double onto the stack. The stack must have room for this element. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mPUSHn` instead. See also `XPUSHn` and `mXPUSHn`.

```
void    PUSHn(NV nv)
```

PUSHp

Push a string onto the stack. The stack must have room for this element. The `len` indicates the length of the string. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mPUSHp` instead. See also `XPUSHp` and `mXPUSHp`.

```
void    PUSHp(char* str, STRLEN len)
```

PUSHs

Push an SV onto the stack. The stack must have room for this element. Does not handle 'set' magic. Does not use `TARG`. See also `PUSHmortal`, `XPUSHs` and `XPUSHmortal`.

```
void    PUSHs(SV* sv)
```

PUSHu

Push an unsigned integer onto the stack. The stack must have room for this element. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mPUSHu` instead. See also `XPUSHu` and `mXPUSHu`.

```
        void    PUSHu(UV uv)
```

PUTBACK

Closing bracket for XSUB arguments. This is usually handled by `xsubpp`. See `PUSHMARK` and *perlcall* for other uses.

```
                PUTBACK;
```

SP

Stack pointer. This is usually handled by `xsubpp`. See `dSP` and `SPAGAIN`.

SPAGAIN

Refetch the stack pointer. Used after a callback. See *perlcall*.

```
                SPAGAIN;
```

XPUSHi

Push an integer onto the stack, extending the stack if necessary. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mXPUSHi` instead. See also `PUSHi` and `mPUSHi`.

```
        void    XPUSHi(IV iv)
```

XPUSHmortal

Push a new mortal SV onto the stack, extending the stack if necessary. Does not handle 'set' magic. Does not use `TARG`. See also `XPUSHs`, `PUSHmortal` and `PUSHs`.

```
        void    XPUSHmortal()
```

XPUSHn

Push a double onto the stack, extending the stack if necessary. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mXPUSHn` instead. See also `PUSHn` and `mPUSHn`.

```
        void    XPUSHn(NV nv)
```

XPUSHp

Push a string onto the stack, extending the stack if necessary. The `len` indicates the length of the string. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mXPUSHp` instead. See also `PUSHp` and `mPUSHp`.

```
        void    XPUSHp(char* str, STRLEN len)
```

XPUSHs

Push an SV onto the stack, extending the stack if necessary. Does not handle 'set' magic. Does not use `TARG`. See also `XPUSHmortal`, `PUSHs` and `PUSHmortal`.

```
        void    XPUSHs(SV* sv)
```

XPUSHu

Push an unsigned integer onto the stack, extending the stack if necessary. Handles 'set' magic. Uses `TARG`, so `dTARGET` or `dXSTARG` should be called to declare it. Do not call multiple `TARG`-oriented macros to return lists from XSUB's - see `mXPUSHu` instead. See also `PUSHu` and `mPUSHu`.

```
        void    XPUSHu(UV uv)
```

XSRETURN

Return from XSUB, indicating number of items on the stack. This is usually handled by `xsubpp`.

```
        void    XSRETURN(int nitems)
```

XSRETURN_EMPTY

Return an empty list from an XSUB immediately.

```
                XSRETURN_EMPTY;
```

XSRETURN_IV

Return an integer from an XSUB immediately. Uses `XST_mIV`.

```
        void    XSRETURN_IV(IV iv)
```

XSRETURN_NO

Return `&PL_sv_no` from an XSUB immediately. Uses `XST_mNO`.

```
                XSRETURN_NO;
```

XSRETURN_NV

Return a double from an XSUB immediately. Uses `XST_mNV`.

```
        void    XSRETURN_NV(NV nv)
```

XSRETURN_PV

Return a copy of a string from an XSUB immediately. Uses `XST_mPV`.

```
        void    XSRETURN_PV(char* str)
```

XSRETURN_UNDEF

Return `&PL_sv_undef` from an XSUB immediately. Uses `XST_mUNDEF`.

```
                XSRETURN_UNDEF;
```

XSRETURN_UV

Return an integer from an XSUB immediately. Uses `XST_mUV`.

```
        void    XSRETURN_UV(IV uv)
```

XSRETURN_YES

Return `&PL_sv_yes` from an XSUB immediately. Uses `XST_mYES`.

```
                XSRETURN_YES;
```

XST_mIV

Place an integer into the specified position `pos` on the stack. The value is stored in a new mortal SV.

```
        void    XST_mIV(int pos, IV iv)
```

XST_mNO

Place `&PL_sv_no` into the specified position `pos` on the stack.

```
        void    XST_mNO(int pos)
```

XST_mNV

Place a double into the specified position `pos` on the stack. The value is stored in a new mortal SV.

```
        void    XST_mNV(int pos, NV nv)
```

XST_mPV

Place a copy of a string into the specified position `pos` on the stack. The value is stored in a new mortal SV.

```
        void    XST_mPV(int pos, char* str)
```

XST_mUNDEF

Place `&PL_sv_undef` into the specified position `pos` on the stack.

```
        void    XST_mUNDEF(int pos)
```

XST_mYES

Place `&PL_sv_yes` into the specified position `pos` on the stack.

```
        void    XST_mYES(int pos)
```

72.21 SV Flags

svtype

An enum of flags for Perl types. These are found in the file **sv.h** in the `svtype` enum. Test these flags with the `SvTYPE` macro.

SVt_IV

Integer type flag for scalars. See `svtype`.

SVt_NV

Double type flag for scalars. See `svtype`.

SVt_PV

Pointer type flag for scalars. See `svtype`.

SVt_PVAV

Type flag for arrays. See `svtype`.

SVt_PVCV

Type flag for code refs. See `svtype`.

SVt_PVHV

Type flag for hashes. See `svtype`.

SVt_PVMG

Type flag for blessed scalars. See `svtype`.

72.22 SV Manipulation Functions

get_sv

Returns the SV of the specified Perl scalar. If `create` is set and the Perl variable does not exist then it will be created. If `create` is not set and the variable does not exist then NULL is returned.

NOTE: the perl_ form of this function is deprecated.

```
        SV*     get_sv(const char* name, I32 create)
```

looks_like_number

Test if the content of an SV looks like a number (or is a number). `Inf` and `Infinity` are treated as numbers (so will not issue a non-numeric warning), even if your atof() doesn't grok them.

```
        I32     looks_like_number(SV* sv)
```

newRV_inc

Creates an RV wrapper for an SV. The reference count for the original SV is incremented.

```
        SV*     newRV_inc(SV* sv)
```

newRV_noinc

Creates an RV wrapper for an SV. The reference count for the original SV is **not** incremented.

```
        SV*     newRV_noinc(SV *sv)
```

NEWSV

Creates a new SV. A non-zero `len` parameter indicates the number of bytes of preallocated string space the SV should have. An extra byte for a tailing NUL is also reserved. (SvPOK is not set for the SV even if string space is allocated.) The reference count for the new SV is set to 1. `id` is an integer id between 0 and 1299 (used to identify leaks).

```
        SV*     NEWSV(int id, STRLEN len)
```

newSV

Create a new null SV, or if len > 0, create a new empty SVt_PV type SV with an initial PV allocation of len+1. Normally accessed via the `NEWSV` macro.

```
        SV*     newSV(STRLEN len)
```

newSViv

Creates a new SV and copies an integer into it. The reference count for the SV is set to 1.

```
        SV*     newSViv(IV i)
```

newSVnv

Creates a new SV and copies a floating point value into it. The reference count for the SV is set to 1.

```
        SV*     newSVnv(NV n)
```

newSVpv

Creates a new SV and copies a string into it. The reference count for the SV is set to 1. If `len` is zero, Perl will compute the length using strlen(). For efficiency, consider using `newSVpvn` instead.

```
        SV*     newSVpv(const char* s, STRLEN len)
```

newSVpvf

Creates a new SV and initializes it with the string formatted like `sprintf`.

```
        SV*     newSVpvf(const char* pat, ...)
```

newSVpvn

Creates a new SV and copies a string into it. The reference count for the SV is set to 1. Note that if `len` is zero, Perl will create a zero length string. You are responsible for ensuring that the source string is at least `len` bytes long. If the `s` argument is NULL the new SV will be undefined.

```
        SV*     newSVpvn(const char* s, STRLEN len)
```

newSVpvn_share

Creates a new SV with its SvPVX pointing to a shared string in the string table. If the string does not already exist in the table, it is created first. Turns on READONLY and FAKE. The string's hash is stored in the UV slot of the SV; if the `hash` parameter is non-zero, that value is used; otherwise the hash is computed. The idea here is that as the string table is used for shared hash keys these strings will have SvPVX == HeKEY and hash lookup will avoid string compare.

```
        SV*     newSVpvn_share(const char* s, I32 len, U32 hash)
```

newSVrv

Creates a new SV for the RV, `rv`, to point to. If `rv` is not an RV then it will be upgraded to one. If `classname` is non-null then the new SV will be blessed in the specified package. The new SV is returned and its reference count is 1.

```
        SV*     newSVrv(SV* rv, const char* classname)
```

newSVsv

Creates a new SV which is an exact duplicate of the original SV. (Uses `sv_setsv`).

```
        SV*     newSVsv(SV* old)
```

newSVuv

Creates a new SV and copies an unsigned integer into it. The reference count for the SV is set to 1.

```
        SV*     newSVuv(UV u)
```

SvCUR

Returns the length of the string which is in the SV. See `SvLEN`.

```
        STRLEN  SvCUR(SV* sv)
```

SvCUR_set

Set the length of the string which is in the SV. See `SvCUR`.

```
        void    SvCUR_set(SV* sv, STRLEN len)
```

SvEND

Returns a pointer to the last character in the string which is in the SV. See `SvCUR`. Access the character as *(SvEND(sv)).

```
        char*   SvEND(SV* sv)
```

SvGROW

Expands the character buffer in the SV so that it has room for the indicated number of bytes (remember to reserve space for an extra trailing NUL character). Calls `sv_grow` to perform the expansion if necessary. Returns a pointer to the character buffer.

```
        char *  SvGROW(SV* sv, STRLEN len)
```

SvIOK

Returns a boolean indicating whether the SV contains an integer.

```
        bool    SvIOK(SV* sv)
```

SvIOKp

Returns a boolean indicating whether the SV contains an integer. Checks the **private** setting. Use `SvIOK`.

```
        bool    SvIOKp(SV* sv)
```

SvIOK_notUV

Returns a boolean indicating whether the SV contains a signed integer.

```
        bool    SvIOK_notUV(SV* sv)
```

SvIOK_off

Unsets the IV status of an SV.

```
        void    SvIOK_off(SV* sv)
```

SvIOK_on

Tells an SV that it is an integer.

```
        void    SvIOK_on(SV* sv)
```

SvIOK_only

Tells an SV that it is an integer and disables all other OK bits.

```
        void    SvIOK_only(SV* sv)
```

SvIOK_only_UV

Tells and SV that it is an unsigned integer and disables all other OK bits.

```
        void    SvIOK_only_UV(SV* sv)
```

SvIOK_UV

Returns a boolean indicating whether the SV contains an unsigned integer.

```
        bool    SvIOK_UV(SV* sv)
```

SvIsCOW

Returns a boolean indicating whether the SV is Copy-On-Write. (either shared hash key scalars, or full Copy On Write scalars if 5.9.0 is configured for COW)

```
        bool    SvIsCOW(SV* sv)
```

SvIsCOW_shared_hash

Returns a boolean indicating whether the SV is Copy-On-Write shared hash key scalar.

```
        bool    SvIsCOW_shared_hash(SV* sv)
```

SvIV

Coerces the given SV to an integer and returns it. See `SvIVx` for a version which guarantees to evaluate sv only once.

```
        IV      SvIV(SV* sv)
```

SvIVx

Coerces the given SV to an integer and returns it. Guarantees to evaluate sv only once. Use the more efficient `SvIV` otherwise.

```
        IV      SvIVx(SV* sv)
```

SvIVX

Returns the raw value in the SV's IV slot, without checks or conversions. Only use when you are sure SvIOK is true. See also `SvIV()`.

```
        IV      SvIVX(SV* sv)
```

SvLEN

Returns the size of the string buffer in the SV, not including any part attributable to `SvOOK`. See `SvCUR`.

```
        STRLEN  SvLEN(SV* sv)
```

SvNIOK

Returns a boolean indicating whether the SV contains a number, integer or double.

```
        bool    SvNIOK(SV* sv)
```

SvNIOKp

Returns a boolean indicating whether the SV contains a number, integer or double. Checks the **private** setting. Use `SvNIOK`.

```
        bool    SvNIOKp(SV* sv)
```

SvNIOK_off

Unsets the NV/IV status of an SV.

```
        void    SvNIOK_off(SV* sv)
```

SvNOK

Returns a boolean indicating whether the SV contains a double.

```
        bool    SvNOK(SV* sv)
```

SvNOKp

Returns a boolean indicating whether the SV contains a double. Checks the **private** setting. Use `SvNOK`.

```
        bool    SvNOKp(SV* sv)
```

SvNOK_off

Unsets the NV status of an SV.

```
        void    SvNOK_off(SV* sv)
```

SvNOK_on

Tells an SV that it is a double.

```
        void    SvNOK_on(SV* sv)
```

SvNOK_only

Tells an SV that it is a double and disables all other OK bits.

```
        void    SvNOK_only(SV* sv)
```

SvNV

Coerce the given SV to a double and return it. See `SvNVx` for a version which guarantees to evaluate sv only once.

```
        NV      SvNV(SV* sv)
```

SvNVx

Coerces the given SV to a double and returns it. Guarantees to evaluate sv only once. Use the more efficient `SvNV` otherwise.

```
        NV      SvNVx(SV* sv)
```

SvNVX

Returns the raw value in the SV's NV slot, without checks or conversions. Only use when you are sure SvNOK is true. See also `SvNV()`.

```
        NV      SvNVX(SV* sv)
```

SvOK

Returns a boolean indicating whether the value is an SV. It also tells whether the value is defined or not.

```
        bool    SvOK(SV* sv)
```

SvOOK

Returns a boolean indicating whether the SvIVX is a valid offset value for the SvPVX. This hack is used internally to speed up removal of characters from the beginning of a SvPV. When SvOOK is true, then the start of the allocated string buffer is really (SvPVX - SvIVX).

```
        bool    SvOOK(SV* sv)
```

SvPOK

Returns a boolean indicating whether the SV contains a character string.

```
bool    SvPOK(SV* sv)
```

SvPOKp

Returns a boolean indicating whether the SV contains a character string. Checks the **private** setting. Use `SvPOK`.

```
bool    SvPOKp(SV* sv)
```

SvPOK_off

Unsets the PV status of an SV.

```
void    SvPOK_off(SV* sv)
```

SvPOK_on

Tells an SV that it is a string.

```
void    SvPOK_on(SV* sv)
```

SvPOK_only

Tells an SV that it is a string and disables all other OK bits. Will also turn off the UTF-8 status.

```
void    SvPOK_only(SV* sv)
```

SvPOK_only_UTF8

Tells an SV that it is a string and disables all other OK bits, and leaves the UTF-8 status as it was.

```
void    SvPOK_only_UTF8(SV* sv)
```

SvPV

Returns a pointer to the string in the SV, or a stringified form of the SV if the SV does not contain a string. The SV may cache the stringified version becoming `SvPOK`. Handles 'get' magic. See also `SvPVx` for a version which guarantees to evaluate sv only once.

```
char*   SvPV(SV* sv, STRLEN len)
```

SvPVbyte

Like `SvPV`, but converts sv to byte representation first if necessary.

```
char*   SvPVbyte(SV* sv, STRLEN len)
```

SvPVbytex

Like `SvPV`, but converts sv to byte representation first if necessary. Guarantees to evaluate sv only once; use the more efficient `SvPVbyte` otherwise.

```
char*   SvPVbytex(SV* sv, STRLEN len)
```

SvPVbytex_force

Like `SvPV_force`, but converts sv to byte representation first if necessary. Guarantees to evaluate sv only once; use the more efficient `SvPVbyte_force` otherwise.

```
char*   SvPVbytex_force(SV* sv, STRLEN len)
```

SvPVbyte_force

Like `SvPV_force`, but converts sv to byte representation first if necessary.

```
        char*   SvPVbyte_force(SV* sv, STRLEN len)
```

SvPVbyte_nolen

Like `SvPV_nolen`, but converts sv to byte representation first if necessary.

```
        char*   SvPVbyte_nolen(SV* sv)
```

SvPVutf8

Like `SvPV`, but converts sv to utf8 first if necessary.

```
        char*   SvPVutf8(SV* sv, STRLEN len)
```

SvPVutf8x

Like `SvPV`, but converts sv to utf8 first if necessary. Guarantees to evaluate sv only once; use the more efficient `SvPVutf8` otherwise.

```
        char*   SvPVutf8x(SV* sv, STRLEN len)
```

SvPVutf8x_force

Like `SvPV_force`, but converts sv to utf8 first if necessary. Guarantees to evaluate sv only once; use the more efficient `SvPVutf8_force` otherwise.

```
        char*   SvPVutf8x_force(SV* sv, STRLEN len)
```

SvPVutf8_force

Like `SvPV_force`, but converts sv to utf8 first if necessary.

```
        char*   SvPVutf8_force(SV* sv, STRLEN len)
```

SvPVutf8_nolen

Like `SvPV_nolen`, but converts sv to utf8 first if necessary.

```
        char*   SvPVutf8_nolen(SV* sv)
```

SvPVX

Returns a pointer to the physical string in the SV. The SV must contain a string.

```
        char*   SvPVX(SV* sv)
```

SvPVx

A version of `SvPV` which guarantees to evaluate sv only once.

```
        char*   SvPVx(SV* sv, STRLEN len)
```

SvPV_force

Like `SvPV` but will force the SV into containing just a string (`SvPOK_only`). You want force if you are going to update the `SvPVX` directly.

```
        char*   SvPV_force(SV* sv, STRLEN len)
```

SvPV_force_nomg

Like `SvPV` but will force the SV into containing just a string (`SvPOK_only`). You want force if you are going to update the `SvPVX` directly. Doesn't process magic.

```
        char*   SvPV_force_nomg(SV* sv, STRLEN len)
```

SvPV_nolen

Returns a pointer to the string in the SV, or a stringified form of the SV if the SV does not contain a string. The SV may cache the stringified form becoming `SvPOK`. Handles 'get' magic.

```
        char*   SvPV_nolen(SV* sv)
```

SvREFCNT

Returns the value of the object's reference count.

```
        U32     SvREFCNT(SV* sv)
```

SvREFCNT_dec

Decrements the reference count of the given SV.

```
        void    SvREFCNT_dec(SV* sv)
```

SvREFCNT_inc

Increments the reference count of the given SV.

```
        SV*     SvREFCNT_inc(SV* sv)
```

SvROK

Tests if the SV is an RV.

```
        bool    SvROK(SV* sv)
```

SvROK_off

Unsets the RV status of an SV.

```
        void    SvROK_off(SV* sv)
```

SvROK_on

Tells an SV that it is an RV.

```
        void    SvROK_on(SV* sv)
```

SvRV

Dereferences an RV to return the SV.

```
        SV*     SvRV(SV* sv)
```

SvSTASH

Returns the stash of the SV.

```
        HV*     SvSTASH(SV* sv)
```

SvTAINT

Taints an SV if tainting is enabled.

```
        void    SvTAINT(SV* sv)
```

SvTAINTED

Checks to see if an SV is tainted. Returns TRUE if it is, FALSE if not.

```
        bool    SvTAINTED(SV* sv)
```

SvTAINTED_off

Untaints an SV. Be *very* careful with this routine, as it short-circuits some of Perl's fundamental security features. XS module authors should not use this function unless they fully understand all the implications of unconditionally untainting the value. Untainting should be done in the standard perl fashion, via a carefully crafted regexp, rather than directly untainting variables.

```
        void    SvTAINTED_off(SV* sv)
```

SvTAINTED_on

Marks an SV as tainted if tainting is enabled.

```
        void    SvTAINTED_on(SV* sv)
```

SvTRUE

Returns a boolean indicating whether Perl would evaluate the SV as true or false, defined or undefined. Does not handle 'get' magic.

```
        bool    SvTRUE(SV* sv)
```

SvTYPE

Returns the type of the SV. See `svtype`.

```
        svtype  SvTYPE(SV* sv)
```

SvUOK

Returns a boolean indicating whether the SV contains an unsigned integer.

```
        void    SvUOK(SV* sv)
```

SvUPGRADE

Used to upgrade an SV to a more complex form. Uses `sv_upgrade` to perform the upgrade if necessary. See `svtype`.

```
        void    SvUPGRADE(SV* sv, svtype type)
```

SvUTF8

Returns a boolean indicating whether the SV contains UTF-8 encoded data.

```
        bool    SvUTF8(SV* sv)
```

SvUTF8_off

Unsets the UTF-8 status of an SV.

```
void    SvUTF8_off(SV *sv)
```

SvUTF8_on

Turn on the UTF-8 status of an SV (the data is not changed, just the flag). Do not use frivolously.

```
void    SvUTF8_on(SV *sv)
```

SvUV

Coerces the given SV to an unsigned integer and returns it. See `SvUVx` for a version which guarantees to evaluate sv only once.

```
UV      SvUV(SV* sv)
```

SvUVx

Coerces the given SV to an unsigned integer and returns it. Guarantees to evaluate sv only once. Use the more efficient `SvUV` otherwise.

```
UV      SvUVx(SV* sv)
```

SvUVX

Returns the raw value in the SV's UV slot, without checks or conversions. Only use when you are sure SvIOK is true. See also `SvUV()`.

```
UV      SvUVX(SV* sv)
```

sv_2bool

This function is only called on magical items, and is only used by sv_true() or its macro equivalent.

```
bool    sv_2bool(SV* sv)
```

sv_2cv

Using various gambits, try to get a CV from an SV; in addition, try if possible to set `*st` and `*gvp` to the stash and GV associated with it.

```
CV*     sv_2cv(SV* sv, HV** st, GV** gvp, I32 lref)
```

sv_2io

Using various gambits, try to get an IO from an SV: the IO slot if its a GV; or the recursive result if we're an RV; or the IO slot of the symbol named after the PV if we're a string.

```
IO*     sv_2io(SV* sv)
```

sv_2iv

Return the integer value of an SV, doing any necessary string conversion, magic etc. Normally used via the `SvIV(sv)` and `SvIVx(sv)` macros.

```
IV      sv_2iv(SV* sv)
```

sv_2mortal

Marks an existing SV as mortal. The SV will be destroyed "soon", either by an explicit call to FREETMPS, or by an implicit call at places such as statement boundaries. See also `sv_newmortal` and `sv_mortalcopy`.

```
        SV*     sv_2mortal(SV* sv)
```

sv_2nv

Return the num value of an SV, doing any necessary string or integer conversion, magic etc. Normally used via the `SvNV(sv)` and `SvNVx(sv)` macros.

```
        NV      sv_2nv(SV* sv)
```

sv_2pvbyte

Return a pointer to the byte-encoded representation of the SV, and set *lp to its length. May cause the SV to be downgraded from UTF-8 as a side-effect.

Usually accessed via the `SvPVbyte` macro.

```
        char*   sv_2pvbyte(SV* sv, STRLEN* lp)
```

sv_2pvbyte_nolen

Return a pointer to the byte-encoded representation of the SV. May cause the SV to be downgraded from UTF-8 as a side-effect.

Usually accessed via the `SvPVbyte_nolen` macro.

```
        char*   sv_2pvbyte_nolen(SV* sv)
```

sv_2pvutf8

Return a pointer to the UTF-8-encoded representation of the SV, and set *lp to its length. May cause the SV to be upgraded to UTF-8 as a side-effect.

Usually accessed via the `SvPVutf8` macro.

```
        char*   sv_2pvutf8(SV* sv, STRLEN* lp)
```

sv_2pvutf8_nolen

Return a pointer to the UTF-8-encoded representation of the SV. May cause the SV to be upgraded to UTF-8 as a side-effect.

Usually accessed via the `SvPVutf8_nolen` macro.

```
        char*   sv_2pvutf8_nolen(SV* sv)
```

sv_2pv_flags

Returns a pointer to the string value of an SV, and sets *lp to its length. If flags includes SV_GMAGIC, does an mg_get() first. Coerces sv to a string if necessary. Normally invoked via the `SvPV_flags` macro. `sv_2pv()` and `sv_2pv_nomg` usually end up here too.

```
        char*   sv_2pv_flags(SV* sv, STRLEN* lp, I32 flags)
```

sv_2pv_nolen

Like `sv_2pv()`, but doesn't return the length too. You should usually use the macro wrapper `SvPV_nolen(sv)` instead. char* sv_2pv_nolen(SV* sv)

sv_2uv

Return the unsigned integer value of an SV, doing any necessary string conversion, magic etc. Normally used via the `SvUV(sv)` and `SvUVx(sv)` macros.

```
        UV      sv_2uv(SV* sv)
```

sv_backoff

Remove any string offset. You should normally use the `SvOOK_off` macro wrapper instead.

```
        int     sv_backoff(SV* sv)
```

sv_bless

Blesses an SV into a specified package. The SV must be an RV. The package must be designated by its stash (see `gv_stashpv()`). The reference count of the SV is unaffected.

```
        SV*     sv_bless(SV* sv, HV* stash)
```

sv_catpv

Concatenates the string onto the end of the string which is in the SV. If the SV has the UTF-8 status set, then the bytes appended should be valid UTF-8. Handles 'get' magic, but not 'set' magic. See `sv_catpv_mg`.

```
        void    sv_catpv(SV* sv, const char* ptr)
```

sv_catpvf

Processes its arguments like `sprintf` and appends the formatted output to an SV. If the appended data contains "wide" characters (including, but not limited to, SVs with a UTF-8 PV formatted with %s, and characters >255 formatted with %c), the original SV might get upgraded to UTF-8. Handles 'get' magic, but not 'set' magic. `SvSETMAGIC()` must typically be called after calling this function to handle 'set' magic.

```
        void    sv_catpvf(SV* sv, const char* pat, ...)
```

sv_catpvf_mg

Like `sv_catpvf`, but also handles 'set' magic.

```
        void    sv_catpvf_mg(SV *sv, const char* pat, ...)
```

sv_catpvn

Concatenates the string onto the end of the string which is in the SV. The `len` indicates number of bytes to copy. If the SV has the UTF-8 status set, then the bytes appended should be valid UTF-8. Handles 'get' magic, but not 'set' magic. See `sv_catpvn_mg`.

```
        void    sv_catpvn(SV* sv, const char* ptr, STRLEN len)
```

sv_catpvn_flags

Concatenates the string onto the end of the string which is in the SV. The `len` indicates number of bytes to copy. If the SV has the UTF-8 status set, then the bytes appended should be valid UTF-8. If `flags` has `SV_GMAGIC` bit set, will `mg_get` on `dsv` if appropriate, else not. `sv_catpvn` and `sv_catpvn_nomg` are implemented in terms of this function.

```
        void    sv_catpvn_flags(SV* sv, const char* ptr, STRLEN len, I32 flags)
```

sv_catpvn_mg

Like `sv_catpvn`, but also handles 'set' magic.

```
        void    sv_catpvn_mg(SV *sv, const char *ptr, STRLEN len)
```

sv_catpv_mg

Like `sv_catpv`, but also handles 'set' magic.

```
        void    sv_catpv_mg(SV *sv, const char *ptr)
```

sv_catsv

Concatenates the string from SV `ssv` onto the end of the string in SV `dsv`. Modifies `dsv` but not `ssv`. Handles 'get' magic, but not 'set' magic. See `sv_catsv_mg`.

```
        void    sv_catsv(SV* dsv, SV* ssv)
```

sv_catsv_flags

Concatenates the string from SV `ssv` onto the end of the string in SV `dsv`. Modifies `dsv` but not `ssv`. If `flags` has `SV_GMAGIC` bit set, will `mg_get` on the SVs if appropriate, else not. `sv_catsv` and `sv_catsv_nomg` are implemented in terms of this function.

```
        void    sv_catsv_flags(SV* dsv, SV* ssv, I32 flags)
```

sv_catsv_mg

Like `sv_catsv`, but also handles 'set' magic.

```
        void    sv_catsv_mg(SV *dstr, SV *sstr)
```

sv_chop

Efficient removal of characters from the beginning of the string buffer. SvPOK(sv) must be true and the `ptr` must be a pointer to somewhere inside the string buffer. The `ptr` becomes the first character of the adjusted string. Uses the "OOK hack". Beware: after this function returns, `ptr` and SvPVX(sv) may no longer refer to the same chunk of data.

```
        void    sv_chop(SV* sv, char* ptr)
```

sv_clear

Clear an SV: call any destructors, free up any memory used by the body, and free the body itself. The SV's head is *not* freed, although its type is set to all 1's so that it won't inadvertently be assumed to be live during global destruction etc. This function should only be called when REFCNT is zero. Most of the time you'll want to call `sv_free()` (or its macro wrapper `SvREFCNT_dec`) instead.

```
        void    sv_clear(SV* sv)
```

sv_cmp

Compares the strings in two SVs. Returns -1, 0, or 1 indicating whether the string in `sv1` is less than, equal to, or greater than the string in `sv2`. Is UTF-8 and 'use bytes' aware, handles get magic, and will coerce its args to strings if necessary. See also `sv_cmp_locale`.

```
        I32     sv_cmp(SV* sv1, SV* sv2)
```

sv_cmp_locale

Compares the strings in two SVs in a locale-aware manner. Is UTF-8 and 'use bytes' aware, handles get magic, and will coerce its args to strings if necessary. See also `sv_cmp_locale`. See also `sv_cmp`.

```
        I32     sv_cmp_locale(SV* sv1, SV* sv2)
```

sv_collxfrm

Add Collate Transform magic to an SV if it doesn't already have it.

Any scalar variable may carry PERL_MAGIC_collxfrm magic that contains the scalar data of the variable, but transformed to such a format that a normal memory comparison can be used to compare the data according to the locale settings.

```
        char*   sv_collxfrm(SV* sv, STRLEN* nxp)
```

sv_copypv

Copies a stringified representation of the source SV into the destination SV. Automatically performs any necessary mg_get and coercion of numeric values into strings. Guaranteed to preserve UTF-8 flag even from overloaded objects. Similar in nature to sv_2pv[_flags] but operates directly on an SV instead of just the string. Mostly uses sv_2pv_flags to do its work, except when that would lose the UTF-8'ness of the PV.

```
        void    sv_copypv(SV* dsv, SV* ssv)
```

sv_dec

Auto-decrement of the value in the SV, doing string to numeric conversion if necessary. Handles 'get' magic.

```
        void    sv_dec(SV* sv)
```

sv_derived_from

Returns a boolean indicating whether the SV is derived from the specified class. This is the function that implements `UNIVERSAL::isa`. It works for class names as well as for objects.

```
        bool    sv_derived_from(SV* sv, const char* name)
```

sv_eq

Returns a boolean indicating whether the strings in the two SVs are identical. Is UTF-8 and 'use bytes' aware, handles get magic, and will coerce its args to strings if necessary.

```
        I32     sv_eq(SV* sv1, SV* sv2)
```

sv_force_normal

Undo various types of fakery on an SV: if the PV is a shared string, make a private copy; if we're a ref, stop refing; if we're a glob, downgrade to an xpvmg. See also `sv_force_normal_flags`.

```
        void    sv_force_normal(SV *sv)
```

sv_force_normal_flags

Undo various types of fakery on an SV: if the PV is a shared string, make a private copy; if we're a ref, stop refing; if we're a glob, downgrade to an xpvmg. The `flags` parameter gets passed to `sv_unref_flags()` when unrefing. `sv_force_normal` calls this function with flags set to 0.

```
        void    sv_force_normal_flags(SV *sv, U32 flags)
```

sv_free

Decrement an SV's reference count, and if it drops to zero, call `sv_clear` to invoke destructors and free up any memory used by the body; finally, deallocate the SV's head itself. Normally called via a wrapper macro `SvREFCNT_dec`.

```
void    sv_free(SV* sv)
```

sv_gets

Get a line from the filehandle and store it into the SV, optionally appending to the currently-stored string.

```
char*   sv_gets(SV* sv, PerlIO* fp, I32 append)
```

sv_grow

Expands the character buffer in the SV. If necessary, uses `sv_unref` and upgrades the SV to `SVt_PV`. Returns a pointer to the character buffer. Use the `SvGROW` wrapper instead.

```
char*   sv_grow(SV* sv, STRLEN newlen)
```

sv_inc

Auto-increment of the value in the SV, doing string to numeric conversion if necessary. Handles 'get' magic.

```
void    sv_inc(SV* sv)
```

sv_insert

Inserts a string at the specified offset/length within the SV. Similar to the Perl substr() function.

```
void    sv_insert(SV* bigsv, STRLEN offset, STRLEN len, char* little, STRLEN littlelen)
```

sv_isa

Returns a boolean indicating whether the SV is blessed into the specified class. This does not check for subtypes; use `sv_derived_from` to verify an inheritance relationship.

```
int     sv_isa(SV* sv, const char* name)
```

sv_isobject

Returns a boolean indicating whether the SV is an RV pointing to a blessed object. If the SV is not an RV, or if the object is not blessed, then this will return false.

```
int     sv_isobject(SV* sv)
```

sv_iv

A private implementation of the `SvIVx` macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
IV      sv_iv(SV* sv)
```

sv_len

Returns the length of the string in the SV. Handles magic and type coercion. See also `SvCUR`, which gives raw access to the xpv_cur slot.

```
STRLEN  sv_len(SV* sv)
```

sv_len_utf8

Returns the number of characters in the string in an SV, counting wide UTF-8 bytes as a single character. Handles magic and type coercion.

```
        STRLEN  sv_len_utf8(SV* sv)
```

sv_magic

Adds magic to an SV. First upgrades `sv` to type `SVt_PVMG` if necessary, then adds a new magic item of type `how` to the head of the magic list.

```
        void    sv_magic(SV* sv, SV* obj, int how, const char* name, I32 namlen)
```

sv_magicext

Adds magic to an SV, upgrading it if necessary. Applies the supplied vtable and returns pointer to the magic added.

Note that sv_magicext will allow things that sv_magic will not. In particular you can add magic to SvREADONLY SVs and and more than one instance of the same 'how'

I `namelen` is greater then zero then a savepvn() *copy* of `name` is stored, if `namelen` is zero then `name` is stored as-is and - as another special case - if `(name && namelen == HEf_SVKEY)` then `name` is assumed to contain an `SV*` and has its REFCNT incremented

(This is now used as a subroutine by sv_magic.)

```
        MAGIC * sv_magicext(SV* sv, SV* obj, int how, MGVTBL *vtbl, const char* name, I32 namlen
```

sv_mortalcopy

Creates a new SV which is a copy of the original SV (using `sv_setsv`). The new SV is marked as mortal. It will be destroyed "soon", either by an explicit call to FREETMPS, or by an implicit call at places such as statement boundaries. See also `sv_newmortal` and `sv_2mortal`.

```
        SV*     sv_mortalcopy(SV* oldsv)
```

sv_newmortal

Creates a new null SV which is mortal. The reference count of the SV is set to 1. It will be destroyed "soon", either by an explicit call to FREETMPS, or by an implicit call at places such as statement boundaries. See also `sv_mortalcopy` and `sv_2mortal`.

```
        SV*     sv_newmortal()
```

sv_newref

Increment an SV's reference count. Use the `SvREFCNT_inc()` wrapper instead.

```
        SV*     sv_newref(SV* sv)
```

sv_nv

A private implementation of the `SvNVx` macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
        NV      sv_nv(SV* sv)
```

sv_pos_b2u

Converts the value pointed to by offsetp from a count of bytes from the start of the string, to a count of the equivalent number of UTF-8 chars. Handles magic and type coercion.

```
        void    sv_pos_b2u(SV* sv, I32* offsetp)
```

sv_pos_u2b

Converts the value pointed to by offsetp from a count of UTF-8 chars from the start of the string, to a count of the equivalent number of bytes; if lenp is non-zero, it does the same to lenp, but this time starting from the offset, rather than from the start of the string. Handles magic and type coercion.

```
        void    sv_pos_u2b(SV* sv, I32* offsetp, I32* lenp)
```

sv_pv

Use the SvPV_nolen macro instead

```
        char*   sv_pv(SV *sv)
```

sv_pvbyte

Use SvPVbyte_nolen instead.

```
        char*   sv_pvbyte(SV *sv)
```

sv_pvbyten

A private implementation of the SvPVbyte macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
        char*   sv_pvbyten(SV *sv, STRLEN *len)
```

sv_pvbyten_force

A private implementation of the SvPVbytex_force macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
        char*   sv_pvbyten_force(SV* sv, STRLEN* lp)
```

sv_pvn

A private implementation of the SvPV macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
        char*   sv_pvn(SV *sv, STRLEN *len)
```

sv_pvn_force

Get a sensible string out of the SV somehow. A private implementation of the SvPV_force macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
        char*   sv_pvn_force(SV* sv, STRLEN* lp)
```

sv_pvn_force_flags

Get a sensible string out of the SV somehow. If flags has SV_GMAGIC bit set, will mg_get on sv if appropriate, else not. sv_pvn_force and sv_pvn_force_nomg are implemented in terms of this function. You normally want to use the various wrapper macros instead: see SvPV_force and SvPV_force_nomg

```
        char*   sv_pvn_force_flags(SV* sv, STRLEN* lp, I32 flags)
```

sv_pvutf8

Use the SvPVutf8_nolen macro instead

```
char*   sv_pvutf8(SV *sv)
```

sv_pvutf8n

A private implementation of the `SvPVutf8` macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
char*   sv_pvutf8n(SV *sv, STRLEN *len)
```

sv_pvutf8n_force

A private implementation of the `SvPVutf8_force` macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
char*   sv_pvutf8n_force(SV* sv, STRLEN* lp)
```

sv_reftype

Returns a string describing what the SV is a reference to.

```
char*   sv_reftype(SV* sv, int ob)
```

sv_replace

Make the first argument a copy of the second, then delete the original. The target SV physically takes over ownership of the body of the source SV and inherits its flags; however, the target keeps any magic it owns, and any magic in the source is discarded. Note that this is a rather specialist SV copying operation; most of the time you'll want to use `sv_setsv` or one of its many macro front-ends.

```
void    sv_replace(SV* sv, SV* nsv)
```

sv_report_used

Dump the contents of all SVs not yet freed. (Debugging aid).

```
void    sv_report_used()
```

sv_reset

Underlying implementation for the `reset` Perl function. Note that the perl-level function is vaguely deprecated.

```
void    sv_reset(char* s, HV* stash)
```

sv_rvweaken

Weaken a reference: set the `SvWEAKREF` flag on this RV; give the referred-to SV `PERL_MAGIC_backref` magic if it hasn't already; and push a back-reference to this RV onto the array of backreferences associated with that magic.

```
SV*     sv_rvweaken(SV *sv)
```

sv_setiv

Copies an integer into the given SV, upgrading first if necessary. Does not handle 'set' magic. See also `sv_setiv_mg`.

```
void    sv_setiv(SV* sv, IV num)
```

sv_setiv_mg

Like `sv_setiv`, but also handles 'set' magic.

```
        void    sv_setiv_mg(SV *sv, IV i)
```

sv_setnv

Copies a double into the given SV, upgrading first if necessary. Does not handle 'set' magic. See also `sv_setnv_mg`.

```
        void    sv_setnv(SV* sv, NV num)
```

sv_setnv_mg

Like `sv_setnv`, but also handles 'set' magic.

```
        void    sv_setnv_mg(SV *sv, NV num)
```

sv_setpv

Copies a string into an SV. The string must be null-terminated. Does not handle 'set' magic. See `sv_setpv_mg`.

```
        void    sv_setpv(SV* sv, const char* ptr)
```

sv_setpvf

Processes its arguments like `sprintf` and sets an SV to the formatted output. Does not handle 'set' magic. See `sv_setpvf_mg`.

```
        void    sv_setpvf(SV* sv, const char* pat, ...)
```

sv_setpvf_mg

Like `sv_setpvf`, but also handles 'set' magic.

```
        void    sv_setpvf_mg(SV *sv, const char* pat, ...)
```

sv_setpviv

Copies an integer into the given SV, also updating its string value. Does not handle 'set' magic. See `sv_setpviv_mg`.

```
        void    sv_setpviv(SV* sv, IV num)
```

sv_setpviv_mg

Like `sv_setpviv`, but also handles 'set' magic.

```
        void    sv_setpviv_mg(SV *sv, IV iv)
```

sv_setpvn

Copies a string into an SV. The `len` parameter indicates the number of bytes to be copied. If the `ptr` argument is NULL the SV will become undefined. Does not handle 'set' magic. See `sv_setpvn_mg`.

```
        void    sv_setpvn(SV* sv, const char* ptr, STRLEN len)
```

sv_setpvn_mg

Like `sv_setpvn`, but also handles 'set' magic.

```
        void    sv_setpvn_mg(SV *sv, const char *ptr, STRLEN len)
```

sv_setpv_mg

Like `sv_setpv`, but also handles 'set' magic.

```
        void    sv_setpv_mg(SV *sv, const char *ptr)
```

sv_setref_iv

Copies an integer into a new SV, optionally blessing the SV. The `rv` argument will be upgraded to an RV. That RV will be modified to point to the new SV. The `classname` argument indicates the package for the blessing. Set `classname` to `Nullch` to avoid the blessing. The new SV will have a reference count of 1, and the RV will be returned.

```
        SV*     sv_setref_iv(SV* rv, const char* classname, IV iv)
```

sv_setref_nv

Copies a double into a new SV, optionally blessing the SV. The `rv` argument will be upgraded to an RV. That RV will be modified to point to the new SV. The `classname` argument indicates the package for the blessing. Set `classname` to `Nullch` to avoid the blessing. The new SV will have a reference count of 1, and the RV will be returned.

```
        SV*     sv_setref_nv(SV* rv, const char* classname, NV nv)
```

sv_setref_pv

Copies a pointer into a new SV, optionally blessing the SV. The `rv` argument will be upgraded to an RV. That RV will be modified to point to the new SV. If the `pv` argument is NULL then `PL_sv_undef` will be placed into the SV. The `classname` argument indicates the package for the blessing. Set `classname` to `Nullch` to avoid the blessing. The new SV will have a reference count of 1, and the RV will be returned.

Do not use with other Perl types such as HV, AV, SV, CV, because those objects will become corrupted by the pointer copy process.

Note that `sv_setref_pvn` copies the string while this copies the pointer.

```
        SV*     sv_setref_pv(SV* rv, const char* classname, void* pv)
```

sv_setref_pvn

Copies a string into a new SV, optionally blessing the SV. The length of the string must be specified with `n`. The `rv` argument will be upgraded to an RV. That RV will be modified to point to the new SV. The `classname` argument indicates the package for the blessing. Set `classname` to `Nullch` to avoid the blessing. The new SV will have a reference count of 1, and the RV will be returned.

Note that `sv_setref_pv` copies the pointer while this copies the string.

```
        SV*     sv_setref_pvn(SV* rv, const char* classname, char* pv, STRLEN n)
```

sv_setref_uv

Copies an unsigned integer into a new SV, optionally blessing the SV. The `rv` argument will be upgraded to an RV. That RV will be modified to point to the new SV. The `classname` argument indicates the package for the blessing. Set `classname` to `Nullch` to avoid the blessing. The new SV will have a reference count of 1, and the RV will be returned.

```
        SV*     sv_setref_uv(SV* rv, const char* classname, UV uv)
```

sv_setsv

Copies the contents of the source SV `ssv` into the destination SV `dsv`. The source SV may be destroyed if it is mortal, so don't use this function if the source SV needs to be reused. Does not handle 'set' magic. Loosely speaking, it performs a copy-by-value, obliterating any previous content of the destination.

You probably want to use one of the assortment of wrappers, such as `SvSetSV`, `SvSetSV_nosteal`, `SvSetMagicSV` and `SvSetMagicSV_nosteal`.

```
        void    sv_setsv(SV* dsv, SV* ssv)
```

sv_setsv_flags

Copies the contents of the source SV `ssv` into the destination SV `dsv`. The source SV may be destroyed if it is mortal, so don't use this function if the source SV needs to be reused. Does not handle 'set' magic. Loosely speaking, it performs a copy-by-value, obliterating any previous content of the destination. If the `flags` parameter has the `SV_GMAGIC` bit set, will `mg_get` on `ssv` if appropriate, else not. `sv_setsv` and `sv_setsv_nomg` are implemented in terms of this function.

You probably want to use one of the assortment of wrappers, such as `SvSetSV`, `SvSetSV_nosteal`, `SvSetMagicSV` and `SvSetMagicSV_nosteal`.

This is the primary function for copying scalars, and most other copy-ish functions and macros use this underneath.

```
        void    sv_setsv_flags(SV* dsv, SV* ssv, I32 flags)
```

sv_setsv_mg

Like `sv_setsv`, but also handles 'set' magic.

```
        void    sv_setsv_mg(SV *dstr, SV *sstr)
```

sv_setuv

Copies an unsigned integer into the given SV, upgrading first if necessary. Does not handle 'set' magic. See also `sv_setuv_mg`.

```
        void    sv_setuv(SV* sv, UV num)
```

sv_setuv_mg

Like `sv_setuv`, but also handles 'set' magic.

```
        void    sv_setuv_mg(SV *sv, UV u)
```

sv_taint

Taint an SV. Use `SvTAINTED_on` instead. void sv_taint(SV* sv)

sv_tainted

Test an SV for taintedness. Use `SvTAINTED` instead. bool sv_tainted(SV* sv)

sv_true

Returns true if the SV has a true value by Perl's rules. Use the `SvTRUE` macro instead, which may call `sv_true()` or may instead use an in-line version.

```
        I32     sv_true(SV *sv)
```

sv_unmagic

Removes all magic of type `type` from an SV.

```
        int     sv_unmagic(SV* sv, int type)
```

sv_unref

Unsets the RV status of the SV, and decrements the reference count of whatever was being referenced by the RV. This can almost be thought of as a reversal of `newSVrv`. This is `sv_unref_flags` with the `flag` being zero. See `SvROK_off`.

```
        void    sv_unref(SV* sv)
```

sv_unref_flags

Unsets the RV status of the SV, and decrements the reference count of whatever was being referenced by the RV. This can almost be thought of as a reversal of `newSVrv`. The `cflags` argument can contain `SV_IMMEDIATE_UNREF` to force the reference count to be decremented (otherwise the decrementing is conditional on the reference count being different from one or the reference being a readonly SV). See `SvROK_off`.

```
        void    sv_unref_flags(SV* sv, U32 flags)
```

sv_untaint

Untaint an SV. Use `SvTAINTED_off` instead. void sv_untaint(SV* sv)

sv_upgrade

Upgrade an SV to a more complex form. Generally adds a new body type to the SV, then copies across as much information as possible from the old body. You generally want to use the `SvUPGRADE` macro wrapper. See also `svtype`.

```
        bool    sv_upgrade(SV* sv, U32 mt)
```

sv_usepvn

Tells an SV to use `ptr` to find its string value. Normally the string is stored inside the SV but sv_usepvn allows the SV to use an outside string. The `ptr` should point to memory that was allocated by `malloc`. The string length, `len`, must be supplied. This function will realloc the memory pointed to by `ptr`, so that pointer should not be freed or used by the programmer after giving it to sv_usepvn. Does not handle 'set' magic. See `sv_usepvn_mg`.

```
        void    sv_usepvn(SV* sv, char* ptr, STRLEN len)
```

sv_usepvn_mg

Like `sv_usepvn`, but also handles 'set' magic.

```
        void    sv_usepvn_mg(SV *sv, char *ptr, STRLEN len)
```

sv_utf8_decode

If the PV of the SV is an octet sequence in UTF-8 and contains a multiple-byte character, the `SvUTF8` flag is turned on so that it looks like a character. If the PV contains only single-byte characters, the `SvUTF8` flag stays being off. Scans PV for validity and returns false if the PV is invalid UTF-8.

NOTE: this function is experimental and may change or be removed without notice.

```
        bool    sv_utf8_decode(SV *sv)
```

sv_utf8_downgrade

Attempts to convert the PV of an SV from characters to bytes. If the PV contains a character beyond byte, this conversion will fail; in this case, either returns false or, if `fail_ok` is not true, croaks.

This is not as a general purpose Unicode to byte encoding interface: use the Encode extension for that.

NOTE: this function is experimental and may change or be removed without notice.

```
        bool    sv_utf8_downgrade(SV *sv, bool fail_ok)
```

sv_utf8_encode

Converts the PV of an SV to UTF-8, but then turns the SvUTF8 flag off so that it looks like octets again.

```
        void    sv_utf8_encode(SV *sv)
```

sv_utf8_upgrade

Converts the PV of an SV to its UTF-8-encoded form. Forces the SV to string form if it is not already. Always sets the SvUTF8 flag to avoid future validity checks even if all the bytes have hibit clear.

This is not as a general purpose byte encoding to Unicode interface: use the Encode extension for that.

```
        STRLEN  sv_utf8_upgrade(SV *sv)
```

sv_utf8_upgrade_flags

Converts the PV of an SV to its UTF-8-encoded form. Forces the SV to string form if it is not already. Always sets the SvUTF8 flag to avoid future validity checks even if all the bytes have hibit clear. If `flags` has `SV_GMAGIC` bit set, will `mg_get` on `sv` if appropriate, else not. `sv_utf8_upgrade` and `sv_utf8_upgrade_nomg` are implemented in terms of this function.

This is not as a general purpose byte encoding to Unicode interface: use the Encode extension for that.

```
        STRLEN  sv_utf8_upgrade_flags(SV *sv, I32 flags)
```

sv_uv

A private implementation of the `SvUVx` macro for compilers which can't cope with complex macro expressions. Always use the macro instead.

```
        UV      sv_uv(SV* sv)
```

sv_vcatpvfn

Processes its arguments like `vsprintf` and appends the formatted output to an SV. Uses an array of SVs if the C style variable argument list is missing (NULL). When running with taint checks enabled, indicates via `maybe_tainted` if results are untrustworthy (often due to the use of locales).

Usually used via one of its frontends `sv_catpvf` and `sv_catpvf_mg`.

```
        void    sv_vcatpvfn(SV* sv, const char* pat, STRLEN patlen, va_list* args, SV** svargs, I3
```

sv_vsetpvfn

Works like `vcatpvfn` but copies the text into the SV instead of appending it.

Usually used via one of its frontends `sv_setpvf` and `sv_setpvf_mg`.

```
        void    sv_vsetpvfn(SV* sv, const char* pat, STRLEN patlen, va_list* args, SV** svargs, I3
```

72.23 Unicode Support

bytes_from_utf8

Converts a string `s` of length `len` from UTF-8 into byte encoding. Unlike <utf8_to_bytes> but like `bytes_to_utf8`, returns a pointer to the newly-created string, and updates `len` to contain the new length. Returns the original string if no conversion occurs, `len` is unchanged. Do nothing if `is_utf8` points to 0. Sets `is_utf8` to 0 if `s` is converted or contains all 7bit characters.

NOTE: this function is experimental and may change or be removed without notice.

```
U8*     bytes_from_utf8(U8 *s, STRLEN *len, bool *is_utf8)
```

bytes_to_utf8

Converts a string `s` of length `len` from ASCII into UTF-8 encoding. Returns a pointer to the newly-created string, and sets `len` to reflect the new length.

If you want to convert to UTF-8 from other encodings than ASCII, see sv_recode_to_utf8().

NOTE: this function is experimental and may change or be removed without notice.

```
U8*     bytes_to_utf8(U8 *s, STRLEN *len)
```

ibcmp_utf8

Return true if the strings s1 and s2 differ case-insensitively, false if not (if they are equal case-insensitively). If u1 is true, the string s1 is assumed to be in UTF-8-encoded Unicode. If u2 is true, the string s2 is assumed to be in UTF-8-encoded Unicode. If u1 or u2 are false, the respective string is assumed to be in native 8-bit encoding.

If the pe1 and pe2 are non-NULL, the scanning pointers will be copied in there (they will point at the beginning of the *next* character). If the pointers behind pe1 or pe2 are non-NULL, they are the end pointers beyond which scanning will not continue under any circustances. If the byte lengths l1 and l2 are non-zero, s1+l1 and s2+l2 will be used as goal end pointers that will also stop the scan, and which qualify towards defining a successful match: all the scans that define an explicit length must reach their goal pointers for a match to succeed).

For case-insensitiveness, the "casefolding" of Unicode is used instead of upper/lowercasing both the characters, see http://www.unicode.org/unicode/reports/tr21/ (Case Mappings).

```
I32     ibcmp_utf8(const char* a, char **pe1, UV l1, bool u1, const char* b, char **pe2, U
```

is_utf8_char

Tests if some arbitrary number of bytes begins in a valid UTF-8 character. Note that an INVARIANT (i.e. ASCII) character is a valid UTF-8 character. The actual number of bytes in the UTF-8 character will be returned if it is valid, otherwise 0.

```
STRLEN  is_utf8_char(U8 *p)
```

is_utf8_string

Returns true if first `len` bytes of the given string form a valid UTF-8 string, false otherwise. Note that 'a valid UTF-8 string' does not mean 'a string that contains code points above 0x7F encoded in UTF-8' because a valid ASCII string is a valid UTF-8 string.

```
bool    is_utf8_string(U8 *s, STRLEN len)
```

is_utf8_string_loc

Like is_ut8_string but store the location of the failure in the last argument.

```
bool    is_utf8_string_loc(U8 *s, STRLEN len, U8 **p)
```

pv_uni_display

Build to the scalar dsv a displayable version of the string spv, length len, the displayable version being at most pvlim bytes long (if longer, the rest is truncated and "..." will be appended).

The flags argument can have UNI_DISPLAY_ISPRINT set to display isPRINT()able characters as themselves, UNI_DISPLAY_BACKSLASH to display the \\[nrfta\\] as the backslashed versions (like '\n') (UNI_DISPLAY_BACKSLASH is preferred over UNI_DISPLAY_ISPRINT for \\). UNI_DISPLAY_QQ (and its alias UNI_DISPLAY_REGEX) have both UNI_DISPLAY_BACKSLASH and UNI_DISPLAY_ISPRINT turned on.

The pointer to the PV of the dsv is returned.

```
        char*   pv_uni_display(SV *dsv, U8 *spv, STRLEN len, STRLEN pvlim, UV flags)
```

sv_cat_decode

The encoding is assumed to be an Encode object, the PV of the ssv is assumed to be octets in that encoding and decoding the input starts from the position which (PV + *offset) pointed to. The dsv will be concatenated the decoded UTF-8 string from ssv. Decoding will terminate when the string tstr appears in decoding output or the input ends on the PV of the ssv. The value which the offset points will be modified to the last input position on the ssv.

Returns TRUE if the terminator was found, else returns FALSE.

```
        bool    sv_cat_decode(SV* dsv, SV *encoding, SV *ssv, int *offset, char* tstr, int tlen)
```

sv_recode_to_utf8

The encoding is assumed to be an Encode object, on entry the PV of the sv is assumed to be octets in that encoding, and the sv will be converted into Unicode (and UTF-8).

If the sv already is UTF-8 (or if it is not POK), or if the encoding is not a reference, nothing is done to the sv. If the encoding is not an `Encode::XS` Encoding object, bad things will happen. (See *lib/encoding.pm* and *Encode*).

The PV of the sv is returned.

```
        char*   sv_recode_to_utf8(SV* sv, SV *encoding)
```

sv_uni_display

Build to the scalar dsv a displayable version of the scalar sv, the displayable version being at most pvlim bytes long (if longer, the rest is truncated and "..." will be appended).

The flags argument is as in pv_uni_display().

The pointer to the PV of the dsv is returned.

```
        char*   sv_uni_display(SV *dsv, SV *ssv, STRLEN pvlim, UV flags)
```

to_utf8_case

The "p" contains the pointer to the UTF-8 string encoding the character that is being converted.

The "ustrp" is a pointer to the character buffer to put the conversion result to. The "lenp" is a pointer to the length of the result.

The "swashp" is a pointer to the swash to use.

Both the special and normal mappings are stored lib/unicore/To/Foo.pl, and loaded by SWASHGET, using lib/utf8_heavy.pl. The special (usually, but not always, a multicharacter mapping), is tried first.

The "special" is a string like "utf8::ToSpecLower", which means the hash %utf8::ToSpecLower. The access to the hash is through Perl_to_utf8_case().

The "normal" is a string like "ToLower" which means the swash %utf8::ToLower.

```
        UV      to_utf8_case(U8 *p, U8* ustrp, STRLEN *lenp, SV **swash, char *normal, char *speci
```

to_utf8_fold

Convert the UTF-8 encoded character at p to its foldcase version and store that in UTF-8 in ustrp and its length in bytes in lenp. Note that the ustrp needs to be at least UTF8_MAXLEN_FOLD+1 bytes since the foldcase version may be longer than the original character (up to three characters).

The first character of the foldcased version is returned (but note, as explained above, that there may be more.)

```
        UV      to_utf8_fold(U8 *p, U8* ustrp, STRLEN *lenp)
```

to_utf8_lower

Convert the UTF-8 encoded character at p to its lowercase version and store that in UTF-8 in ustrp and its length in bytes in lenp. Note that the ustrp needs to be at least UTF8_MAXLEN_UCLC+1 bytes since the lowercase version may be longer than the original character (up to two characters).

The first character of the lowercased version is returned (but note, as explained above, that there may be more.)

```
        UV      to_utf8_lower(U8 *p, U8* ustrp, STRLEN *lenp)
```

to_utf8_title

Convert the UTF-8 encoded character at p to its titlecase version and store that in UTF-8 in ustrp and its length in bytes in lenp. Note that the ustrp needs to be at least UTF8_MAXLEN_UCLC+1 bytes since the titlecase version may be longer than the original character (up to two characters).

The first character of the titlecased version is returned (but note, as explained above, that there may be more.)

```
        UV      to_utf8_title(U8 *p, U8* ustrp, STRLEN *lenp)
```

to_utf8_upper

Convert the UTF-8 encoded character at p to its uppercase version and store that in UTF-8 in ustrp and its length in bytes in lenp. Note that the ustrp needs to be at least UTF8_MAXLEN_UCLC+1 bytes since the uppercase version may be longer than the original character (up to two characters).

The first character of the uppercased version is returned (but note, as explained above, that there may be more.)

```
        UV      to_utf8_upper(U8 *p, U8* ustrp, STRLEN *lenp)
```

utf8n_to_uvchr

Returns the native character value of the first character in the string `s` which is assumed to be in UTF-8 encoding; `retlen` will be set to the length, in bytes, of that character.

Allows length and flags to be passed to low level routine.

```
        UV      utf8n_to_uvchr(U8 *s, STRLEN curlen, STRLEN* retlen, U32 flags)
```

utf8n_to_uvuni

Bottom level UTF-8 decode routine. Returns the unicode code point value of the first character in the string `s` which is assumed to be in UTF-8 encoding and no longer than `curlen`; `retlen` will be set to the length, in bytes, of that character.

If `s` does not point to a well-formed UTF-8 character, the behaviour is dependent on the value of `flags`: if it contains UTF8_CHECK_ONLY, it is assumed that the caller will raise a warning, and this function will silently just set `retlen` to `-1` and return zero. If the `flags` does not contain UTF8_CHECK_ONLY, warnings about malformations will be given, `retlen` will be set to the expected length of the UTF-8 character in bytes, and zero will be returned.

The `flags` can also contain various flags to allow deviations from the strict UTF-8 encoding (see *utf8.h*).

Most code should use utf8_to_uvchr() rather than call this directly.

```
        UV      utf8n_to_uvuni(U8 *s, STRLEN curlen, STRLEN* retlen, U32 flags)
```

utf8_distance

Returns the number of UTF-8 characters between the UTF-8 pointers a and b.

WARNING: use only if you *know* that the pointers point inside the same UTF-8 buffer.

```
        IV      utf8_distance(U8 *a, U8 *b)
```

utf8_hop

Return the UTF-8 pointer s displaced by off characters, either forward or backward.

WARNING: do not use the following unless you *know* off is within the UTF-8 data pointed to by s *and* that on entry s is aligned on the first byte of character or just after the last byte of a character.

```
        U8*     utf8_hop(U8 *s, I32 off)
```

utf8_length

Return the length of the UTF-8 char encoded string s in characters. Stops at e (inclusive). If e < s or if the scan would end up past e, croaks.

```
        STRLEN  utf8_length(U8* s, U8 *e)
```

utf8_to_bytes

Converts a string s of length len from UTF-8 into byte encoding. Unlike bytes_to_utf8, this over-writes the original string, and updates len to contain the new length. Returns zero on failure, setting len to -1.

NOTE: this function is experimental and may change or be removed without notice.

```
        U8*     utf8_to_bytes(U8 *s, STRLEN *len)
```

utf8_to_uvchr

Returns the native character value of the first character in the string s which is assumed to be in UTF-8 encoding; retlen will be set to the length, in bytes, of that character.

If s does not point to a well-formed UTF-8 character, zero is returned and retlen is set, if possible, to -1.

```
        UV      utf8_to_uvchr(U8 *s, STRLEN* retlen)
```

utf8_to_uvuni

Returns the Unicode code point of the first character in the string s which is assumed to be in UTF-8 encoding; retlen will be set to the length, in bytes, of that character.

This function should only be used when returned UV is considered an index into the Unicode semantic tables (e.g. swashes).

If s does not point to a well-formed UTF-8 character, zero is returned and retlen is set, if possible, to -1.

```
        UV      utf8_to_uvuni(U8 *s, STRLEN* retlen)
```

uvchr_to_utf8

Adds the UTF-8 representation of the Native codepoint uv to the end of the string d; d should be have at least UTF8_MAXLEN+1 free bytes available. The return value is the pointer to the byte after the end of the new character. In other words,

```
    d = uvchr_to_utf8(d, uv);
```

is the recommended wide native character-aware way of saying

```
*(d++) = uv;
```

```
        U8*     uvchr_to_utf8(U8 *d, UV uv)
```

uvuni_to_utf8_flags

Adds the UTF-8 representation of the Unicode codepoint `uv` to the end of the string `d`; `d` should be have at least `UTF8_MAXLEN+1` free bytes available. The return value is the pointer to the byte after the end of the new character. In other words,

```
d = uvuni_to_utf8_flags(d, uv, flags);
```

or, in most cases,

```
d = uvuni_to_utf8(d, uv);
```

(which is equivalent to)

```
d = uvuni_to_utf8_flags(d, uv, 0);
```

is the recommended Unicode-aware way of saying

```
*(d++) = uv;
```

```
        U8*     uvuni_to_utf8_flags(U8 *d, UV uv, UV flags)
```

72.24 Variables created by `xsubpp` and `xsubpp` internal functions

ax

Variable which is setup by `xsubpp` to indicate the stack base offset, used by the `ST`, `XSprePUSH` and `XSRETURN` macros. The `dMARK` macro must be called prior to setup the `MARK` variable.

```
        I32     ax
```

CLASS

Variable which is setup by `xsubpp` to indicate the class name for a C++ XS constructor. This is always a `char*`. See `THIS`.

```
        char*   CLASS
```

dAX

Sets up the `ax` variable. This is usually handled automatically by `xsubpp` by calling `dXSARGS`.

```
                dAX;
```

dITEMS

Sets up the `items` variable. This is usually handled automatically by `xsubpp` by calling `dXSARGS`.

```
                dITEMS;
```

dXSARGS

Sets up stack and mark pointers for an XSUB, calling dSP and dMARK. Sets up the `ax` and `items` variables by calling `dAX` and `dITEMS`. This is usually handled automatically by `xsubpp`.

```
                dXSARGS;
```

dXSI32

Sets up the `ix` variable for an XSUB which has aliases. This is usually handled automatically by `xsubpp`.

```
                dXSI32;
```

items

Variable which is setup by `xsubpp` to indicate the number of items on the stack. See Variable-length Parameter Lists in *perlxs*.

```
        I32     items
```

ix

Variable which is setup by `xsubpp` to indicate which of an XSUB's aliases was used to invoke it. See The ALIAS: Keyword in *perlxs*.

```
        I32     ix
```

newXSproto

Used by `xsubpp` to hook up XSUBs as Perl subs. Adds Perl prototypes to the subs.

RETVAL

Variable which is setup by `xsubpp` to hold the return value for an XSUB. This is always the proper type for the XSUB. See The RETVAL Variable in *perlxs*.

```
        (whatever)      RETVAL
```

ST

Used to access elements on the XSUB's stack.

```
        SV*     ST(int ix)
```

THIS

Variable which is setup by `xsubpp` to designate the object in a C++ XSUB. This is always the proper type for the C++ object. See `CLASS` and Using XS With C++ in *perlxs*.

```
        (whatever)      THIS
```

XS

Macro to declare an XSUB and its C parameter list. This is handled by `xsubpp`.

XS_VERSION

The version identifier for an XS module. This is usually handled automatically by `ExtUtils::MakeMaker`. See `XS_VERSION_BOOTCHECK`.

XS_VERSION_BOOTCHECK

Macro to verify that a PM module's $VERSION variable matches the XS module's `XS_VERSION` variable. This is usually handled automatically by `xsubpp`. See The VERSIONCHECK: Keyword in *perlxs*.

```
                XS_VERSION_BOOTCHECK;
```

72.25 Warning and Dieing

croak

This is the XSUB-writer's interface to Perl's `die` function. Normally call this function the same way you call the C `printf` function. Calling `croak` returns control directly to Perl, sidestepping the normal C order of execution. See `warn`.

If you want to throw an exception object, assign the object to `$@` and then pass `Nullch` to croak():

```
errsv = get_sv("@", TRUE);
sv_setsv(errsv, exception_object);
croak(Nullch);
```

```
        void    croak(const char* pat, ...)
```

warn

This is the XSUB-writer's interface to Perl's `warn` function. Call this function the same way you call the C `printf` function. See `croak`.

```
        void    warn(const char* pat, ...)
```

72.26 AUTHORS

Until May 1997, this document was maintained by Jeff Okamoto <okamoto@corp.hp.com>. It is now maintained as part of Perl itself.

With lots of help and suggestions from Dean Roehrich, Malcolm Beattie, Andreas Koenig, Paul Hudson, Ilya Zakharevich, Paul Marquess, Neil Bowers, Matthew Green, Tim Bunce, Spider Boardman, Ulrich Pfeifer, Stephen McCamant, and Gurusamy Sarathy.

API Listing originally by Dean Roehrich <roehrich@cray.com>.

Updated to be autogenerated from comments in the source by Benjamin Stuhl.

Autogenerated documentation of purely **internal** Perl functions

73.1 DESCRIPTION

This file is the autogenerated documentation of functions in the Perl interpreter that are documented using Perl's internal documentation format but are not marked as part of the Perl API. In other words, **they are not for use in extensions**!

73.2 CV reference counts and CvOUTSIDE

CvWEAKOUTSIDE

Each CV has a pointer, `CvOUTSIDE()`, to its lexically enclosing CV (if any). Because pointers to anonymous sub prototypes are stored in `&` pad slots, it is a possible to get a circular reference, with the parent pointing to the child and vice-versa. To avoid the ensuing memory leak, we do not increment the reference count of the CV pointed to by `CvOUTSIDE` in the *one specific instance* that the parent has a `&` pad slot pointing back to us. In this case, we set the `CvWEAKOUTSIDE` flag in the child. This allows us to determine under what circumstances we should decrement the refcount of the parent when freeing the child.

There is a further complication with non-closure anonymous subs (ie those that do not refer to any lexicals outside that sub). In this case, the anonymous prototype is shared rather than being cloned. This has the consequence that the parent may be freed while there are still active children, eg

```
    BEGIN { $a = sub { eval '$x' } }
```

In this case, the BEGIN is freed immediately after execution since there are no active references to it: the anon sub prototype has `CvWEAKOUTSIDE` set since it's not a closure, and $a points to the same CV, so it doesn't contribute to BEGIN's refcount either. When $a is executed, the `eval '$x'` causes the chain of `CvOUTSIDE`s to be followed, and the freed BEGIN is accessed.

To avoid this, whenever a CV and its associated pad is freed, any `&` entries in the pad are explicitly removed from the pad, and if the refcount of the pointed-to anon sub is still positive, then that child's `CvOUTSIDE` is set to point to its grandparent. This will only occur in the single specific case of a non-closure anon prototype having one or more active references (such as `$a` above).

One other thing to consider is that a CV may be merely undefined rather than freed, eg `undef &foo`. In this case, its refcount may not have reached zero, but we still delete its pad and its `CvROOT` etc. Since various children may still have their `CvOUTSIDE` pointing at this undefined CV, we keep its own `CvOUTSIDE` for the time being, so that the chain of lexical scopes is unbroken. For example, the following should print 123:

```
my $x = 123;
sub tmp { sub { eval '$x' } }
my $a = tmp();
undef &tmp;
print  $a->();
```

```
    bool    CvWEAKOUTSIDE(CV *cv)
```

73.3 Functions in file pad.h

CX_CURPAD_SAVE

Save the current pad in the given context block structure.

```
    void    CX_CURPAD_SAVE(struct context)
```

CX_CURPAD_SV

Access the SV at offset po in the saved current pad in the given context block structure (can be used as an lvalue).

```
    SV *    CX_CURPAD_SV(struct context, PADOFFSET po)
```

PAD_BASE_SV

Get the value from slot po in the base (DEPTH=1) pad of a padlist

```
    SV *    PAD_BASE_SV     (PADLIST padlist, PADOFFSET po)
```

PAD_CLONE_VARS

|CLONE_PARAMS* param Clone the state variables associated with running and compiling pads.

```
    void    PAD_CLONE_VARS(PerlInterpreter *proto_perl \)
```

PAD_COMPNAME_FLAGS

Return the flags for the current compiling pad name at offset po. Assumes a valid slot entry.

```
    U32     PAD_COMPNAME_FLAGS(PADOFFSET po)
```

PAD_COMPNAME_GEN

The generation number of the name at offset po in the current compiling pad (lvalue). Note that SvCUR is hijacked for this purpose.

```
    STRLEN  PAD_COMPNAME_GEN(PADOFFSET po)
```

PAD_COMPNAME_OURSTASH

Return the stash associated with an our variable. Assumes the slot entry is a valid our lexical.

```
    HV *    PAD_COMPNAME_OURSTASH(PADOFFSET po)
```

PAD_COMPNAME_PV

Return the name of the current compiling pad name at offset po. Assumes a valid slot entry.

```
    char *  PAD_COMPNAME_PV(PADOFFSET po)
```

PAD_COMPNAME_TYPE

Return the type (stash) of the current compiling pad name at offset `po`. Must be a valid name. Returns null if not typed.

```
        HV *    PAD_COMPNAME_TYPE(PADOFFSET po)
```

PAD_DUP

Clone a padlist.

```
        void    PAD_DUP(PADLIST dstpad, PADLIST srcpad, CLONE_PARAMS* param)
```

PAD_RESTORE_LOCAL

Restore the old pad saved into the local variable opad by PAD_SAVE_LOCAL()

```
        void    PAD_RESTORE_LOCAL(PAD *opad)
```

PAD_SAVE_LOCAL

Save the current pad to the local variable opad, then make the current pad equal to npad

```
        void    PAD_SAVE_LOCAL(PAD *opad, PAD *npad)
```

PAD_SAVE_SETNULLPAD

Save the current pad then set it to null.

```
        void    PAD_SAVE_SETNULLPAD()
```

PAD_SETSV

Set the slot at offset `po` in the current pad to `sv`

```
        SV *    PAD_SETSV       (PADOFFSET po, SV* sv)
```

PAD_SET_CUR

Set the current pad to be pad `n` in the padlist, saving the previous current pad.

```
        void    PAD_SET_CUR     (PADLIST padlist, I32 n)
```

PAD_SET_CUR_NOSAVE

like PAD_SET_CUR, but without the save

```
        void    PAD_SET_CUR_NOSAVE      (PADLIST padlist, I32 n)
```

PAD_SV

Get the value at offset `po` in the current pad

```
        void    PAD_SV  (PADOFFSET po)
```

PAD_SVl

Lightweight and lvalue version of `PAD_SV`. Get or set the value at offset `po` in the current pad. Unlike `PAD_SV`, does not print diagnostics with -DX. For internal use only.

```
        SV *    PAD_SVl (PADOFFSET po)
```

SAVECLEARSV

Clear the pointed to pad value on scope exit. (ie the runtime action of 'my')

```
        void    SAVECLEARSV     (SV **svp)
```

SAVECOMPPAD

save PL_comppad and PL_curpad

```
        void    SAVECOMPPAD()
```

SAVEPADSV

Save a pad slot (used to restore after an iteration)

XXX DAPM it would make more sense to make the arg a PADOFFSET void SAVEPADSV (PADOFFSET po)

73.4 Functions in file pp_ctl.c

find_runcv

Locate the CV corresponding to the currently executing sub or eval. If db_seqp is non_null, skip CVs that are in the DB package and populate *db_seqp with the cop sequence number at the point that the DB:: code was entered. (allows debuggers to eval in the scope of the breakpoint rather than in in the scope of the debugger itself).

```
        CV*     find_runcv(U32 *db_seqp)
```

73.5 Global Variables

PL_DBsingle

When Perl is run in debugging mode, with the **-d** switch, this SV is a boolean which indicates whether subs are being single-stepped. Single-stepping is automatically turned on after every step. This is the C variable which corresponds to Perl's $DB::single variable. See `PL_DBsub`.

```
        SV *    PL_DBsingle
```

PL_DBsub

When Perl is run in debugging mode, with the **-d** switch, this GV contains the SV which holds the name of the sub being debugged. This is the C variable which corresponds to Perl's $DB::sub variable. See `PL_DBsingle`.

```
        GV *    PL_DBsub
```

PL_DBtrace

Trace variable used when Perl is run in debugging mode, with the **-d** switch. This is the C variable which corresponds to Perl's $DB::trace variable. See `PL_DBsingle`.

```
        SV *    PL_DBtrace
```

PL_dowarn

The C variable which corresponds to Perl's $ˆW warning variable.

```
        bool    PL_dowarn
```

PL_last_in_gv

The GV which was last used for a filehandle input operation. (`<FH>`)

```
GV*     PL_last_in_gv
```

PL_ofs_sv

The output field separator - `$,` in Perl space.

```
SV*     PL_ofs_sv
```

PL_rs

The input record separator - `$/` in Perl space.

```
SV*     PL_rs
```

73.6 GV Functions

is_gv_magical

Returns `TRUE` if given the name of a magical GV.

Currently only useful internally when determining if a GV should be created even in rvalue contexts.

`flags` is not used at present but available for future extension to allow selecting particular classes of magical variable.

```
bool    is_gv_magical(char *name, STRLEN len, U32 flags)
```

73.7 IO Functions

start_glob

Function called by `do_readline` to spawn a glob (or do the glob inside perl on VMS). This code used to be inline, but now perl uses `File::Glob` this glob starter is only used by miniperl during the build process. Moving it away shrinks pp_hot.c; shrinking pp_hot.c helps speed perl up.

```
PerlIO* start_glob(SV* pattern, IO *io)
```

73.8 Pad Data Structures

CvPADLIST

CV's can have CvPADLIST(cv) set to point to an AV.

For these purposes "forms" are a kind-of CV, eval""s are too (except they're not callable at will and are always thrown away after the eval"" is done executing).

XSUBs don't have CvPADLIST set - dXSTARG fetches values from PL_curpad, but that is really the callers pad (a slot of which is allocated by every entersub).

The CvPADLIST AV has does not have AvREAL set, so REFCNT of component items is managed "manual" (mostly in pad.c) rather than normal av.c rules. The items in the AV are not SVs as for a normal AV, but other AVs:

0'th Entry of the CvPADLIST is an AV which represents the "names" or rather the "static type information" for lexicals.

The CvDEPTH'th entry of CvPADLIST AV is an AV which is the stack frame at that depth of recursion into the CV. The 0'th slot of a frame AV is an AV which is @_. other entries are storage for variables and op targets.

During compilation: `PL_comppad_name` is set to the names AV. `PL_comppad` is set to the frame AV for the frame CvDEPTH == 1. `PL_curpad` is set to the body of the frame AV (i.e. AvARRAY(PL_comppad)).

During execution, `PL_comppad` and `PL_curpad` refer to the live frame of the currently executing sub.

Iterating over the names AV iterates over all possible pad items. Pad slots that are SVs_PADTMP (targets/GVs/constants) end up having &PL_sv_undef "names" (see pad_alloc()).

Only my/our variable (SVs_PADMY/SVs_PADOUR) slots get valid names. The rest are op targets/GVs/constants which are statically allocated or resolved at compile time. These don't have names by which they can be looked up from Perl code at run time through eval"" like my/our variables can be. Since they can't be looked up by "name" but only by their index allocated at compile time (which is usually in PL_op->op_targ), wasting a name SV for them doesn't make sense.

The SVs in the names AV have their PV being the name of the variable. NV+1..IV inclusive is a range of cop_seq numbers for which the name is valid. For typed lexicals name SV is SVt_PVMG and SvSTASH points at the type. For `our` lexicals, the type is SVt_PVGV, and GvSTASH points at the stash of the associated global (so that duplicate `our` delarations in the same package can be detected). SvCUR is sometimes hijacked to store the generation number during compilation.

If SvFAKE is set on the name SV then slot in the frame AVs are a REFCNT'ed references to a lexical from "outside". In this case, the name SV does not have a cop_seq range, since it is in scope throughout.

If the 'name' is '&' the corresponding entry in frame AV is a CV representing a possible closure. (SvFAKE and name of '&' is not a meaningful combination currently but could become so if `my sub foo {}` is implemented.)

```
AV *    CvPADLIST(CV *cv)
```

cv_clone

Clone a CV: make a new CV which points to the same code etc, but which has a newly-created pad built by copying the prototype pad and capturing any outer lexicals.

```
CV*     cv_clone(CV* proto)
```

cv_dump

dump the contents of a CV

```
void    cv_dump(CV *cv, char *title)
```

do_dump_pad

Dump the contents of a padlist

```
void    do_dump_pad(I32 level, PerlIO *file, PADLIST *padlist, int full)
```

intro_my

"Introduce" my variables to visible status.

```
U32     intro_my()
```

pad_add_anon

Add an anon code entry to the current compiling pad

```
PADOFFSET       pad_add_anon(SV* sv, OPCODE op_type)
```

pad_add_name

Create a new name in the current pad at the specified offset. If `typestash` is valid, the name is for a typed lexical; set the name's stash to that value. If `ourstash` is valid, it's an our lexical, set the name's GvSTASH to that value

Also, if the name is @.. or %.., create a new array or hash for that slot

If fake, it means we're cloning an existing entry

```
        PADOFFSET       pad_add_name(char *name, HV* typestash, HV* ourstash, bool clone)
```

pad_alloc

Allocate a new my or tmp pad entry. For a my, simply push a null SV onto the end of PL_comppad, but for a tmp, scan the pad from PL_padix upwards for a slot which has no name and and no active value.

```
        PADOFFSET       pad_alloc(I32 optype, U32 tmptype)
```

pad_block_start

Update the pad compilation state variables on entry to a new block

```
        void    pad_block_start(int full)
```

pad_check_dup

Check for duplicate declarations: report any of: * a my in the current scope with the same name; * an our (anywhere in the pad) with the same name and the same stash as `ourstash` `is_our` indicates that the name to check is an 'our' declaration

```
        void    pad_check_dup(char* name, bool is_our, HV* ourstash)
```

pad_findlex

Find a named lexical anywhere in a chain of nested pads. Add fake entries in the inner pads if it's found in an outer one. innercv is the CV *inside* the chain of outer CVs to be searched. If newoff is non-null, this is a run-time cloning: don't add fake entries, just find the lexical and add a ref to it at newoff in the current pad.

```
        PADOFFSET       pad_findlex(char* name, PADOFFSET newoff, CV* innercv)
```

pad_findmy

Given a lexical name, try to find its offset, first in the current pad, or failing that, in the pads of any lexically enclosing subs (including the complications introduced by eval). If the name is found in an outer pad, then a fake entry is added to the current pad. Returns the offset in the current pad, or NOT_IN_PAD on failure.

```
        PADOFFSET       pad_findmy(char* name)
```

pad_fixup_inner_anons

For any anon CVs in the pad, change CvOUTSIDE of that CV from old_cv to new_cv if necessary. Needed when a newly-compiled CV has to be moved to a pre-existing CV struct.

```
        void    pad_fixup_inner_anons(PADLIST *padlist, CV *old_cv, CV *new_cv)
```

pad_free

Free the SV at offet po in the current pad.

```
        void    pad_free(PADOFFSET po)
```

pad_leavemy

Cleanup at end of scope during compilation: set the max seq number for lexicals in this scope and warn of any lexicals that never got introduced.

```
        void    pad_leavemy()
```

pad_new

Create a new compiling padlist, saving and updating the various global vars at the same time as creating the pad itself. The following flags can be OR'ed together:

```
padnew_CLONE        this pad is for a cloned CV
padnew_SAVE         save old globals
padnew_SAVESUB      also save extra stuff for start of sub

    PADLIST*        pad_new(int flags)
```

pad_push

Push a new pad frame onto the padlist, unless there's already a pad at this depth, in which case don't bother creating a new one. If has_args is true, give the new pad an @_ in slot zero.

```
void    pad_push(PADLIST *padlist, int depth, int has_args)
```

pad_reset

Mark all the current temporaries for reuse

```
void    pad_reset()
```

pad_setsv

Set the entry at offset po in the current pad to sv. Use the macro PAD_SETSV() rather than calling this function directly.

```
void    pad_setsv(PADOFFSET po, SV* sv)
```

pad_swipe

Abandon the tmp in the current pad at offset po and replace with a new one.

```
void    pad_swipe(PADOFFSET po, bool refadjust)
```

pad_tidy

Tidy up a pad after we've finished compiling it: * remove most stuff from the pads of anonsub prototypes; * give it a @_; * mark tmps as such.

```
void    pad_tidy(padtidy_type type)
```

pad_undef

Free the padlist associated with a CV. If parts of it happen to be current, we null the relevant PL_*pad* global vars so that we don't have any dangling references left. We also repoint the CvOUTSIDE of any about-to-be-orphaned inner subs to the outer of this cv.

(This function should really be called pad_free, but the name was already taken)

```
void    pad_undef(CV* cv)
```

73.9 Stack Manipulation Macros

djSP

Declare Just SP. This is actually identical to dSP, and declares a local copy of perl's stack pointer, available via the SP macro. See SP. (Available for backward source code compatibility with the old (Perl 5.005) thread model.)

```
        djSP;
```

LVRET

True if this op will be the return value of an lvalue subroutine

73.10 SV Manipulation Functions

report_uninit

Print appropriate "Use of uninitialized variable" warning

```
void    report_uninit()
```

sv_add_arena

Given a chunk of memory, link it to the head of the list of arenas, and split it into a list of free SVs.

```
void    sv_add_arena(char* ptr, U32 size, U32 flags)
```

sv_clean_all

Decrement the refcnt of each remaining SV, possibly triggering a cleanup. This function may have to be called multiple times to free SVs which are in complex self-referential hierarchies.

```
I32     sv_clean_all()
```

sv_clean_objs

Attempt to destroy all objects not yet freed

```
void    sv_clean_objs()
```

sv_free_arenas

Deallocate the memory used by all arenas. Note that all the individual SV heads and bodies within the arenas must already have been freed.

```
void    sv_free_arenas()
```

73.11 AUTHORS

The autodocumentation system was originally added to the Perl core by Benjamin Stuhl. Documentation is by whoever was kind enough to document their functions.

Chapter 74

perliol

C API for Perl's implementation of IO in Layers.

74.1 SYNOPSIS

```
    /* Defining a layer ... */
    #include <perliol.h>
```

74.2 DESCRIPTION

This document describes the behavior and implementation of the PerlIO abstraction described in *perlapio* when `USE_PERLIO` is defined (and `USE_SFIO` is not).

74.2.1 History and Background

The PerlIO abstraction was introduced in perl5.003_02 but languished as just an abstraction until perl5.7.0. However during that time a number of perl extensions switched to using it, so the API is mostly fixed to maintain (source) compatibility.

The aim of the implementation is to provide the PerlIO API in a flexible and platform neutral manner. It is also a trial of an "Object Oriented C, with vtables" approach which may be applied to perl6.

74.2.2 Basic Structure

PerlIO is a stack of layers.

The low levels of the stack work with the low-level operating system calls (file descriptors in C) getting bytes in and out, the higher layers of the stack buffer, filter, and otherwise manipulate the I/O, and return characters (or bytes) to Perl. Terms *above* and *below* are used to refer to the relative positioning of the stack layers.

A layer contains a "vtable", the table of I/O operations (at C level a table of function pointers), and status flags. The functions in the vtable implement operations like "open", "read", and "write".

When I/O, for example "read", is requested, the request goes from Perl first down the stack using "read" functions of each layer, then at the bottom the input is requested from the operating system services, then the result is returned up the stack, finally being interpreted as Perl data.

The requests do not necessarily go always all the way down to the operating system: that's where PerlIO buffering comes into play.

When you do an open() and specify extra PerlIO layers to be deployed, the layers you specify are "pushed" on top of the already existing default stack. One way to see it is that "operating system is on the left" and "Perl is on the right".

What exact layers are in this default stack depends on a lot of things: your operating system, Perl version, Perl compile time configuration, and Perl runtime configuration. See *PerlIO*, PERLIO in *perlrun*, and *open* for more information.

binmode() operates similarly to open(): by default the specified layers are pushed on top of the existing stack.

However, note that even as the specified layers are "pushed on top" for open() and binmode(), this doesn't mean that the effects are limited to the "top": PerlIO layers can be very 'active' and inspect and affect layers also deeper in the stack. As an example there is a layer called "raw" which repeatedly "pops" layers until it reaches the first layer that has declared itself capable of handling binary data. The "pushed" layers are processed in left-to-right order.

sysopen() operates (unsurprisingly) at a lower level in the stack than open(). For example in UNIX or UNIX-like systems sysopen() operates directly at the level of file descriptors: in the terms of PerlIO layers, it uses only the "unix" layer, which is a rather thin wrapper on top of the UNIX file descriptors.

74.2.3 Layers vs Disciplines

Initial discussion of the ability to modify IO streams behaviour used the term "discipline" for the entities which were added. This came (I believe) from the use of the term in "sfio", which in turn borrowed it from "line disciplines" on Unix terminals. However, this document (and the C code) uses the term "layer".

This is, I hope, a natural term given the implementation, and should avoid connotations that are inherent in earlier uses of "discipline" for things which are rather different.

74.2.4 Data Structures

The basic data structure is a PerlIOl:

```
        typedef struct _PerlIO PerlIOl;
        typedef struct _PerlIO_funcs PerlIO_funcs;
        typedef PerlIOl *PerlIO;

        struct _PerlIO
        {
         PerlIOl *      next;       /* Lower layer */
         PerlIO_funcs * tab;        /* Functions for this layer */
         IV             flags;      /* Various flags for state */
        };
```

A `PerlIOl *` is a pointer to the struct, and the *application* level `PerlIO *` is a pointer to a `PerlIOl *` - i.e. a pointer to a pointer to the struct. This allows the application level `PerlIO *` to remain constant while the actual `PerlIOl *` underneath changes. (Compare perl's `SV *` which remains constant while its `sv_any` field changes as the scalar's type changes.) An IO stream is then in general represented as a pointer to this linked-list of "layers".

It should be noted that because of the double indirection in a `PerlIO *`, a `&(perlio->next)` "is" a `PerlIO *`, and so to some degree at least one layer can use the "standard" API on the next layer down.

A "layer" is composed of two parts:

1. The functions and attributes of the "layer class".
2. The per-instance data for a particular handle.

74.2.5 Functions and Attributes

The functions and attributes are accessed via the "tab" (for table) member of `PerlIOl`. The functions (methods of the layer "class") are fixed, and are defined by the `PerlIO_funcs` type. They are broadly the same as the public `PerlIO_xxxxx` functions:

```
struct _PerlIO_funcs
{
 Size_t              fsize;
 char *              name;
 Size_t              size;
 IV          kind;
 IV          (*Pushed)(pTHX_ PerlIO *f,const char *mode,SV *arg, PerlIO_funcs *tab);
 IV          (*Popped)(pTHX_ PerlIO *f);
 PerlIO *    (*Open)(pTHX_ PerlIO_funcs *tab,
                     AV *layers, IV n,
                     const char *mode,
                     int fd, int imode, int perm,
                     PerlIO *old,
                     int narg, SV **args);
 IV          (*Binmode)(pTHX_ PerlIO *f);
 SV *        (*Getarg)(pTHX_ PerlIO *f, CLONE_PARAMS *param, int flags)
 IV          (*Fileno)(pTHX_ PerlIO *f);
 PerlIO *    (*Dup)(pTHX_ PerlIO *f, PerlIO *o, CLONE_PARAMS *param, int flags)
 /* Unix-like functions - cf sfio line disciplines */
 SSize_t     (*Read)(pTHX_ PerlIO *f, void *vbuf, Size_t count);
 SSize_t     (*Unread)(pTHX_ PerlIO *f, const void *vbuf, Size_t count);
 SSize_t     (*Write)(pTHX_ PerlIO *f, const void *vbuf, Size_t count);
 IV          (*Seek)(pTHX_ PerlIO *f, Off_t offset, int whence);
 Off_t       (*Tell)(pTHX_ PerlIO *f);
 IV          (*Close)(pTHX_ PerlIO *f);
 /* Stdio-like buffered IO functions */
 IV          (*Flush)(pTHX_ PerlIO *f);
 IV          (*Fill)(pTHX_ PerlIO *f);
 IV          (*Eof)(pTHX_ PerlIO *f);
 IV          (*Error)(pTHX_ PerlIO *f);
 void        (*Clearerr)(pTHX_ PerlIO *f);
 void        (*Setlinebuf)(pTHX_ PerlIO *f);
 /* Perl's snooping functions */
 STDCHAR *   (*Get_base)(pTHX_ PerlIO *f);
 Size_t      (*Get_bufsiz)(pTHX_ PerlIO *f);
 STDCHAR *   (*Get_ptr)(pTHX_ PerlIO *f);
 SSize_t     (*Get_cnt)(pTHX_ PerlIO *f);
 void        (*Set_ptrcnt)(pTHX_ PerlIO *f,STDCHAR *ptr,SSize_t cnt);
};
```

The first few members of the struct give a function table size for compatibility check "name" for the layer, the size to `malloc` for the per-instance data, and some flags which are attributes of the class as whole (such as whether it is a buffering layer), then follow the functions which fall into four basic groups:

1. Opening and setup functions
2. Basic IO operations
3. Stdio class buffering options.
4. Functions to support Perl's traditional "fast" access to the buffer.

A layer does not have to implement all the functions, but the whole table has to be present. Unimplemented slots can be NULL (which will result in an error when called) or can be filled in with stubs to "inherit" behaviour from a "base class". This "inheritance" is fixed for all instances of the layer, but as the layer chooses which stubs to populate the table, limited "multiple inheritance" is possible.

74.2.6 Per-instance Data

The per-instance data are held in memory beyond the basic PerlIOl struct, by making a PerlIOl the first member of the layer's struct thus:

```
typedef struct
{
 struct _PerlIO base;       /* Base "class" info */
 STDCHAR *      buf;        /* Start of buffer */
 STDCHAR *      end;        /* End of valid part of buffer */
 STDCHAR *      ptr;        /* Current position in buffer */
 Off_t          posn;       /* Offset of buf into the file */
 Size_t         bufsiz;     /* Real size of buffer */
 IV             oneword;    /* Emergency buffer */
} PerlIOBuf;
```

In this way (as for perl's scalars) a pointer to a PerlIOBuf can be treated as a pointer to a PerlIOl.

74.2.7 Layers in action.

```
            table           perlio         unix
        |           |
        +-----------+    +----------+    +--------+
PerlIO ->|           |--->|  next    |--->|  NULL  |
        +-----------+    +----------+    +--------+
        |           |    |  buffer  |    |   fd   |
        +-----------+    |          |    +--------+
        |           |    +----------+
```

The above attempts to show how the layer scheme works in a simple case. The application's `PerlIO *` points to an entry in the table(s) representing open (allocated) handles. For example the first three slots in the table correspond to `stdin`,`stdout` and `stderr`. The table in turn points to the current "top" layer for the handle - in this case an instance of the generic buffering layer "perlio". That layer in turn points to the next layer down - in this case the lowlevel "unix" layer.

The above is roughly equivalent to a "stdio" buffered stream, but with much more flexibility:

- If Unix level `read`/`write`/`lseek` is not appropriate for (say) sockets then the "unix" layer can be replaced (at open time or even dynamically) with a "socket" layer.
- Different handles can have different buffering schemes. The "top" layer could be the "mmap" layer if reading disk files was quicker using `mmap` than `read`. An "unbuffered" stream can be implemented simply by not having a buffer layer.
- Extra layers can be inserted to process the data as it flows through. This was the driving need for including the scheme in perl 5.7.0+ - we needed a mechanism to allow data to be translated between perl's internal encoding (conceptually at least Unicode as UTF-8), and the "native" format used by the system. This is provided by the ":encoding(xxxx)" layer which typically sits above the buffering layer.
- A layer can be added that does "\n" to CRLF translation. This layer can be used on any platform, not just those that normally do such things.

74.2.8 Per-instance flag bits

The generic flag bits are a hybrid of `O_XXXXX` style flags deduced from the mode string passed to `PerlIO_open()`, and state bits for typical buffer layers.

PERLIO_F_EOF

End of file.

PERLIO_F_CANWRITE

Writes are permitted, i.e. opened as "w" or "r+" or "a", etc.

PERLIO_F_CANREAD

Reads are permitted i.e. opened "r" or "w+" (or even "a+" - ick).

PERLIO_F_ERROR

An error has occurred (for `PerlIO_error()`).

PERLIO_F_TRUNCATE

Truncate file suggested by open mode.

PERLIO_F_APPEND

All writes should be appends.

PERLIO_F_CRLF

Layer is performing Win32-like "\n" mapped to CR,LF for output and CR,LF mapped to "\n" for input. Normally the provided "crlf" layer is the only layer that need bother about this. `PerlIO_binmode()` will mess with this flag rather than add/remove layers if the `PERLIO_K_CANCRLF` bit is set for the layers class.

PERLIO_F_UTF8

Data written to this layer should be UTF-8 encoded; data provided by this layer should be considered UTF-8 encoded. Can be set on any layer by ":utf8" dummy layer. Also set on ":encoding" layer.

PERLIO_F_UNBUF

Layer is unbuffered - i.e. write to next layer down should occur for each write to this layer.

PERLIO_F_WRBUF

The buffer for this layer currently holds data written to it but not sent to next layer.

PERLIO_F_RDBUF

The buffer for this layer currently holds unconsumed data read from layer below.

PERLIO_F_LINEBUF

Layer is line buffered. Write data should be passed to next layer down whenever a "\n" is seen. Any data beyond the "\n" should then be processed.

PERLIO_F_TEMP

File has been `unlink()`ed, or should be deleted on `close()`.

PERLIO_F_OPEN

Handle is open.

PERLIO_F_FASTGETS

This instance of this layer supports the "fast `gets`" interface. Normally set based on `PERLIO_K_FASTGETS` for the class and by the existence of the function(s) in the table. However a class that normally provides that interface may need to avoid it on a particular instance. The "pending" layer needs to do this when it is pushed above a layer which does not support the interface. (Perl's `sv_gets()` does not expect the streams fast `gets` behaviour to change during one "get".)

74.2.9 Methods in Detail

fsize

```
        Size_t fsize;
```

Size of the function table. This is compared against the value PerlIO code "knows" as a compatibility check. Future versions *may* be able to tolerate layers compiled against an old version of the headers.

name

```
        char * name;
```

The name of the layer whose open() method Perl should invoke on open(). For example if the layer is called APR, you will call:

```
  open $fh, ">:APR", ...
```

and Perl knows that it has to invoke the PerlIOAPR_open() method implemented by the APR layer.

size

```
        Size_t size;
```

The size of the per-instance data structure, e.g.:

```
  sizeof(PerlIOAPR)
```

If this field is zero then `PerlIO_pushed` does not malloc anything and assumes layer's Pushed function will do any required layer stack manipulation - used to avoid malloc/free overhead for dummy layers. If the field is non-zero it must be at least the size of `PerlIOl`, `PerlIO_pushed` will allocate memory for the layer's data structures and link new layer onto the stream's stack. (If the layer's Pushed method returns an error indication the layer is popped again.)

kind

```
        IV kind;
```

- PERLIO_K_BUFFERED
  The layer is buffered.
- PERLIO_K_RAW
  The layer is acceptable to have in a binmode(FH) stack - i.e. it does not (or will configure itself not to) transform bytes passing through it.
- PERLIO_K_CANCRLF
  Layer can translate between "\n" and CRLF line ends.
- PERLIO_K_FASTGETS
  Layer allows buffer snooping.
- PERLIO_K_MULTIARG
  Used when the layer's open() accepts more arguments than usual. The extra arguments should come not before the `MODE` argument. When this flag is used it's up to the layer to validate the args.

Pushed

```
        IV      (*Pushed)(pTHX_ PerlIO *f,const char *mode, SV *arg);
```

The only absolutely mandatory method. Called when the layer is pushed onto the stack. The `mode` argument may be NULL if this occurs post-open. The `arg` will be non-`NULL` if an argument string was passed. In most cases this should call `PerlIOBase_pushed()` to convert `mode` into the appropriate `PERLIO_F_XXXXX` flags in addition to any actions the layer itself takes. If a layer is not expecting an argument it need neither save the one passed to it, nor provide `Getarg()` (it could perhaps `Perl_warn` that the argument was un-expected).

Returns 0 on success. On failure returns -1 and should set errno.

Popped

```
        IV      (*Popped)(pTHX_ PerlIO *f);
```

Called when the layer is popped from the stack. A layer will normally be popped after `Close()` is called. But a layer can be popped without being closed if the program is dynamically managing layers on the stream. In such cases `Popped()` should free any resources (buffers, translation tables, ...) not held directly in the layer's struct. It should also `Unread()` any unconsumed data that has been read and buffered from the layer below back to that layer, so that it can be re-provided to what ever is now above.

Returns 0 on success and failure. If `Popped()` returns *true* then *perlio.c* assumes that either the layer has popped itself, or the layer is super special and needs to be retained for other reasons. In most cases it should return *false*.

Open

```
        PerlIO *        (*Open)(...);
```

The `Open()` method has lots of arguments because it combines the functions of perl's `open`, `PerlIO_open`, perl's `sysopen`, `PerlIO_fdopen` and `PerlIO_reopen`. The full prototype is as follows:

```
 PerlIO *       (*Open)(pTHX_ PerlIO_funcs *tab,
                        AV *layers, IV n,
                        const char *mode,
                        int fd, int imode, int perm,
                        PerlIO *old,
                        int narg, SV **args);
```

Open should (perhaps indirectly) call `PerlIO_allocate()` to allocate a slot in the table and associate it with the layers information for the opened file, by calling `PerlIO_push`. The *layers* AV is an array of all the layers destined for the `PerlIO *`, and any arguments passed to them, *n* is the index into that array of the layer being called. The macro `PerlIOArg` will return a (possibly `NULL`) SV * for the argument passed to the layer.

The *mode* string is an "`fopen()`-like" string which would match the regular expression `/^[I#]?[rwa]\+?[bt]?$/`.

The `'I'` prefix is used during creation of `stdin`..`stderr` via special `PerlIO_fdopen` calls; the `'#'` prefix means that this is `sysopen` and that *imode* and *perm* should be passed to `PerlLIO_open3`; `'r'` means **r**ead, `'w'` means **w**rite and `'a'` means **a**ppend. The `'+'` suffix means that both reading and writing/appending are permitted. The `'b'` suffix means file should be binary, and `'t'` means it is text. (Almost all layers should do the IO in binary mode, and ignore the b/t bits. The `:crlf` layer should be pushed to handle the distinction.)

If *old* is not `NULL` then this is a `PerlIO_reopen`. Perl itself does not use this (yet?) and semantics are a little vague.

If *fd* not negative then it is the numeric file descriptor *fd*, which will be open in a manner compatible with the supplied mode string, the call is thus equivalent to `PerlIO_fdopen`. In this case *nargs* will be zero.

If *nargs* is greater than zero then it gives the number of arguments passed to `open`, otherwise it will be 1 if for example `PerlIO_open` was called. In simple cases SvPV_nolen(*args) is the pathname to open.

Having said all that translation-only layers do not need to provide `Open()` at all, but rather leave the opening to a lower level layer and wait to be "pushed". If a layer does provide `Open()` it should normally call the `Open()` method of next layer down (if any) and then push itself on top if that succeeds.

If `PerlIO_push` was performed and open has failed, it must `PerlIO_pop` itself, since if it's not, the layer won't be removed and may cause bad problems.

Returns `NULL` on failure.

Binmode

```
IV        (*Binmode)(pTHX_ PerlIO *f);
```

Optional. Used when `:raw` layer is pushed (explicitly or as a result of binmode(FH)). If not present layer will be popped. If present should configure layer as binary (or pop itself) and return 0. If it returns -1 for error `binmode` will fail with layer still on the stack.

Getarg

```
SV *      (*Getarg)(pTHX_ PerlIO *f,
                    CLONE_PARAMS *param, int flags);
```

Optional. If present should return an SV * representing the string argument passed to the layer when it was pushed. e.g. ":encoding(ascii)" would return an SvPV with value "ascii". (*param* and *flags* arguments can be ignored in most cases)

`Dup` uses `Getarg` to retrieve the argument originally passed to `Pushed`, so you must implement this function if your layer has an extra argument to `Pushed` and will ever be `Dup`ed.

Fileno

```
IV        (*Fileno)(pTHX_ PerlIO *f);
```

Returns the Unix/Posix numeric file descriptor for the handle. Normally `PerlIOBase_fileno()` (which just asks next layer down) will suffice for this.

Returns -1 on error, which is considered to include the case where the layer cannot provide such a file descriptor.

Dup

```
PerlIO * (*Dup)(pTHX_ PerlIO *f, PerlIO *o,
                CLONE_PARAMS *param, int flags);
```

XXX: Needs more docs.

Used as part of the "clone" process when a thread is spawned (in which case param will be non-NULL) and when a stream is being duplicated via '&' in the `open`.

Similar to `Open`, returns PerlIO* on success, `NULL` on failure.

Read

```
SSize_t (*Read)(pTHX_ PerlIO *f, void *vbuf, Size_t count);
```

Basic read operation.

Typically will call `Fill` and manipulate pointers (possibly via the API). `PerlIOBuf_read()` may be suitable for derived classes which provide "fast gets" methods.

Returns actual bytes read, or -1 on an error.

Unread

```
SSize_t (*Unread)(pTHX_ PerlIO *f,
                  const void *vbuf, Size_t count);
```

A superset of stdio's `ungetc()`. Should arrange for future reads to see the bytes in `vbuf`. If there is no obviously better implementation then `PerlIOBase_unread()` provides the function by pushing a "fake" "pending" layer above the calling layer.

Returns the number of unread chars.

Write

```
SSize_t (*Write)(PerlIO *f, const void *vbuf, Size_t count);
```

Basic write operation.

Returns bytes written or -1 on an error.

Seek

```
IV      (*Seek)(pTHX_ PerlIO *f, Off_t offset, int whence);
```

Position the file pointer. Should normally call its own `Flush` method and then the `Seek` method of next layer down.

Returns 0 on success, -1 on failure.

Tell

```
Off_t   (*Tell)(pTHX_ PerlIO *f);
```

Return the file pointer. May be based on layers cached concept of position to avoid overhead.

Returns -1 on failure to get the file pointer.

Close

```
IV      (*Close)(pTHX_ PerlIO *f);
```

Close the stream. Should normally call `PerlIOBase_close()` to flush itself and close layers below, and then deallocate any data structures (buffers, translation tables, ...) not held directly in the data structure.

Returns 0 on success, -1 on failure.

Flush

```
IV      (*Flush)(pTHX_ PerlIO *f);
```

Should make stream's state consistent with layers below. That is, any buffered write data should be written, and file position of lower layers adjusted for data read from below but not actually consumed. (Should perhaps `Unread()` such data to the lower layer.)

Returns 0 on success, -1 on failure.

Fill

```
IV      (*Fill)(pTHX_ PerlIO *f);
```

The buffer for this layer should be filled (for read) from layer below. When you "subclass" PerlIOBuf layer, you want to use its *_read* method and to supply your own fill method, which fills the PerlIOBuf's buffer.

Returns 0 on success, -1 on failure.

Eof

```
IV      (*Eof)(pTHX_ PerlIO *f);
```

Return end-of-file indicator. `PerlIOBase_eof()` is normally sufficient.

Returns 0 on end-of-file, 1 if not end-of-file, -1 on error.

Error

```
IV      (*Error)(pTHX_ PerlIO *f);
```

Return error indicator. `PerlIOBase_error()` is normally sufficient.

Returns 1 if there is an error (usually when `PERLIO_F_ERROR` is set, 0 otherwise.

Clearerr

```
void    (*Clearerr)(pTHX_ PerlIO *f);
```

Clear end-of-file and error indicators. Should call `PerlIOBase_clearerr()` to set the `PERLIO_F_XXXXX` flags, which may suffice.

Setlinebuf

```
void    (*Setlinebuf)(pTHX_ PerlIO *f);
```

Mark the stream as line buffered. `PerlIOBase_setlinebuf()` sets the PERLIO_F_LINEBUF flag and is normally sufficient.

Get_base

```
STDCHAR *       (*Get_base)(pTHX_ PerlIO *f);
```

Allocate (if not already done so) the read buffer for this layer and return pointer to it. Return NULL on failure.

Get_bufsiz

```
Size_t  (*Get_bufsiz)(pTHX_ PerlIO *f);
```

Return the number of bytes that last `Fill()` put in the buffer.

Get_ptr

```
STDCHAR *       (*Get_ptr)(pTHX_ PerlIO *f);
```

Return the current read pointer relative to this layer's buffer.

Get_cnt

```
SSize_t (*Get_cnt)(pTHX_ PerlIO *f);
```

Return the number of bytes left to be read in the current buffer.

Set_ptrcnt

```
void    (*Set_ptrcnt)(pTHX_ PerlIO *f,
                      STDCHAR *ptr, SSize_t cnt);
```

Adjust the read pointer and count of bytes to match `ptr` and/or `cnt`. The application (or layer above) must ensure they are consistent. (Checking is allowed by the paranoid.)

74.2.10 Utilities

To ask for the next layer down use PerlIONext(PerlIO *f).

To check that a PerlIO* is valid use PerlIOValid(PerlIO *f). (All this does is really just to check that the pointer is non-NULL and that the pointer behind that is non-NULL.)

PerlIOBase(PerlIO *f) returns the "Base" pointer, or in other words, the `PerlIOl*` pointer.

PerlIOSelf(PerlIO* f, type) return the PerlIOBase cast to a type.

Perl_PerlIO_or_Base(PerlIO* f, callback, base, failure, args) either calls the *callback* from the functions of the layer *f* (just by the name of the IO function, like "Read") with the *args*, or if there is no such callback, calls the *base* version of the callback with the same args, or if the f is invalid, set errno to EBADF and return *failure*.

Perl_PerlIO_or_fail(PerlIO* f, callback, failure, args) either calls the *callback* of the functions of the layer *f* with the *args*, or if there is no such callback, set errno to EINVAL. Or if the f is invalid, set errno to EBADF and return *failure*.

Perl_PerlIO_or_Base_void(PerlIO* f, callback, base, args) either calls the *callback* of the functions of the layer *f* with the *args*, or if there is no such callback, calls the *base* version of the callback with the same args, or if the f is invalid, set errno to EBADF.

Perl_PerlIO_or_fail_void(PerlIO* f, callback, args) either calls the *callback* of the functions of the layer *f* with the *args*, or if there is no such callback, set errno to EINVAL. Or if the f is invalid, set errno to EBADF.

74.2.11 Implementing PerlIO Layers

If you find the implementation document unclear or not sufficient, look at the existing PerlIO layer implementations, which include:

- C implementations

  The *perlio.c* and *perliol.h* in the Perl core implement the "unix", "perlio", "stdio", "crlf", "utf8", "byte", "raw", "pending" layers, and also the "mmap" and "win32" layers if applicable. (The "win32" is currently unfinished and unused, to see what is used instead in Win32, see Querying the layers of filehandles in *PerlIO* .)

  PerlIO::encoding, PerlIO::scalar, PerlIO::via in the Perl core.

  PerlIO::gzip and APR::PerlIO (mod_perl 2.0) on CPAN.

- Perl implementations

  PerlIO::via::QuotedPrint in the Perl core and PerlIO::via::* on CPAN.

If you are creating a PerlIO layer, you may want to be lazy, in other words, implement only the methods that interest you. The other methods you can either replace with the "blank" methods

```
    PerlIOBase_noop_ok
    PerlIOBase_noop_fail
```

(which do nothing, and return zero and -1, respectively) or for certain methods you may assume a default behaviour by using a NULL method. The Open method looks for help in the 'parent' layer. The following table summarizes the behaviour:

```
    method      behaviour with NULL

    Clearerr    PerlIOBase_clearerr
    Close       PerlIOBase_close
    Dup         PerlIOBase_dup
    Eof         PerlIOBase_eof
    Error       PerlIOBase_error
    Fileno      PerlIOBase_fileno
    Fill        FAILURE
    Flush       SUCCESS
    Getarg      SUCCESS
    Get_base    FAILURE
    Get_bufsiz  FAILURE
    Get_cnt     FAILURE
    Get_ptr     FAILURE
    Open        INHERITED
    Popped      SUCCESS
    Pushed      SUCCESS
    Read        PerlIOBase_read
    Seek        FAILURE
    Set_cnt     FAILURE
    Set_ptrcnt  FAILURE
    Setlinebuf  PerlIOBase_setlinebuf
    Tell        FAILURE
    Unread      PerlIOBase_unread
    Write       FAILURE

 FAILURE        Set errno (to EINVAL in UNIXish, to LIB$_INVARG in VMS) and
                return -1 (for numeric return values) or NULL (for pointers)
 INHERITED      Inherited from the layer below
 SUCCESS        Return 0 (for numeric return values) or a pointer
```

74.2.12 Core Layers

The file `perlio.c` provides the following layers:

"unix"

A basic non-buffered layer which calls Unix/POSIX `read()`, `write()`, `lseek()`, `close()`. No buffering. Even on platforms that distinguish between O_TEXT and O_BINARY this layer is always O_BINARY.

"perlio"

A very complete generic buffering layer which provides the whole of PerlIO API. It is also intended to be used as a "base class" for other layers. (For example its `Read()` method is implemented in terms of the `Get_cnt()`/`Get_ptr()`/`Set_ptrcnt()` methods).

"perlio" over "unix" provides a complete replacement for stdio as seen via PerlIO API. This is the default for USE_PERLIO when system's stdio does not permit perl's "fast gets" access, and which do not distinguish between `O_TEXT` and `O_BINARY`.

"stdio"

A layer which provides the PerlIO API via the layer scheme, but implements it by calling system's stdio. This is (currently) the default if system's stdio provides sufficient access to allow perl's "fast gets" access and which do not distinguish between `O_TEXT` and `O_BINARY`.

"crlf"

A layer derived using "perlio" as a base class. It provides Win32-like "\n" to CR,LF translation. Can either be applied above "perlio" or serve as the buffer layer itself. "crlf" over "unix" is the default if system distinguishes between `O_TEXT` and `O_BINARY` opens. (At some point "unix" will be replaced by a "native" Win32 IO layer on that platform, as Win32's read/write layer has various drawbacks.) The "crlf" layer is a reasonable model for a layer which transforms data in some way.

"mmap"

If Configure detects `mmap()` functions this layer is provided (with "perlio" as a "base") which does "read" operations by mmap()ing the file. Performance improvement is marginal on modern systems, so it is mainly there as a proof of concept. It is likely to be unbundled from the core at some point. The "mmap" layer is a reasonable model for a minimalist "derived" layer.

"pending"

An "internal" derivative of "perlio" which can be used to provide Unread() function for layers which have no buffer or cannot be bothered. (Basically this layer's `Fill()` pops itself off the stack and so resumes reading from layer below.)

"raw"

A dummy layer which never exists on the layer stack. Instead when "pushed" it actually pops the stack removing itself, it then calls Binmode function table entry on all the layers in the stack - normally this (via PerlIOBase_binmode) removes any layers which do not have `PERLIO_K_RAW` bit set. Layers can modify that behaviour by defining their own Binmode entry.

"utf8"

Another dummy layer. When pushed it pops itself and sets the `PERLIO_F_UTF8` flag on the layer which was (and now is once more) the top of the stack.

In addition *perlio.c* also provides a number of `PerlIOBase_xxxx()` functions which are intended to be used in the table slots of classes which do not need to do anything special for a particular method.

74.2.13 Extension Layers

Layers can made available by extension modules. When an unknown layer is encountered the PerlIO code will perform the equivalent of :

```
use PerlIO 'layer';
```

Where *layer* is the unknown layer. *PerlIO.pm* will then attempt to:

```
require PerlIO::layer;
```

If after that process the layer is still not defined then the `open` will fail.

The following extension layers are bundled with perl:

":encoding"

```
use Encoding;
```

makes this layer available, although *PerlIO.pm* "knows" where to find it. It is an example of a layer which takes an argument as it is called thus:

```
open( $fh, "<:encoding(iso-8859-7)", $pathname );
```

":scalar"

Provides support for reading data from and writing data to a scalar.

```
open( $fh, "+<:scalar", \$scalar );
```

When a handle is so opened, then reads get bytes from the string value of *$ scalar*, and writes change the value. In both cases the position in *$ scalar* starts as zero but can be altered via `seek`, and determined via `tell`.

Please note that this layer is implied when calling open() thus:

```
open( $fh, "+<", \$scalar );
```

":via"

Provided to allow layers to be implemented as Perl code. For instance:

```
use PerlIO::via::StripHTML;
open( my $fh, "<:via(StripHTML)", "index.html" );
```

See *PerlIO::via* for details.

74.3 TODO

Things that need to be done to improve this document.

- Explain how to make a valid fh without going through open()(i.e. apply a layer). For example if the file is not opened through perl, but we want to get back a fh, like it was opened by Perl.

  How PerlIO_apply_layera fits in, where its docs, was it made public?

  Currently the example could be something like this:

```
PerlIO *foo_to_PerlIO(pTHX_ char *mode, ...)
{
    char *mode; /* "w", "r", etc */
    const char *layers = ":APR"; /* the layer name */
    PerlIO *f = PerlIO_allocate(aTHX);
    if (!f) {
        return NULL;
    }

    PerlIO_apply_layers(aTHX_ f, mode, layers);

    if (f) {
        PerlIOAPR *st = PerlIOSelf(f, PerlIOAPR);
        /* fill in the st struct, as in _open() */
        st->file = file;
        PerlIOBase(f)->flags |= PERLIO_F_OPEN;

        return f;
    }
    return NULL;
}
```

- fix/add the documentation in places marked as XXX.
- The handling of errors by the layer is not specified. e.g. when $! should be set explicitly, when the error handling should be just delegated to the top layer.

  Probably give some hints on using SETERRNO() or pointers to where they can be found.
- I think it would help to give some concrete examples to make it easier to understand the API. Of course I agree that the API has to be concise, but since there is no second document that is more of a guide, I think that it'd make it easier to start with the doc which is an API, but has examples in it in places where things are unclear, to a person who is not a PerlIO guru (yet).

Chapter 75

perlapio

Perl's IO abstraction interface.

75.1 SYNOPSIS

```
    #define PERLIO_NOT_STDIO 0    /* For co-existence with stdio only */
    #include <perlio.h>           /* Usually via #include <perl.h> */

    PerlIO *PerlIO_stdin(void);
    PerlIO *PerlIO_stdout(void);
    PerlIO *PerlIO_stderr(void);

    PerlIO *PerlIO_open(const char *path,const char *mode);
    PerlIO *PerlIO_fdopen(int fd, const char *mode);
    PerlIO *PerlIO_reopen(const char *path, const char *mode, PerlIO *old);  /* deprecated */
    int     PerlIO_close(PerlIO *f);

    int     PerlIO_stdoutf(const char *fmt,...)
    int     PerlIO_puts(PerlIO *f,const char *string);
    int     PerlIO_putc(PerlIO *f,int ch);
    int     PerlIO_write(PerlIO *f,const void *buf,size_t numbytes);
    int     PerlIO_printf(PerlIO *f, const char *fmt,...);
    int     PerlIO_vprintf(PerlIO *f, const char *fmt, va_list args);
    int     PerlIO_flush(PerlIO *f);

    int     PerlIO_eof(PerlIO *f);
    int     PerlIO_error(PerlIO *f);
    void    PerlIO_clearerr(PerlIO *f);

    int     PerlIO_getc(PerlIO *d);
    int     PerlIO_ungetc(PerlIO *f,int ch);
    int     PerlIO_read(PerlIO *f, void *buf, size_t numbytes);

    int     PerlIO_fileno(PerlIO *f);

    void    PerlIO_setlinebuf(PerlIO *f);

    Off_t   PerlIO_tell(PerlIO *f);
    int     PerlIO_seek(PerlIO *f, Off_t offset, int whence);
    void    PerlIO_rewind(PerlIO *f);
    int     PerlIO_getpos(PerlIO *f, SV *save);        /* prototype changed */
    int     PerlIO_setpos(PerlIO *f, SV *saved);       /* prototype changed */

    int     PerlIO_fast_gets(PerlIO *f);
    int     PerlIO_has_cntptr(PerlIO *f);
    int     PerlIO_get_cnt(PerlIO *f);
    char   *PerlIO_get_ptr(PerlIO *f);
    void    PerlIO_set_ptrcnt(PerlIO *f, char *ptr, int count);

    int     PerlIO_canset_cnt(PerlIO *f);              /* deprecated */
    void    PerlIO_set_cnt(PerlIO *f, int count);      /* deprecated */

    int     PerlIO_has_base(PerlIO *f);
    char   *PerlIO_get_base(PerlIO *f);
    int     PerlIO_get_bufsiz(PerlIO *f);

    PerlIO *PerlIO_importFILE(FILE *stdio, const char *mode);
    FILE   *PerlIO_exportFILE(PerlIO *f, int flags);
    FILE   *PerlIO_findFILE(PerlIO *f);
    void    PerlIO_releaseFILE(PerlIO *f,FILE *stdio);

    int     PerlIO_apply_layers(PerlIO *f, const char *mode, const char *layers);
    int     PerlIO_binmode(PerlIO *f, int ptype, int imode, const char *layers);
    void    PerlIO_debug(const char *fmt,...)
```

75.2 DESCRIPTION

Perl's source code, and extensions that want maximum portability, should use the above functions instead of those defined in ANSI C's *stdio.h*. The perl headers (in particular "perlio.h") will `#define` them to the I/O mechanism selected at Configure time.

The functions are modeled on those in *stdio.h*, but parameter order has been "tidied up a little".

`PerlIO *` takes the place of FILE *. Like FILE * it should be treated as opaque (it is probably safe to assume it is a pointer to something).

There are currently three implementations:

1. USE_STDIO

   All above are #define'd to stdio functions or are trivial wrapper functions which call stdio. In this case *only* PerlIO * is a FILE *. This has been the default implementation since the abstraction was introduced in perl5.003_02.

2. USE_SFIO

   A "legacy" implementation in terms of the "sfio" library. Used for some specialist applications on Unix machines ("sfio" is not widely ported away from Unix). Most of above are #define'd to the sfio functions. PerlIO * is in this case Sfio_t *.

3. USE_PERLIO

   Introduced just after perl5.7.0, this is a re-implementation of the above abstraction which allows perl more control over how IO is done as it decouples IO from the way the operating system and C library choose to do things. For USE_PERLIO PerlIO * has an extra layer of indirection - it is a pointer-to-a-pointer. This allows the PerlIO * to remain with a known value while swapping the implementation around underneath *at run time*. In this case all the above are true (but very simple) functions which call the underlying implementation.

   This is the only implementation for which `PerlIO_apply_layers()` does anything "interesting".

   The USE_PERLIO implementation is described in *perliol*.

Because "perlio.h" is a thin layer (for efficiency) the semantics of these functions are somewhat dependent on the underlying implementation. Where these variations are understood they are noted below.

Unless otherwise noted, functions return 0 on success, or a negative value (usually `EOF` which is usually -1) and set `errno` on error.

PerlIO_stdin(), PerlIO_stdout(), PerlIO_stderr()

Use these rather than `stdin`, `stdout`, `stderr`. They are written to look like "function calls" rather than variables because this makes it easier to *make them* function calls if platform cannot export data to loaded modules, or if (say) different "threads" might have different values.

PerlIO_open(path, mode), PerlIO_fdopen(fd,mode)

These correspond to fopen()/fdopen() and the arguments are the same. Return `NULL` and set `errno` if there is an error. There may be an implementation limit on the number of open handles, which may be lower than the limit on the number of open files - `errno` may not be set when `NULL` is returned if this limit is exceeded.

PerlIO_reopen(path,mode,f)

While this currently exists in all three implementations perl itself does not use it. *As perl does not use it, it is not well tested.*

Perl prefers to `dup` the new low-level descriptor to the descriptor used by the existing PerlIO. This may become the behaviour of this function in the future.

PerlIO_printf(f,fmt,...), PerlIO_vprintf(f,fmt,a)

These are fprintf()/vfprintf() equivalents.

PerlIO_stdoutf(fmt,...)

This is printf() equivalent. printf is #defined to this function, so it is (currently) legal to use `printf(fmt,...)` in perl sources.

PerlIO_read(f,buf,count), PerlIO_write(f,buf,count)

These correspond functionally to fread() and fwrite() but the arguments and return values are different. The PerlIO_read() and PerlIO_write() signatures have been modeled on the more sane low level read() and write() functions instead: The "file" argument is passed first, there is only one "count", and the return value can distinguish between error and `EOF`.

Returns a byte count if successful (which may be zero or positive), returns negative value and sets `errno` on error. Depending on implementation `errno` may be `EINTR` if operation was interrupted by a signal.

PerlIO_close(f)

Depending on implementation `errno` may be `EINTR` if operation was interrupted by a signal.

PerlIO_puts(f,s), PerlIO_putc(f,c)

These correspond to fputs() and fputc(). Note that arguments have been revised to have "file" first.

PerlIO_ungetc(f,c)

This corresponds to ungetc(). Note that arguments have been revised to have "file" first. Arranges that next read operation will return the byte **c**. Despite the implied "character" in the name only values in the range 0..0xFF are defined. Returns the byte **c** on success or -1 (`EOF`) on error. The number of bytes that can be "pushed back" may vary, only 1 character is certain, and then only if it is the last character that was read from the handle.

PerlIO_getc(f)

This corresponds to getc(). Despite the c in the name only byte range 0..0xFF is supported. Returns the character read or -1 (`EOF`) on error.

PerlIO_eof(f)

This corresponds to feof(). Returns a true/false indication of whether the handle is at end of file. For terminal devices this may or may not be "sticky" depending on the implementation. The flag is cleared by PerlIO_seek(), or PerlIO_rewind().

PerlIO_error(f)

This corresponds to ferror(). Returns a true/false indication of whether there has been an IO error on the handle.

PerlIO_fileno(f)

This corresponds to fileno(), note that on some platforms, the meaning of "fileno" may not match Unix. Returns -1 if the handle has no open descriptor associated with it.

PerlIO_clearerr(f)

This corresponds to clearerr(), i.e., clears 'error' and (usually) 'eof' flags for the "stream". Does not return a value.

PerlIO_flush(f)

This corresponds to fflush(). Sends any buffered write data to the underlying file. If called with `NULL` this may flush all open streams (or core dump with some USE_STDIO implementattions). Calling on a handle open for read only, or on which last operation was a read of some kind may lead to undefined behaviour on some USE_STDIO implementations. The USE_PERLIO (layers) implementation tries to behave better: it flushes all open streams when passed `NULL`, and attempts to retain data on read streams either in the buffer or by seeking the handle to the current logical position.

PerlIO_seek(f,offset,whence)

This corresponds to fseek(). Sends buffered write data to the underlying file, or discards any buffered read data, then positions the file desciptor as specified by **offset** and **whence** (sic). This is the correct thing to do when switching between read and write on the same handle (see issues with PerlIO_flush() above). Offset is of type `Off_t` which is a perl Configure value which may not be same as stdio's `off_t`.

PerlIO_tell(f)

This corresponds to ftell(). Returns the current file position, or (Off_t) -1 on error. May just return value system "knows" without making a system call or checking the underlying file descriptor (so use on shared file descriptors is not safe without a PerlIO_seek()). Return value is of type `Off_t` which is a perl Configure value which may not be same as stdio's `off_t`.

PerlIO_getpos(f,p), PerlIO_setpos(f,p)

These correspond (loosely) to fgetpos() and fsetpos(). Rather than stdio's Fpos_t they expect a "Perl Scalar Value" to be passed. What is stored there should be considered opaque. The layout of the data may vary from handle to handle. When not using stdio or if platform does not have the stdio calls then they are implemented in terms of PerlIO_tell() and PerlIO_seek().

PerlIO_rewind(f)

This corresponds to rewind(). It is usually defined as being

```
    PerlIO_seek(f,(Off_t)0L, SEEK_SET);
    PerlIO_clearerr(f);
```

PerlIO_tmpfile()

This corresponds to tmpfile(), i.e., returns an anonymous PerlIO or NULL on error. The system will attempt to automatically delete the file when closed. On Unix the file is usually `unlink`-ed just after it is created so it does not matter how it gets closed. On other systems the file may only be deleted if closed via PerlIO_close() and/or the program exits via `exit`. Depending on the implementation there may be "race conditions" which allow other processes access to the file, though in general it will be safer in this regard than ad. hoc. schemes.

PerlIO_setlinebuf(f)

This corresponds to setlinebuf(). Does not return a value. What constitutes a "line" is implementation dependent but usually means that writing "\n" flushes the buffer. What happens with things like "this\nthat" is uncertain. (Perl core uses it *only* when "dumping"; it has nothing to do with $| auto-flush.)

75.2.1 Co-existence with stdio

There is outline support for co-existence of PerlIO with stdio. Obviously if PerlIO is implemented in terms of stdio there is no problem. However in other cases then mechanisms must exist to create a FILE * which can be passed to library code which is going to use stdio calls.

The first step is to add this line:

```
   #define PERLIO_NOT_STDIO 0
```

before including any perl header files. (This will probably become the default at some point). That prevents "perlio.h" from attempting to #define stdio functions onto PerlIO functions.

XS code is probably better using "typemap" if it expects FILE * arguments. The standard typemap will be adjusted to comprehend any changes in this area.

PerlIO_importFILE(f,mode)

Used to get a PerlIO * from a FILE *.

The mode argument should be a string as would be passed to fopen/PerlIO_open. If it is NULL then - for legacy support - the code will (depending upon the platform and the implementation) either attempt to empirically determine the mode in which *f* is open, or use "r+" to indicate a read/write stream.

Once called the FILE * should *ONLY* be closed by calling `PerlIO_close()` on the returned PerlIO *.

The PerlIO is set to textmode. Use PerlIO_binmode if this is not the desired mode.

This is **not** the reverse of PerlIO_exportFILE().

PerlIO_exportFILE(f,mode)

Given a PerlIO * create a 'native' FILE * suitable for passing to code expecting to be compiled and linked with ANSI C *stdio.h*. The mode argument should be a string as would be passed to fopen/PerlIO_open. If it is NULL then - for legacy support - the FILE * is opened in same mode as the PerlIO *.

The fact that such a FILE * has been 'exported' is recorded, (normally by pushing a new :stdio "layer" onto the PerlIO *), which may affect future PerlIO operations on the original PerlIO *. You should not call `fclose()` on the file unless you call `PerlIO_releaseFILE()` to disassociate it from the PerlIO *. (Do not use PerlIO_importFILE() for doing the disassociation.)

Calling this function repeatedly will create a FILE * on each call (and will push an :stdio layer each time as well).

PerlIO_releaseFILE(p,f)

Calling PerlIO_releaseFILE informs PerlIO that all use of FILE * is complete. It is removed from the list of 'exported' FILE *s, and the associated PerlIO * should revert to its original behaviour.

Use this to disassociate a file from a PerlIO * that was associated using PerlIO_exportFILE().

PerlIO_findFILE(f)

Returns a native FILE * used by a stdio layer. If there is none, it will create one with PerlIO_exportFILE. In either case the FILE * should be considered as belonging to PerlIO subsystem and should only be closed by calling `PerlIO_close()`.

75.2.2 "Fast gets" Functions

In addition to standard-like API defined so far above there is an "implementation" interface which allows perl to get at internals of PerlIO. The following calls correspond to the various FILE_xxx macros determined by Configure - or their equivalent in other implementations. This section is really of interest to only those concerned with detailed perl-core behaviour, implementing a PerlIO mapping or writing code which can make use of the "read ahead" that has been done by the IO system in the same way perl does. Note that any code that uses these interfaces must be prepared to do things the traditional way if a handle does not support them.

PerlIO_fast_gets(f)

Returns true if implementation has all the interfaces required to allow perl's `sv_gets` to "bypass" normal IO mechanism. This can vary from handle to handle.

```
  PerlIO_fast_gets(f) = PerlIO_has_cntptr(f) && \
                        PerlIO_canset_cnt(f) && \
                        'Can set pointer into buffer'
```

PerlIO_has_cntptr(f)

Implementation can return pointer to current position in the "buffer" and a count of bytes available in the buffer. Do not use this - use PerlIO_fast_gets.

PerlIO_get_cnt(f)

Return count of readable bytes in the buffer. Zero or negative return means no more bytes available.

PerlIO_get_ptr(f)

Return pointer to next readable byte in buffer, accessing via the pointer (dereferencing) is only safe if PerlIO_get_cnt() has returned a positive value. Only positive offsets up to value returned by PerlIO_get_cnt() are allowed.

PerlIO_set_ptrcnt(f,p,c)

Set pointer into buffer, and a count of bytes still in the buffer. Should be used only to set pointer to within range implied by previous calls to `PerlIO_get_ptr` and `PerlIO_get_cnt`. The two values *must* be consistent with each other (implementation may only use one or the other or may require both).

PerlIO_canset_cnt(f)

Implementation can adjust its idea of number of bytes in the buffer. Do not use this - use PerlIO_fast_gets.

PerlIO_set_cnt(f,c)

Obscure - set count of bytes in the buffer. Deprecated. Only usable if PerlIO_canset_cnt() returns true. Currently used in only doio.c to force count less than -1 to -1. Perhaps should be PerlIO_set_empty or similar. This call may actually do nothing if "count" is deduced from pointer and a "limit". Do not use this - use PerlIO_set_ptrcnt().

PerlIO_has_base(f)

Returns true if implementation has a buffer, and can return pointer to whole buffer and its size. Used by perl for **-T** / **-B** tests. Other uses would be very obscure...

PerlIO_get_base(f)

Return *start* of buffer. Access only positive offsets in the buffer up to the value returned by PerlIO_get_bufsiz().

PerlIO_get_bufsiz(f)

Return the *total number of bytes* in the buffer, this is neither the number that can be read, nor the amount of memory allocated to the buffer. Rather it is what the operating system and/or implementation happened to `read()` (or whatever) last time IO was requested.

75.2.3 Other Functions

PerlIO_apply_layers(f,mode,layers)

The new interface to the USE_PERLIO implementation. The layers ":crlf" and ":raw" are only ones allowed for other implementations and those are silently ignored. (As of perl5.8 ":raw" is deprecated.) Use PerlIO_binmode() below for the portable case.

PerlIO_binmode(f,ptype,imode,layers)

The hook used by perl's `binmode` operator. **ptype** is perl's character for the kind of IO:

'<' read

'>' write

'+' read/write

imode is `O_BINARY` or `O_TEXT`.

layers is a string of layers to apply, only ":crlf" makes sense in the non USE_PERLIO case. (As of perl5.8 ":raw" is deprecated in favour of passing NULL.)

Portable cases are:

```
    PerlIO_binmode(f,ptype,O_BINARY,Nullch);
and
    PerlIO_binmode(f,ptype,O_TEXT,":crlf");
```

On Unix these calls probably have no effect whatsoever. Elsewhere they alter "\n" to CR,LF translation and possibly cause a special text "end of file" indicator to be written or honoured on read. The effect of making the call after doing any IO to the handle depends on the implementation. (It may be ignored, affect any data which is already buffered as well, or only apply to subsequent data.)

PerlIO_debug(fmt,...)

PerlIO_debug is a printf()-like function which can be used for debugging. No return value. Its main use is inside PerlIO where using real printf, warn() etc. would recursively call PerlIO and be a problem.

PerlIO_debug writes to the file named by $ENV{'PERLIO_DEBUG'} typical use might be

```
  Bourne shells (sh, ksh, bash, zsh, ash, ...):
   PERLIO_DEBUG=/dev/tty ./perl somescript some args

  Csh/Tcsh:
   setenv PERLIO_DEBUG /dev/tty
   ./perl somescript some args

  If you have the "env" utility:
   env PERLIO_DEBUG=/dev/tty ./perl somescript some args

  Win32:
   set PERLIO_DEBUG=CON
   perl somescript some args
```

If $ENV{'PERLIO_DEBUG'} is not set PerlIO_debug() is a no-op.

Chapter 76

perlhack

How to hack at the Perl internals

76.1 DESCRIPTION

This document attempts to explain how Perl development takes place, and ends with some suggestions for people wanting to become bona fide porters.

The perl5-porters mailing list is where the Perl standard distribution is maintained and developed. The list can get anywhere from 10 to 150 messages a day, depending on the heatedness of the debate. Most days there are two or three patches, extensions, features, or bugs being discussed at a time.

A searchable archive of the list is at either:

```
    http://www.xray.mpe.mpg.de/mailing-lists/perl5-porters/
```

or

```
    http://archive.develooper.com/perl5-porters@perl.org/
```

List subscribers (the porters themselves) come in several flavours. Some are quiet curious lurkers, who rarely pitch in and instead watch the ongoing development to ensure they're forewarned of new changes or features in Perl. Some are representatives of vendors, who are there to make sure that Perl continues to compile and work on their platforms. Some patch any reported bug that they know how to fix, some are actively patching their pet area (threads, Win32, the regexp engine), while others seem to do nothing but complain. In other words, it's your usual mix of technical people.

Over this group of porters presides Larry Wall. He has the final word in what does and does not change in the Perl language. Various releases of Perl are shepherded by a "pumpking", a porter responsible for gathering patches, deciding on a patch-by-patch feature-by-feature basis what will and will not go into the release. For instance, Gurusamy Sarathy was the pumpking for the 5.6 release of Perl, and Jarkko Hietaniemi is the pumpking for the 5.8 release, and Hugo van der Sanden will be the pumpking for the 5.10 release.

In addition, various people are pumpkings for different things. For instance, Andy Dougherty and Jarkko Hietaniemi share the *Configure* pumpkin.

Larry sees Perl development along the lines of the US government: there's the Legislature (the porters), the Executive branch (the pumpkings), and the Supreme Court (Larry). The legislature can discuss and submit patches to the executive branch all they like, but the executive branch is free to veto them. Rarely, the Supreme Court will side with the executive branch over the legislature, or the legislature over the executive branch. Mostly, however, the legislature and the executive branch are supposed to get along and work out their differences without impeachment or court cases.

You might sometimes see reference to Rule 1 and Rule 2. Larry's power as Supreme Court is expressed in The Rules:

1. Larry is always by definition right about how Perl should behave. This means he has final veto power on the core functionality.

2. Larry is allowed to change his mind about any matter at a later date, regardless of whether he previously invoked Rule 1.

Got that? Larry is always right, even when he was wrong. It's rare to see either Rule exercised, but they are often alluded to.

New features and extensions to the language are contentious, because the criteria used by the pumpkings, Larry, and other porters to decide which features should be implemented and incorporated are not codified in a few small design goals as with some other languages. Instead, the heuristics are flexible and often difficult to fathom. Here is one person's list, roughly in decreasing order of importance, of heuristics that new features have to be weighed against:

Does concept match the general goals of Perl?

These haven't been written anywhere in stone, but one approximation is:

```
 1. Keep it fast, simple, and useful.
 2. Keep features/concepts as orthogonal as possible.
 3. No arbitrary limits (platforms, data sizes, cultures).
 4. Keep it open and exciting to use/patch/advocate Perl everywhere.
 5. Either assimilate new technologies, or build bridges to them.
```

Where is the implementation?

All the talk in the world is useless without an implementation. In almost every case, the person or people who argue for a new feature will be expected to be the ones who implement it. Porters capable of coding new features have their own agendas, and are not available to implement your (possibly good) idea.

Backwards compatibility

It's a cardinal sin to break existing Perl programs. New warnings are contentious–some say that a program that emits warnings is not broken, while others say it is. Adding keywords has the potential to break programs, changing the meaning of existing token sequences or functions might break programs.

Could it be a module instead?

Perl 5 has extension mechanisms, modules and XS, specifically to avoid the need to keep changing the Perl interpreter. You can write modules that export functions, you can give those functions prototypes so they can be called like built-in functions, you can even write XS code to mess with the runtime data structures of the Perl interpreter if you want to implement really complicated things. If it can be done in a module instead of in the core, it's highly unlikely to be added.

Is the feature generic enough?

Is this something that only the submitter wants added to the language, or would it be broadly useful? Sometimes, instead of adding a feature with a tight focus, the porters might decide to wait until someone implements the more generalized feature. For instance, instead of implementing a "delayed evaluation" feature, the porters are waiting for a macro system that would permit delayed evaluation and much more.

Does it potentially introduce new bugs?

Radical rewrites of large chunks of the Perl interpreter have the potential to introduce new bugs. The smaller and more localized the change, the better.

Does it preclude other desirable features?

A patch is likely to be rejected if it closes off future avenues of development. For instance, a patch that placed a true and final interpretation on prototypes is likely to be rejected because there are still options for the future of prototypes that haven't been addressed.

Is the implementation robust?

Good patches (tight code, complete, correct) stand more chance of going in. Sloppy or incorrect patches might be placed on the back burner until the pumpking has time to fix, or might be discarded altogether without further notice.

Is the implementation generic enough to be portable?

The worst patches make use of a system-specific features. It's highly unlikely that nonportable additions to the Perl language will be accepted.

Is the implementation tested?

Patches which change behaviour (fixing bugs or introducing new features) must include regression tests to verify that everything works as expected. Without tests provided by the original author, how can anyone else changing perl in the future be sure that they haven't unwittingly broken the behaviour the patch implements? And without tests, how can the patch's author be confident that his/her hard work put into the patch won't be accidentally thrown away by someone in the future?

Is there enough documentation?

Patches without documentation are probably ill-thought out or incomplete. Nothing can be added without documentation, so submitting a patch for the appropriate manpages as well as the source code is always a good idea.

Is there another way to do it?

Larry said "Although the Perl Slogan is *There's More Than One Way to Do It*, I hesitate to make 10 ways to do something". This is a tricky heuristic to navigate, though–one man's essential addition is another man's pointless cruft.

Does it create too much work?

Work for the pumpking, work for Perl programmers, work for module authors, ... Perl is supposed to be easy.

Patches speak louder than words

Working code is always preferred to pie-in-the-sky ideas. A patch to add a feature stands a much higher chance of making it to the language than does a random feature request, no matter how fervently argued the request might be. This ties into "Will it be useful?", as the fact that someone took the time to make the patch demonstrates a strong desire for the feature.

If you're on the list, you might hear the word "core" bandied around. It refers to the standard distribution. "Hacking on the core" means you're changing the C source code to the Perl interpreter. "A core module" is one that ships with Perl.

76.1.1 Keeping in sync

The source code to the Perl interpreter, in its different versions, is kept in a repository managed by a revision control system (which is currently the Perforce program, see http://perforce.com/). The pumpkings and a few others have access to the repository to check in changes. Periodically the pumpking for the development version of Perl will release a new version, so the rest of the porters can see what's changed. The current state of the main trunk of repository, and patches that describe the individual changes that have happened since the last public release are available at this location:

```
    http://public.activestate.com/gsar/APC/
    ftp://ftp.linux.activestate.com/pub/staff/gsar/APC/
```

If you're looking for a particular change, or a change that affected a particular set of files, you may find the **Perl Repository Browser** useful:

```
    http://public.activestate.com/cgi-bin/perlbrowse
```

You may also want to subscribe to the perl5-changes mailing list to receive a copy of each patch that gets submitted to the maintenance and development "branches" of the perl repository. See http://lists.perl.org/ for subscription information.

If you are a member of the perl5-porters mailing list, it is a good thing to keep in touch with the most recent changes. If not only to verify if what you would have posted as a bug report isn't already solved in the most recent available perl development branch, also known as perl-current, bleading edge perl, bleedperl or bleadperl.

Needless to say, the source code in perl-current is usually in a perpetual state of evolution. You should expect it to be very buggy. Do **not** use it for any purpose other than testing and development.

Keeping in sync with the most recent branch can be done in several ways, but the most convenient and reliable way is using **rsync**, available at ftp://rsync.samba.org/pub/rsync/ . (You can also get the most recent branch by FTP.)

If you choose to keep in sync using rsync, there are two approaches to doing so:

rsync'ing the source tree

Presuming you are in the directory where your perl source resides and you have rsync installed and available, you can 'upgrade' to the bleadperl using:

```
# rsync -avz rsync://ftp.linux.activestate.com/perl-current/ .
```

This takes care of updating every single item in the source tree to the latest applied patch level, creating files that are new (to your distribution) and setting date/time stamps of existing files to reflect the bleadperl status.

Note that this will not delete any files that were in '.' before the rsync. Once you are sure that the rsync is running correctly, run it with the –delete and the –dry-run options like this:

```
# rsync -avz --delete --dry-run rsync://ftp.linux.activestate.com/perl-current/ .
```

This will *simulate* an rsync run that also deletes files not present in the bleadperl master copy. Observe the results from this run closely. If you are sure that the actual run would delete no files precious to you, you could remove the '–dry-run' option.

You can than check what patch was the latest that was applied by looking in the file **.patch**, which will show the number of the latest patch.

If you have more than one machine to keep in sync, and not all of them have access to the WAN (so you are not able to rsync all the source trees to the real source), there are some ways to get around this problem.

Using rsync over the LAN

Set up a local rsync server which makes the rsynced source tree available to the LAN and sync the other machines against this directory.

From http://rsync.samba.org/README.html :

```
"Rsync uses rsh or ssh for communication. It does not need to be
 setuid and requires no special privileges for installation.  It
 does not require an inetd entry or a daemon.  You must, however,
 have a working rsh or ssh system.  Using ssh is recommended for
 its security features."
```

Using pushing over the NFS

Having the other systems mounted over the NFS, you can take an active pushing approach by checking the just updated tree against the other not-yet synced trees. An example would be

```
#!/usr/bin/perl -w

use strict;
use File::Copy;

my %MF = map {
    m/(\S+)/;
    $1 => [ (stat $1)[2, 7, 9] ];     # mode, size, mtime
    } `cat MANIFEST`;

my %remote = map { $_ => "/$_/pro/3gl/CPAN/perl-5.7.1" } qw(host1 host2);
```

```
        foreach my $host (keys %remote) {
            unless (-d $remote{$host}) {
                print STDERR "Cannot Xsync for host $host\n";
                next;
                }
            foreach my $file (keys %MF) {
                my $rfile = "$remote{$host}/$file";
                my ($mode, $size, $mtime) = (stat $rfile)[2, 7, 9];
                defined $size or ($mode, $size, $mtime) = (0, 0, 0);
                $size == $MF{$file}[1] && $mtime == $MF{$file}[2] and next;
                printf "%4s %-34s %8d %9d  %8d %9d\n",
                    $host, $file, $MF{$file}[1], $MF{$file}[2], $size, $mtime;
                unlink $rfile;
                copy ($file, $rfile);
                utime time, $MF{$file}[2], $rfile;
                chmod $MF{$file}[0], $rfile;
                }
            }
```

though this is not perfect. It could be improved with checking file checksums before updating. Not all NFS systems support reliable utime support (when used over the NFS).

rsync'ing the patches

The source tree is maintained by the pumpking who applies patches to the files in the tree. These patches are either created by the pumpking himself using `diff -c` after updating the file manually or by applying patches sent in by posters on the perl5-porters list. These patches are also saved and rsync'able, so you can apply them yourself to the source files.

Presuming you are in a directory where your patches reside, you can get them in sync with

```
 # rsync -avz rsync://ftp.linux.activestate.com/perl-current-diffs/ .
```

This makes sure the latest available patch is downloaded to your patch directory.

It's then up to you to apply these patches, using something like

```
 # last=`ls -t *.gz | sed q`
 # rsync -avz rsync://ftp.linux.activestate.com/perl-current-diffs/ .
 # find . -name '*.gz' -newer $last -exec gzcat {} \; >blead.patch
 # cd ../perl-current
 # patch -p1 -N <../perl-current-diffs/blead.patch
```

or, since this is only a hint towards how it works, use CPAN-patchaperl from Andreas König to have better control over the patching process.

76.1.2 Why rsync the source tree

It's easier to rsync the source tree

Since you don't have to apply the patches yourself, you are sure all files in the source tree are in the right state.

It's more reliable

While both the rsync-able source and patch areas are automatically updated every few minutes, keep in mind that applying patches may sometimes mean careful hand-holding, especially if your version of the `patch` program does not understand how to deal with new files, files with 8-bit characters, or files without trailing newlines.

76.1.3 Why rsync the patches

It's easier to rsync the patches

If you have more than one machine that you want to keep in track with bleadperl, it's easier to rsync the patches only once and then apply them to all the source trees on the different machines.

In case you try to keep in pace on 5 different machines, for which only one of them has access to the WAN, rsync'ing all the source trees should than be done 5 times over the NFS. Having rsync'ed the patches only once, I can apply them to all the source trees automatically. Need you say more ;-)

It's a good reference

If you do not only like to have the most recent development branch, but also like to **fix** bugs, or extend features, you want to dive into the sources. If you are a seasoned perl core diver, you don't need no manuals, tips, roadmaps, perlguts.pod or other aids to find your way around. But if you are a starter, the patches may help you in finding where you should start and how to change the bits that bug you.

The file **Changes** is updated on occasions the pumpking sees as his own little sync points. On those occasions, he releases a tar-ball of the current source tree (i.e. perl@7582.tar.gz), which will be an excellent point to start with when choosing to use the 'rsync the patches' scheme. Starting with perl@7582, which means a set of source files on which the latest applied patch is number 7582, you apply all succeeding patches available from then on (7583, 7584, ...).

You can use the patches later as a kind of search archive.

Finding a start point

If you want to fix/change the behaviour of function/feature Foo, just scan the patches for patches that mention Foo either in the subject, the comments, or the body of the fix. A good chance the patch shows you the files that are affected by that patch which are very likely to be the starting point of your journey into the guts of perl.

Finding how to fix a bug

If you've found *where* the function/feature Foo misbehaves, but you don't know how to fix it (but you do know the change you want to make), you can, again, peruse the patches for similar changes and look how others apply the fix.

Finding the source of misbehaviour

When you keep in sync with bleadperl, the pumpking would love to *see* that the community efforts really work. So after each of his sync points, you are to 'make test' to check if everything is still in working order. If it is, you do 'make ok', which will send an OK report to perlbug@perl.org. (If you do not have access to a mailer from the system you just finished successfully 'make test', you can do 'make okfile', which creates the file `perl.ok`, which you can than take to your favourite mailer and mail yourself).

But of course, as always, things will not always lead to a success path, and one or more test do not pass the 'make test'. Before sending in a bug report (using 'make nok' or 'make nokfile'), check the mailing list if someone else has reported the bug already and if so, confirm it by replying to that message. If not, you might want to trace the source of that misbehaviour **before** sending in the bug, which will help all the other porters in finding the solution.

Here the saved patches come in very handy. You can check the list of patches to see which patch changed what file and what change caused the misbehaviour. If you note that in the bug report, it saves the one trying to solve it, looking for that point.

If searching the patches is too bothersome, you might consider using perl's bugtron to find more information about discussions and ramblings on posted bugs.

If you want to get the best of both worlds, rsync both the source tree for convenience, reliability and ease and rsync the patches for reference.

76.1.4 Working with the source

Because you cannot use the Perforce client, you cannot easily generate diffs against the repository, nor will merges occur when you update via rsync. If you edit a file locally and then rsync against the latest source, changes made in the remote copy will *overwrite* your local versions!

The best way to deal with this is to maintain a tree of symlinks to the rsync'd source. Then, when you want to edit a file, you remove the symlink, copy the real file into the other tree, and edit it. You can then diff your edited file against the original to generate a patch, and you can safely update the original tree.

Perl's *Configure* script can generate this tree of symlinks for you. The following example assumes that you have used rsync to pull a copy of the Perl source into the *perl-rsync* directory. In the directory above that one, you can execute the following commands:

```
mkdir perl-dev
cd perl-dev
../perl-rsync/Configure -Dmksymlinks -Dusedevel -D"optimize=-g"
```

This will start the Perl configuration process. After a few prompts, you should see something like this:

```
Symbolic links are supported.

Checking how to test for symbolic links...
Your builtin 'test -h' may be broken.
Trying external '/usr/bin/test -h'.
You can test for symbolic links with '/usr/bin/test -h'.

Creating the symbolic links...
(First creating the subdirectories...)
(Then creating the symlinks...)
```

The specifics may vary based on your operating system, of course. After you see this, you can abort the *Configure* script, and you will see that the directory you are in has a tree of symlinks to the *perl-rsync* directories and files.

If you plan to do a lot of work with the Perl source, here are some Bourne shell script functions that can make your life easier:

```
    function edit {
        if [ -L $1 ]; then
            mv $1 $1.orig
                cp $1.orig $1
                vi $1
        else
            /bin/vi $1
                fi
    }

    function unedit {
        if [ -L $1.orig ]; then
            rm $1
                mv $1.orig $1
                fi
    }
```

Replace "vi" with your favorite flavor of editor.

Here is another function which will quickly generate a patch for the files which have been edited in your symlink tree:

```
    mkpatchorig() {
        local diffopts
            for f in ‘find . -name ’*.orig’ | sed s,^\./,,‘
                do
                    case ‘echo $f | sed ’s,.orig$,,;s,.*\.,,’‘ in
                        c)   diffopts=-p ;;
                pod) diffopts=’-F^=’ ;;
                *)   diffopts= ;;
                esac
                    diff -du $diffopts $f ‘echo $f | sed ’s,.orig$,,’‘
                    done
    }
```

This function produces patches which include enough context to make your changes obvious. This makes it easier for the Perl pumpking(s) to review them when you send them to the perl5-porters list, and that means they're more likely to get applied.

This function assumed a GNU diff, and may require some tweaking for other diff variants.

76.1.5 Perlbug administration

There is a single remote administrative interface for modifying bug status, category, open issues etc. using the **RT** *bugtracker* system, maintained by *Robert Spier*. Become an administrator, and close any bugs you can get your sticky mitts on:

```
        http://rt.perl.org
```

The bugtracker mechanism for **perl5** bugs in particular is at:

```
        http://bugs6.perl.org/perlbug
```

To email the bug system administrators:

```
        "perlbug-admin" <perlbug-admin@perl.org>
```

76.1.6 Submitting patches

Always submit patches to *perl5-porters@perl.org*. If you're patching a core module and there's an author listed, send the author a copy (see Patching a core module). This lets other porters review your patch, which catches a surprising number of errors in patches. Either use the diff program (available in source code form from ftp://ftp.gnu.org/pub/gnu/ , or use Johan Vromans' *makepatch* (available from *CPAN/authors/id/JV/*). Unified diffs are preferred, but context diffs are accepted. Do not send RCS-style diffs or diffs without context lines. More information is given in the *Porting/patching.pod* file in the Perl source distribution. Please patch against the latest **development** version (e.g., if you're fixing a bug in the 5.005 track, patch against the latest 5.005_5x version). Only patches that survive the heat of the development branch get applied to maintenance versions.

Your patch should update the documentation and test suite. See Writing a test.

To report a bug in Perl, use the program *perlbug* which comes with Perl (if you can't get Perl to work, send mail to the address *perlbug@perl.org* or *perlbug@perl.com*). Reporting bugs through *perlbug* feeds into the automated bug-tracking system, access to which is provided through the web at http://bugs.perl.org/ . It often pays to check the archives of the perl5-porters mailing list to see whether the bug you're reporting has been reported before, and if so whether it was considered a bug. See above for the location of the searchable archives.

The CPAN testers (http://testers.cpan.org/) are a group of volunteers who test CPAN modules on a variety of platforms. Perl Smokers (http://archives.develooper.com/daily-build@perl.org/) automatically tests Perl source releases on platforms with various configurations. Both efforts welcome volunteers.

It's a good idea to read and lurk for a while before chipping in. That way you'll get to see the dynamic of the conversations, learn the personalities of the players, and hopefully be better prepared to make a useful contribution when do you speak up.

If after all this you still think you want to join the perl5-porters mailing list, send mail to *perl5-porters-subscribe@perl.org*. To unsubscribe, send mail to *perl5-porters-unsubscribe@perl.org*.

To hack on the Perl guts, you'll need to read the following things:

perlguts

This is of paramount importance, since it's the documentation of what goes where in the Perl source. Read it over a couple of times and it might start to make sense - don't worry if it doesn't yet, because the best way to study it is to read it in conjunction with poking at Perl source, and we'll do that later on.

You might also want to look at Gisle Aas's illustrated perlguts - there's no guarantee that this will be absolutely up-to-date with the latest documentation in the Perl core, but the fundamentals will be right. (http://gisle.aas.no/perl/illguts/)

perlxstut* and *perlxs

A working knowledge of XSUB programming is incredibly useful for core hacking; XSUBs use techniques drawn from the PP code, the portion of the guts that actually executes a Perl program. It's a lot gentler to learn those techniques from simple examples and explanation than from the core itself.

perlapi

The documentation for the Perl API explains what some of the internal functions do, as well as the many macros used in the source.

Porting/pumpkin.pod

This is a collection of words of wisdom for a Perl porter; some of it is only useful to the pumpkin holder, but most of it applies to anyone wanting to go about Perl development.

The perl5-porters FAQ

This should be available from http://simon-cozens.org/writings/p5p-faq ; alternatively, you can get the FAQ emailed to you by sending mail to `perl5-porters-faq@perl.org`. It contains hints on reading perl5-porters, information on how perl5-porters works and how Perl development in general works.

76.1.7 Finding Your Way Around

Perl maintenance can be split into a number of areas, and certain people (pumpkins) will have responsibility for each area. These areas sometimes correspond to files or directories in the source kit. Among the areas are:

Core modules

Modules shipped as part of the Perl core live in the *lib/* and *ext/* subdirectories: *lib/* is for the pure-Perl modules, and *ext/* contains the core XS modules.

Tests

There are tests for nearly all the modules, built-ins and major bits of functionality. Test files all have a .t suffix. Module tests live in the *lib/* and *ext/* directories next to the module being tested. Others live in *t/*. See Writing a test

Documentation

Documentation maintenance includes looking after everything in the *pod/* directory, (as well as contributing new documentation) and the documentation to the modules in core.

Configure

The configure process is the way we make Perl portable across the myriad of operating systems it supports. Responsibility for the configure, build and installation process, as well as the overall portability of the core code rests with the configure pumpkin - others help out with individual operating systems.

The files involved are the operating system directories, (*win32/*, *os2/*, *vms/* and so on) the shell scripts which generate *config.h* and *Makefile*, as well as the metaconfig files which generate *Configure*. (metaconfig isn't included in the core distribution.)

Interpreter

And of course, there's the core of the Perl interpreter itself. Let's have a look at that in a little more detail.

Before we leave looking at the layout, though, don't forget that *MANIFEST* contains not only the file names in the Perl distribution, but short descriptions of what's in them, too. For an overview of the important files, try this:

```
perl -lne 'print if /^[^\/]+\.[ch]\s+/' MANIFEST
```

76.1.8 Elements of the interpreter

The work of the interpreter has two main stages: compiling the code into the internal representation, or bytecode, and then executing it. Compiled code in *perlguts* explains exactly how the compilation stage happens.

Here is a short breakdown of perl's operation:

Startup

The action begins in *perlmain.c*. (or *miniperlmain.c* for miniperl) This is very high-level code, enough to fit on a single screen, and it resembles the code found in *perlembed*; most of the real action takes place in *perl.c*

First, *perlmain.c* allocates some memory and constructs a Perl interpreter:

```
1 PERL_SYS_INIT3(&argc,&argv,&env);
2
3 if (!PL_do_undump) {
4     my_perl = perl_alloc();
5     if (!my_perl)
6         exit(1);
7     perl_construct(my_perl);
8     PL_perl_destruct_level = 0;
9 }
```

Line 1 is a macro, and its definition is dependent on your operating system. Line 3 references `PL_do_undump`, a global variable - all global variables in Perl start with `PL_`. This tells you whether the current running program was created with the `-u` flag to perl and then *undump*, which means it's going to be false in any sane context.

Line 4 calls a function in *perl.c* to allocate memory for a Perl interpreter. It's quite a simple function, and the guts of it looks like this:

```
my_perl = (PerlInterpreter*)PerlMem_malloc(sizeof(PerlInterpreter));
```

Here you see an example of Perl's system abstraction, which we'll see later: `PerlMem_malloc` is either your system's `malloc`, or Perl's own `malloc` as defined in *malloc.c* if you selected that option at configure time.

Next, in line 7, we construct the interpreter; this sets up all the special variables that Perl needs, the stacks, and so on.

Now we pass Perl the command line options, and tell it to go:

```
exitstatus = perl_parse(my_perl, xs_init, argc, argv, (char **)NULL);
if (!exitstatus) {
    exitstatus = perl_run(my_perl);
}
```

`perl_parse` is actually a wrapper around `S_parse_body`, as defined in *perl.c*, which processes the command line options, sets up any statically linked XS modules, opens the program and calls `yyparse` to parse it.

Parsing

The aim of this stage is to take the Perl source, and turn it into an op tree. We'll see what one of those looks like later. Strictly speaking, there's three things going on here.

`yyparse`, the parser, lives in *perly.c*, although you're better off reading the original YACC input in *perly.y*. (Yes, Virginia, there **is** a YACC grammar for Perl!) The job of the parser is to take your code and 'understand' it, splitting it into sentences, deciding which operands go with which operators and so on.

The parser is nobly assisted by the lexer, which chunks up your input into tokens, and decides what type of thing each token is: a variable name, an operator, a bareword, a subroutine, a core function, and so on. The main point of entry to the lexer is `yylex`, and that and its associated routines can be found in *toke.c*. Perl isn't much like other computer languages; it's highly context sensitive at times, it can be tricky to work out what sort of token something is, or where a token ends. As such, there's a lot of interplay between the tokeniser and the parser, which can get pretty frightening if you're not used to it.

As the parser understands a Perl program, it builds up a tree of operations for the interpreter to perform during execution. The routines which construct and link together the various operations are to be found in *op.c*, and will be examined later.

Optimization

Now the parsing stage is complete, and the finished tree represents the operations that the Perl interpreter needs to perform to execute our program. Next, Perl does a dry run over the tree looking for optimisations: constant expressions such as `3 + 4` will be computed now, and the optimizer will also see if any multiple operations can be replaced with a single one. For instance, to fetch the variable `$foo`, instead of grabbing the glob `*foo` and looking at the scalar component, the optimizer fiddles the op tree to use a function which directly looks up the scalar in question. The main optimizer is `peep` in *op.c*, and many ops have their own optimizing functions.

Running

Now we're finally ready to go: we have compiled Perl byte code, and all that's left to do is run it. The actual execution is done by the `runops_standard` function in *run.c*; more specifically, it's done by these three innocent looking lines:

```
while ((PL_op = CALL_FPTR(PL_op->op_ppaddr)(aTHX))) {
    PERL_ASYNC_CHECK();
}
```

You may be more comfortable with the Perl version of that:

```
PERL_ASYNC_CHECK() while $Perl::op = &{$Perl::op->{function}};
```

Well, maybe not. Anyway, each op contains a function pointer, which stipulates the function which will actually carry out the operation. This function will return the next op in the sequence - this allows for things like `if` which choose the next op dynamically at run time. The `PERL_ASYNC_CHECK` makes sure that things like signals interrupt execution if required.

The actual functions called are known as PP code, and they're spread between four files: *pp_hot.c* contains the 'hot' code, which is most often used and highly optimized, *pp_sys.c* contains all the system-specific functions, *pp_ctl.c* contains the functions which implement control structures (`if`, `while` and the like) and *pp.c* contains everything else. These are, if you like, the C code for Perl's built-in functions and operators.

76.1.9 Internal Variable Types

You should by now have had a look at *perlguts*, which tells you about Perl's internal variable types: SVs, HVs, AVs and the rest. If not, do that now.

These variables are used not only to represent Perl-space variables, but also any constants in the code, as well as some structures completely internal to Perl. The symbol table, for instance, is an ordinary Perl hash. Your code is represented by an SV as it's read into the parser; any program files you call are opened via ordinary Perl filehandles, and so on.

The core Devel::Peek module lets us examine SVs from a Perl program. Let's see, for instance, how Perl treats the constant `"hello"`.

```
  % perl -MDevel::Peek -e 'Dump("hello")'
1 SV = PV(0xa041450) at 0xa04ecbc
2   REFCNT = 1
3   FLAGS = (POK,READONLY,pPOK)
4   PV = 0xa0484e0 "hello"\0
5   CUR = 5
6   LEN = 6
```

Reading Devel::Peek output takes a bit of practise, so let's go through it line by line.

Line 1 tells us we're looking at an SV which lives at 0xa04ecbc in memory. SVs themselves are very simple structures, but they contain a pointer to a more complex structure. In this case, it's a PV, a structure which holds a string value, at location 0xa041450. Line 2 is the reference count; there are no other references to this data, so it's 1.

Line 3 are the flags for this SV - it's OK to use it as a PV, it's a read-only SV (because it's a constant) and the data is a PV internally. Next we've got the contents of the string, starting at location 0xa0484e0.

Line 5 gives us the current length of the string - note that this does **not** include the null terminator. Line 6 is not the length of the string, but the length of the currently allocated buffer; as the string grows, Perl automatically extends the available storage via a routine called SvGROW.

You can get at any of these quantities from C very easily; just add Sv to the name of the field shown in the snippet, and you've got a macro which will return the value: SvCUR(sv) returns the current length of the string, SvREFCOUNT(sv) returns the reference count, SvPV(sv, len) returns the string itself with its length, and so on. More macros to manipulate these properties can be found in *perlguts*.

Let's take an example of manipulating a PV, from sv_catpvn, in *sv.c*

```
 1  void
 2  Perl_sv_catpvn(pTHX_ register SV *sv, register const char *ptr, register STRLEN len)
 3  {
 4      STRLEN tlen;
 5      char *junk;

 6      junk = SvPV_force(sv, tlen);
 7      SvGROW(sv, tlen + len + 1);
 8      if (ptr == junk)
 9          ptr = SvPVX(sv);
10      Move(ptr,SvPVX(sv)+tlen,len,char);
11      SvCUR(sv) += len;
12      *SvEND(sv) = '\0';
13      (void)SvPOK_only_UTF8(sv);          /* validate pointer */
14      SvTAINT(sv);
15  }
```

This is a function which adds a string, ptr, of length len onto the end of the PV stored in sv. The first thing we do in line 6 is make sure that the SV **has** a valid PV, by calling the SvPV_force macro to force a PV. As a side effect, tlen gets set to the current value of the PV, and the PV itself is returned to junk.

In line 7, we make sure that the SV will have enough room to accommodate the old string, the new string and the null terminator. If LEN isn't big enough, SvGROW will reallocate space for us.

Now, if junk is the same as the string we're trying to add, we can grab the string directly from the SV; SvPVX is the address of the PV in the SV.

Line 10 does the actual catenation: the Move macro moves a chunk of memory around: we move the string ptr to the end of the PV - that's the start of the PV plus its current length. We're moving len bytes of type char. After doing so, we need to tell Perl we've extended the string, by altering CUR to reflect the new length. SvEND is a macro which gives us the end of the string, so that needs to be a "\0".

Line 13 manipulates the flags; since we've changed the PV, any IV or NV values will no longer be valid: if we have `$a=10; $a.="6";` we don't want to use the old IV of 10. SvPOK_only_utf8 is a special UTF-8-aware version of SvPOK_only, a macro which turns off the IOK and NOK flags and turns on POK. The final SvTAINT is a macro which launders tainted data if taint mode is turned on.

AVs and HVs are more complicated, but SVs are by far the most common variable type being thrown around. Having seen something of how we manipulate these, let's go on and look at how the op tree is constructed.

76.1.10 Op Trees

First, what is the op tree, anyway? The op tree is the parsed representation of your program, as we saw in our section on parsing, and it's the sequence of operations that Perl goes through to execute your program, as we saw in Running.

An op is a fundamental operation that Perl can perform: all the built-in functions and operators are ops, and there are a series of ops which deal with concepts the interpreter needs internally - entering and leaving a block, ending a statement, fetching a variable, and so on.

The op tree is connected in two ways: you can imagine that there are two "routes" through it, two orders in which you can traverse the tree. First, parse order reflects how the parser understood the code, and secondly, execution order tells perl what order to perform the operations in.

The easiest way to examine the op tree is to stop Perl after it has finished parsing, and get it to dump out the tree. This is exactly what the compiler backends B::Terse, B::Concise and B::Debug do.

Let's have a look at how Perl sees `$a = $b + $c`:

```
 % perl -MO=Terse -e '$a=$b+$c'
 1  LISTOP (0x8179888) leave
 2      OP (0x81798b0) enter
 3      COP (0x8179850) nextstate
 4      BINOP (0x8179828) sassign
 5          BINOP (0x8179800) add [1]
 6              UNOP (0x81796e0) null [15]
 7                  SVOP (0x80fafe0) gvsv  GV (0x80fa4cc) *b
 8              UNOP (0x81797e0) null [15]
 9                  SVOP (0x8179700) gvsv  GV (0x80efeb0) *c
10          UNOP (0x816b4f0) null [15]
11              SVOP (0x816dcf0) gvsv  GV (0x80fa460) *a
```

Let's start in the middle, at line 4. This is a BINOP, a binary operator, which is at location `0x8179828`. The specific operator in question is `sassign` - scalar assignment - and you can find the code which implements it in the function `pp_sassign` in *pp_hot.c*. As a binary operator, it has two children: the add operator, providing the result of `$b+$c`, is uppermost on line 5, and the left hand side is on line 10.

Line 10 is the null op: this does exactly nothing. What is that doing there? If you see the null op, it's a sign that something has been optimized away after parsing. As we mentioned in Optimization, the optimization stage sometimes converts two operations into one, for example when fetching a scalar variable. When this happens, instead of rewriting the op tree and cleaning up the dangling pointers, it's easier just to replace the redundant operation with the null op. Originally, the tree would have looked like this:

```
10          SVOP (0x816b4f0) rv2sv [15]
11              SVOP (0x816dcf0) gv  GV (0x80fa460) *a
```

That is, fetch the `a` entry from the main symbol table, and then look at the scalar component of it: `gvsv` (`pp_gvsv` into *pp_hot.c*) happens to do both these things.

The right hand side, starting at line 5 is similar to what we've just seen: we have the `add` op (`pp_add` also in *pp_hot.c*) add together two `gvsv`s.

Now, what's this about?

```
 1  LISTOP (0x8179888) leave
 2      OP (0x81798b0) enter
 3      COP (0x8179850) nextstate
```

`enter` and `leave` are scoping ops, and their job is to perform any housekeeping every time you enter and leave a block: lexical variables are tidied up, unreferenced variables are destroyed, and so on. Every program will have those first three lines: `leave` is a list, and its children are all the statements in the block. Statements are delimited by `nextstate`, so a block is a collection of `nextstate` ops, with the ops to be performed for each statement being the children of `nextstate`. `enter` is a single op which functions as a marker.

That's how Perl parsed the program, from top to bottom:

```
     Program
        |
    Statement
        |
        =
       / \
      /   \
     $a    +
          / \
        $b   $c
```

However, it's impossible to **perform** the operations in this order: you have to find the values of `$b` and `$c` before you add them together, for instance. So, the other thread that runs through the op tree is the execution order: each op has a field `op_next` which points to the next op to be run, so following these pointers tells us how perl executes the code. We can traverse the tree in this order using the `exec` option to `B::Terse`:

```
% perl -MO=Terse,exec -e '$a=$b+$c'
1  OP (0x8179928) enter
2  COP (0x81798c8) nextstate
3  SVOP (0x81796c8) gvsv  GV (0x80fa4d4) *b
4  SVOP (0x8179798) gvsv  GV (0x80efeb0) *c
5  BINOP (0x8179878) add [1]
6  SVOP (0x816dd38) gvsv  GV (0x80fa468) *a
7  BINOP (0x81798a0) sassign
8  LISTOP (0x8179900) leave
```

This probably makes more sense for a human: enter a block, start a statement. Get the values of `$b` and `$c`, and add them together. Find `$a`, and assign one to the other. Then leave.

The way Perl builds up these op trees in the parsing process can be unravelled by examining *perly.y*, the YACC grammar. Let's take the piece we need to construct the tree for `$a = $b + $c`

```
1 term    :   term ASSIGNOP term
2                { $$ = newASSIGNOP(OPf_STACKED, $1, $2, $3); }
3         |   term ADDOP term
4                { $$ = newBINOP($2, 0, scalar($1), scalar($3)); }
```

If you're not used to reading BNF grammars, this is how it works: You're fed certain things by the tokeniser, which generally end up in upper case. Here, `ADDOP`, is provided when the tokeniser sees + in your code. `ASSIGNOP` is provided when = is used for assigning. These are 'terminal symbols', because you can't get any simpler than them.

The grammar, lines one and three of the snippet above, tells you how to build up more complex forms. These complex forms, 'non-terminal symbols' are generally placed in lower case. `term` here is a non-terminal symbol, representing a single expression.

The grammar gives you the following rule: you can make the thing on the left of the colon if you see all the things on the right in sequence. This is called a "reduction", and the aim of parsing is to completely reduce the input. There are several different ways you can perform a reduction, separated by vertical bars: so, `term` followed by = followed by `term` makes a `term`, and `term` followed by + followed by `term` can also make a `term`.

So, if you see two terms with an = or +, between them, you can turn them into a single expression. When you do this, you execute the code in the block on the next line: if you see =, you'll do the code in line 2. If you see +, you'll do the code in line 4. It's this code which contributes to the op tree.

```
|   term ADDOP term
{ $$ = newBINOP($2, 0, scalar($1), scalar($3)); }
```

What this does is creates a new binary op, and feeds it a number of variables. The variables refer to the tokens: `$1` is the first token in the input, `$2` the second, and so on - think regular expression backreferences. `$$` is the op returned from this reduction. So, we call `newBINOP` to create a new binary operator. The first parameter to `newBINOP`, a function in *op.c*, is the op type. It's an addition operator, so we want the type to be `ADDOP`. We could specify this directly, but it's right there as the second token in the input, so we use `$2`. The second parameter is the op's flags: 0 means 'nothing special'. Then the things to add: the left and right hand side of our expression, in scalar context.

76.1.11 Stacks

When perl executes something like `addop`, how does it pass on its results to the next op? The answer is, through the use of stacks. Perl has a number of stacks to store things it's currently working on, and we'll look at the three most important ones here.

Argument stack

Arguments are passed to PP code and returned from PP code using the argument stack, `ST`. The typical way to handle arguments is to pop them off the stack, deal with them how you wish, and then push the result back onto the stack. This is how, for instance, the cosine operator works:

```
  NV value;
  value = POPn;
  value = Perl_cos(value);
  XPUSHn(value);
```

We'll see a more tricky example of this when we consider Perl's macros below. `POPn` gives you the NV (floating point value) of the top SV on the stack: the `$x` in `cos($x)`. Then we compute the cosine, and push the result back as an NV. The `X` in `XPUSHn` means that the stack should be extended if necessary - it can't be necessary here, because we know there's room for one more item on the stack, since we've just removed one! The `XPUSH*` macros at least guarantee safety.

Alternatively, you can fiddle with the stack directly: `SP` gives you the first element in your portion of the stack, and `TOP*` gives you the top SV/IV/NV/etc. on the stack. So, for instance, to do unary negation of an integer:

```
SETi(-TOPi);
```

Just set the integer value of the top stack entry to its negation.

Argument stack manipulation in the core is exactly the same as it is in XSUBs - see *perlxstut*, *perlxs* and *perlguts* for a longer description of the macros used in stack manipulation.

Mark stack

I say 'your portion of the stack' above because PP code doesn't necessarily get the whole stack to itself: if your function calls another function, you'll only want to expose the arguments aimed for the called function, and not (necessarily) let it get at your own data. The way we do this is to have a 'virtual' bottom-of-stack, exposed to each function. The mark stack keeps bookmarks to locations in the argument stack usable by each function. For instance, when dealing with a tied variable, (internally, something with 'P' magic) Perl has to call methods for accesses to the tied variables. However, we need to separate the arguments exposed to the method to the argument exposed to the original function - the store or fetch or whatever it may be. Here's how the tied `push` is implemented; see `av_push` in *av.c*:

```
1  PUSHMARK(SP);
2  EXTEND(SP,2);
3  PUSHs(SvTIED_obj((SV*)av, mg));
4  PUSHs(val);
5  PUTBACK;
6  ENTER;
7  call_method("PUSH", G_SCALAR|G_DISCARD);
8  LEAVE;
9  POPSTACK;
```

The lines which concern the mark stack are the first, fifth and last lines: they save away, restore and remove the current position of the argument stack.

Let's examine the whole implementation, for practice:

```
1  PUSHMARK(SP);
```

Push the current state of the stack pointer onto the mark stack. This is so that when we've finished adding items to the argument stack, Perl knows how many things we've added recently.

```
EXTEND(SP,2);
PUSHs(SvTIED_obj((SV*)av, mg));
PUSHs(val);
```

We're going to add two more items onto the argument stack: when you have a tied array, the `PUSH` subroutine receives the object and the value to be pushed, and that's exactly what we have here - the tied object, retrieved with `SvTIED_obj`, and the value, the SV `val`.

```
PUTBACK;
```

Next we tell Perl to make the change to the global stack pointer: `dSP` only gave us a local copy, not a reference to the global.

```
ENTER;
call_method("PUSH", G_SCALAR|G_DISCARD);
LEAVE;
```

`ENTER` and `LEAVE` localise a block of code - they make sure that all variables are tidied up, everything that has been localised gets its previous value returned, and so on. Think of them as the `{` and `}` of a Perl block.

To actually do the magic method call, we have to call a subroutine in Perl space: `call_method` takes care of that, and it's described in *perlcall*. We call the `PUSH` method in scalar context, and we're going to discard its return value.

```
POPSTACK;
```

Finally, we remove the value we placed on the mark stack, since we don't need it any more.

Save stack

C doesn't have a concept of local scope, so perl provides one. We've seen that `ENTER` and `LEAVE` are used as scoping braces; the save stack implements the C equivalent of, for example:

```
{
    local $foo = 42;
    ...
}
```

See Localising Changes in *perlguts* for how to use the save stack.

76.1.12 Millions of Macros

One thing you'll notice about the Perl source is that it's full of macros. Some have called the pervasive use of macros the hardest thing to understand, others find it adds to clarity. Let's take an example, the code which implements the addition operator:

```
PP(pp_add)
{
    dSP; dATARGET; tryAMAGICbin(add,opASSIGN);
    {
      dPOPTOPnnrl_ul;
      SETn( left + right );
      RETURN;
    }
}
```

Every line here (apart from the braces, of course) contains a macro. The first line sets up the function declaration as Perl expects for PP code; line 3 sets up variable declarations for the argument stack and the target, the return value of the operation. Finally, it tries to see if the addition operation is overloaded; if so, the appropriate subroutine is called.

Line 5 is another variable declaration - all variable declarations start with `d` - which pops from the top of the argument stack two NVs (hence `nn`) and puts them into the variables `right` and `left`, hence the `rl`. These are the two operands to the addition operator. Next, we call `SETn` to set the NV of the return value to the result of adding the two values. This done, we return - the `RETURN` macro makes sure that our return value is properly handled, and we pass the next operator to run back to the main run loop.

Most of these macros are explained in *perlapi*, and some of the more important ones are explained in *perlxs* as well. Pay special attention to Background and PERL_IMPLICIT_CONTEXT in *perlguts* for information on the `[pad]THX_?` macros.

76.1.13 The .i Targets

You can expand the macros in a *foo.c* file by saying

```
make foo.i
```

which will expand the macros using cpp. Don't be scared by the results.

76.1.14 Poking at Perl

To really poke around with Perl, you'll probably want to build Perl for debugging, like this:

```
./Configure -d -D optimize=-g
make
```

`-g` is a flag to the C compiler to have it produce debugging information which will allow us to step through a running program. *Configure* will also turn on the `DEBUGGING` compilation symbol which enables all the internal debugging code in Perl. There are a whole bunch of things you can debug with this: *perlrun* lists them all, and the best way to find out about them is to play about with them. The most useful options are probably

```
l  Context (loop) stack processing
t  Trace execution
o  Method and overloading resolution
c  String/numeric conversions
```

Some of the functionality of the debugging code can be achieved using XS modules.

```
-Dr => use re 'debug'
-Dx => use O 'Debug'
```

76.1.15 Using a source-level debugger

If the debugging output of `-D` doesn't help you, it's time to step through perl's execution with a source-level debugger.

- We'll use `gdb` for our examples here; the principles will apply to any debugger, but check the manual of the one you're using.

To fire up the debugger, type

```
gdb ./perl
```

You'll want to do that in your Perl source tree so the debugger can read the source code. You should see the copyright message, followed by the prompt.

```
    (gdb)
```

`help` will get you into the documentation, but here are the most useful commands:

run [args]

Run the program with the given arguments.

break function_name

break source.c:xxx

Tells the debugger that we'll want to pause execution when we reach either the named function (but see Internal Functions in *perlguts*!) or the given line in the named source file.

step

Steps through the program a line at a time.

next

Steps through the program a line at a time, without descending into functions.

continue

Run until the next breakpoint.

finish

Run until the end of the current function, then stop again.

'enter'

Just pressing Enter will do the most recent operation again - it's a blessing when stepping through miles of source code.

print

Execute the given C code and print its results. **WARNING**: Perl makes heavy use of macros, and *gdb* does not necessarily support macros (see later §76.1.16). You'll have to substitute them yourself, or to invoke cpp on the source code files (see §76.1.13) So, for instance, you can't say

```
    print SvPV_nolen(sv)
```

but you have to say

```
    print Perl_sv_2pv_nolen(sv)
```

You may find it helpful to have a "macro dictionary", which you can produce by saying `cpp -dM perl.c | sort`. Even then, *cpp* won't recursively apply those macros for you.

76.1.16 gdb macro support

Recent versions of *gdb* have fairly good macro support, but in order to use it you'll need to compile perl with macro definitions included in the debugging information. Using *gcc* version 3.1, this means configuring with `-Doptimize=-g3`. Other compilers might use a different switch (if they support debugging macros at all).

76.1.17 Dumping Perl Data Structures

One way to get around this macro hell is to use the dumping functions in *dump.c*; these work a little like an internal Devel::Peek, but they also cover OPs and other structures that you can't get at from Perl. Let's take an example. We'll use the `$a = $b + $c` we used before, but give it a bit of context: `$b = "6XXXX"; $c = 2.3;`. Where's a good place to stop and poke around?

What about `pp_add`, the function we examined earlier to implement the + operator:

```
    (gdb) break Perl_pp_add
    Breakpoint 1 at 0x46249f: file pp_hot.c, line 309.
```

Notice we use `Perl_pp_add` and not `pp_add` - see Internal Functions in *perlguts*. With the breakpoint in place, we can run our program:

```
    (gdb) run -e '$b = "6XXXX"; $c = 2.3; $a = $b + $c'
```

Lots of junk will go past as gdb reads in the relevant source files and libraries, and then:

```
    Breakpoint 1, Perl_pp_add () at pp_hot.c:309
    309         dSP; dATARGET; tryAMAGICbin(add,opASSIGN);
    (gdb) step
    311           dPOPTOPnnrl_ul;
    (gdb)
```

We looked at this bit of code before, and we said that `dPOPTOPnnrl_ul` arranges for two `NV`s to be placed into `left` and `right` - let's slightly expand it:

```
    #define dPOPTOPnnrl_ul  NV right = POPn; \
                            SV *leftsv = TOPs; \
                            NV left = USE_LEFT(leftsv) ? SvNV(leftsv) : 0.0
```

`POPn` takes the SV from the top of the stack and obtains its NV either directly (if `SvNOK` is set) or by calling the `sv_2nv` function. `TOPs` takes the next SV from the top of the stack - yes, `POPn` uses `TOPs` - but doesn't remove it. We then use `SvNV` to get the NV from `leftsv` in the same way as before - yes, `POPn` uses `SvNV`.

Since we don't have an NV for `$b`, we'll have to use `sv_2nv` to convert it. If we step again, we'll find ourselves there:

```
    Perl_sv_2nv (sv=0xa0675d0) at sv.c:1669
    1669        if (!sv)
    (gdb)
```

We can now use `Perl_sv_dump` to investigate the SV:

```
    SV = PV(0xa057cc0) at 0xa0675d0
    REFCNT = 1
    FLAGS = (POK,pPOK)
    PV = 0xa06a510 "6XXXX"\0
    CUR = 5
    LEN = 6
    $1 = void
```

We know we're going to get `6` from this, so let's finish the subroutine:

```
    (gdb) finish
    Run till exit from #0  Perl_sv_2nv (sv=0xa0675d0) at sv.c:1671
    0x462669 in Perl_pp_add () at pp_hot.c:311
    311           dPOPTOPnnrl_ul;
```

We can also dump out this op: the current op is always stored in `PL_op`, and we can dump it with `Perl_op_dump`. This'll give us similar output to B::Debug.

```
{
13  TYPE = add  ===> 14
    TARG = 1
    FLAGS = (SCALAR,KIDS)
    {
        TYPE = null  ===> (12)
          (was rv2sv)
        FLAGS = (SCALAR,KIDS)
        {
11          TYPE = gvsv  ===> 12
            FLAGS = (SCALAR)
            GV = main::b
        }
    }
```

# finish this later #

76.1.18 Patching

All right, we've now had a look at how to navigate the Perl sources and some things you'll need to know when fiddling with them. Let's now get on and create a simple patch. Here's something Larry suggested: if a `U` is the first active format during a `pack`, (for example, `pack "U3C8", @stuff`) then the resulting string should be treated as UTF-8 encoded.

How do we prepare to fix this up? First we locate the code in question - the `pack` happens at runtime, so it's going to be in one of the *pp* files. Sure enough, `pp_pack` is in *pp.c*. Since we're going to be altering this file, let's copy it to *pp.c˜*.

[Well, it was in *pp.c* when this tutorial was written. It has now been split off with `pp_unpack` to its own file, *pp_pack.c*]

Now let's look over `pp_pack`: we take a pattern into `pat`, and then loop over the pattern, taking each format character in turn into `datum_type`. Then for each possible format character, we swallow up the other arguments in the pattern (a field width, an asterisk, and so on) and convert the next chunk input into the specified format, adding it onto the output SV `cat`.

How do we know if the `U` is the first format in the `pat`? Well, if we have a pointer to the start of `pat` then, if we see a `U` we can test whether we're still at the start of the string. So, here's where `pat` is set up:

```
STRLEN fromlen;
register char *pat = SvPVx(*++MARK, fromlen);
register char *patend = pat + fromlen;
register I32 len;
I32 datumtype;
SV *fromstr;
```

We'll have another string pointer in there:

```
   STRLEN fromlen;
   register char *pat = SvPVx(*++MARK, fromlen);
   register char *patend = pat + fromlen;
 + char *patcopy;
   register I32 len;
   I32 datumtype;
   SV *fromstr;
```

And just before we start the loop, we'll set `patcopy` to be the start of `pat`:

```
    items = SP - MARK;
    MARK++;
    sv_setpvn(cat, "", 0);
 +  patcopy = pat;
    while (pat < patend) {
```

Now if we see a U which was at the start of the string, we turn on the UTF8 flag for the output SV, cat:

```
 +  if (datumtype == 'U' && pat==patcopy+1)
 +      SvUTF8_on(cat);
    if (datumtype == '#') {
        while (pat < patend && *pat != '\n')
            pat++;
```

Remember that it has to be patcopy+1 because the first character of the string is the U which has been swallowed into datumtype!

Oops, we forgot one thing: what if there are spaces at the start of the pattern? pack(" U*", @stuff) will have U as the first active character, even though it's not the first thing in the pattern. In this case, we have to advance patcopy along with pat when we see spaces:

```
    if (isSPACE(datumtype))
        continue;
```

needs to become

```
    if (isSPACE(datumtype)) {
        patcopy++;
        continue;
    }
```

OK. That's the C part done. Now we must do two additional things before this patch is ready to go: we've changed the behaviour of Perl, and so we must document that change. We must also provide some more regression tests to make sure our patch works and doesn't create a bug somewhere else along the line.

The regression tests for each operator live in *t/op/*, and so we make a copy of *t/op/pack.t* to *t/op/pack.t~*. Now we can add our tests to the end. First, we'll test that the U does indeed create Unicode strings.

t/op/pack.t has a sensible ok() function, but if it didn't we could use the one from t/test.pl.

```
 require './test.pl';
 plan( tests => 159 );
```

so instead of this:

```
 print 'not ' unless "1.20.300.4000" eq sprintf "%vd", pack("U*",1,20,300,4000);
 print "ok $test\n"; $test++;
```

we can write the more sensible (see *Test::More* for a full explanation of is() and other testing functions).

```
 is( "1.20.300.4000", sprintf "%vd", pack("U*",1,20,300,4000),
                                       "U* produces unicode" );
```

Now we'll test that we got that space-at-the-beginning business right:

```
 is( "1.20.300.4000", sprintf "%vd", pack("  U*",1,20,300,4000),
                                       "  with spaces at the beginning" );
```

And finally we'll test that we don't make Unicode strings if U is **not** the first active format:

```
isnt( v1.20.300.4000, sprintf "%vd", pack("C0U*",1,20,300,4000),
                                      "U* not first isn't unicode" );
```

Mustn't forget to change the number of tests which appears at the top, or else the automated tester will get confused. This will either look like this:

```
print "1..156\n";
```

or this:

```
plan( tests => 156 );
```

We now compile up Perl, and run it through the test suite. Our new tests pass, hooray!

Finally, the documentation. The job is never done until the paperwork is over, so let's describe the change we've just made. The relevant place is *pod/perlfunc.pod*; again, we make a copy, and then we'll insert this text in the description of pack:

```
=item *

If the pattern begins with a C<U>, the resulting string will be treated
as UTF-8-encoded Unicode. You can force UTF-8 encoding on in a string
with an initial C<U0>, and the bytes that follow will be interpreted as
Unicode characters. If you don't want this to happen, you can begin your
pattern with C<C0> (or anything else) to force Perl not to UTF-8 encode your
string, and then follow this with a C<U*> somewhere in your pattern.
```

All done. Now let's create the patch. *Porting/patching.pod* tells us that if we're making major changes, we should copy the entire directory to somewhere safe before we begin fiddling, and then do

```
    diff -ruN old new > patch
```

However, we know which files we've changed, and we can simply do this:

```
    diff -u pp.c~             pp.c             >  patch
    diff -u t/op/pack.t~      t/op/pack.t      >> patch
    diff -u pod/perlfunc.pod~ pod/perlfunc.pod >> patch
```

We end up with a patch looking a little like this:

```
    --- pp.c~       Fri Jun 02 04:34:10 2000
    +++ pp.c        Fri Jun 16 11:37:25 2000

And finally, we submit it, with our rationale, to perl5-porters. Job done!

76.1.19 Patching a core module

This works just like patching anything else, with an extra consideration. Many core modules also live on CPAN. If this is so, patch the CPAN version instead of the core and send the patch off to the module maintainer (with a copy to p5p). This will help the module maintainer keep the CPAN version in sync with the core version without constantly scanning p5p.

76.1.20 Adding a new function to the core

If, as part of a patch to fix a bug, or just because you have an especially good idea, you decide to add a new function to the core, discuss your ideas on p5p well before you start work. It may be that someone else has already attempted to do what you are considering and can give lots of good advice or even provide you with bits of code that they already started (but never finished).

You have to follow all of the advice given above for patching. It is extremely important to test any addition thoroughly and add new tests to explore all boundary conditions that your new function is expected to handle. If your new function is used only by one module (e.g. toke), then it should probably be named S_your_function (for static); on the other hand, if you expect it to accessible from other functions in Perl, you should name it Perl_your_function. See Internal Functions in *perlguts* for more details.

The location of any new code is also an important consideration. Don't just create a new top level .c file and put your code there; you would have to make changes to Configure (so the Makefile is created properly), as well as possibly lots of include files. This is strictly pumpking business.

It is better to add your function to one of the existing top level source code files, but your choice is complicated by the nature of the Perl distribution. Only the files that are marked as compiled static are located in the perl executable. Everything else is located in the shared library (or DLL if you are running under WIN32). So, for example, if a function was only used by functions located in toke.c, then your code can go in toke.c. If, however, you want to call the function from universal.c, then you should put your code in another location, for example util.c.

In addition to writing your c-code, you will need to create an appropriate entry in embed.pl describing your function, then run 'make regen_headers' to create the entries in the numerous header files that perl needs to compile correctly. See Internal Functions in *perlguts* for information on the various options that you can set in embed.pl. You will forget to do this a few (or many) times and you will get warnings during the compilation phase. Make sure that you mention this when you post your patch to P5P; the pumpking needs to know this.

When you write your new code, please be conscious of existing code conventions used in the perl source files. See *perlstyle* for details. Although most of the guidelines discussed seem to focus on Perl code, rather than c, they all apply (except when they don't ;). See also *Porting/patching.pod* file in the Perl source distribution for lots of details about both formatting and submitting patches of your changes.

Lastly, TEST TEST TEST TEST TEST any code before posting to p5p. Test on as many platforms as you can find. Test as many perl Configure options as you can (e.g. MULTIPLICITY). If you have profiling or memory tools, see EXTERNAL TOOLS FOR DEBUGGING PERL below for how to use them to further test your code. Remember that most of the people on P5P are doing this on their own time and don't have the time to debug your code.

76.1.21 Writing a test

Every module and built-in function has an associated test file (or should...). If you add or change functionality, you have to write a test. If you fix a bug, you have to write a test so that bug never comes back. If you alter the docs, it would be nice to test what the new documentation says.

In short, if you submit a patch you probably also have to patch the tests.

For modules, the test file is right next to the module itself. *lib/strict.t* tests *lib/strict.pm*. This is a recent innovation, so there are some snags (and it would be wonderful for you to brush them out), but it basically works that way. Everything else lives in *t/*.

t/base/

Testing of the absolute basic functionality of Perl. Things like `if`, basic file reads and writes, simple regexes, etc. These are run first in the test suite and if any of them fail, something is *really* broken.

t/cmd/

These test the basic control structures, `if/else`, `while`, subroutines, etc.

t/comp/

Tests basic issues of how Perl parses and compiles itself.

t/io/

Tests for built-in IO functions, including command line arguments.

t/lib/

The old home for the module tests, you shouldn't put anything new in here. There are still some bits and pieces hanging around in here that need to be moved. Perhaps you could move them? Thanks!

t/op/

Tests for perl's built in functions that don't fit into any of the other directories.

t/pod/

Tests for POD directives. There are still some tests for the Pod modules hanging around in here that need to be moved out into *lib/*.

t/run/

Testing features of how perl actually runs, including exit codes and handling of PERL* environment variables.

t/uni/

Tests for the core support of Unicode.

t/win32/

Windows-specific tests.

t/x2p

A test suite for the s2p converter.

The core uses the same testing style as the rest of Perl, a simple "ok/not ok" run through Test::Harness, but there are a few special considerations.

There are three ways to write a test in the core. Test::More, t/test.pl and ad hoc `print $test ? "ok 42\n" : "not ok 42\n"`. The decision of which to use depends on what part of the test suite you're working on. This is a measure to prevent a high-level failure (such as Config.pm breaking) from causing basic functionality tests to fail.

t/base t/comp

Since we don't know if require works, or even subroutines, use ad hoc tests for these two. Step carefully to avoid using the feature being tested.

t/cmd t/run t/io t/op

Now that basic require() and subroutines are tested, you can use the t/test.pl library which emulates the important features of Test::More while using a minimum of core features.

You can also conditionally use certain libraries like Config, but be sure to skip the test gracefully if it's not there.

t/lib ext lib

Now that the core of Perl is tested, Test::More can be used. You can also use the full suite of core modules in the tests.

When you say "make test" Perl uses the *t/TEST* program to run the test suite. All tests are run from the *t/* directory, **not** the directory which contains the test. This causes some problems with the tests in *lib/*, so here's some opportunity for some patching.

You must be triply conscious of cross-platform concerns. This usually boils down to using File::Spec and avoiding things like `fork()` and `system()` unless absolutely necessary.

76.1.22 Special Make Test Targets

There are various special make targets that can be used to test Perl slightly differently than the standard "test" target. Not all them are expected to give a 100% success rate. Many of them have several aliases.

coretest

Run *perl* on all core tests (*t/** and *lib/[a-z]** pragma tests).

test.deparse

Run all the tests through B::Deparse. Not all tests will succeed.

test.taintwarn

Run all tests with the **-t** command-line switch. Not all tests are expected to succeed (until they're specifically fixed, of course).

minitest

Run *miniperl* on *t/base*, *t/comp*, *t/cmd*, *t/run*, *t/io*, *t/op*, and *t/uni* tests.

test.valgrind check.valgrind utest.valgrind ucheck.valgrind

(Only in Linux) Run all the tests using the memory leak + naughty memory access tool "valgrind". The log files will be named *testname.valgrind*.

test.third check.third utest.third ucheck.third

(Only in Tru64) Run all the tests using the memory leak + naughty memory access tool "Third Degree". The log files will be named *perl3.log.testname*.

test.torture torturetest

Run all the usual tests and some extra tests. As of Perl 5.8.0 the only extra tests are Abigail's JAPHs, *t/japh/abigail.t*.

You can also run the torture test with *t/harness* by giving `-torture` argument to *t/harness*.

utest ucheck test.utf8 check.utf8

Run all the tests with -Mutf8. Not all tests will succeed.

test_harness

Run the test suite with the *t/harness* controlling program, instead of *t/TEST*. *t/harness* is more sophisticated, and uses the *Test::Harness* module, thus using this test target supposes that perl mostly works. The main advantage for our purposes is that it prints a detailed summary of failed tests at the end. Also, unlike *t/TEST*, it doesn't redirect stderr to stdout.

76.1.23 Running tests by hand

You can run part of the test suite by hand by using one the following commands from the *t/* directory :

```
./perl -I../lib TEST list-of-.t-files
```

or

```
./perl -I../lib harness list-of-.t-files
```

(if you don't specify test scripts, the whole test suite will be run.)

You can run an individual test by a command similar to

```
./perl -I../lib patho/to/foo.t
```

except that the harnesses set up some environment variables that may affect the execution of the test :

PERL_CORE=1

indicates that we're running this test part of the perl core test suite. This is useful for modules that have a dual life on CPAN.

PERL_DESTRUCT_LEVEL=2

is set to 2 if it isn't set already (see PERL_DESTRUCT_LEVEL)

PERL

(used only by *t/TEST*) if set, overrides the path to the perl executable that should be used to run the tests (the default being *./perl*).

PERL_SKIP_TTY_TEST

if set, tells to skip the tests that need a terminal. It's actually set automatically by the Makefile, but can also be forced artificially by running 'make test_notty'.

76.2 EXTERNAL TOOLS FOR DEBUGGING PERL

Sometimes it helps to use external tools while debugging and testing Perl. This section tries to guide you through using some common testing and debugging tools with Perl. This is meant as a guide to interfacing these tools with Perl, not as any kind of guide to the use of the tools themselves.

NOTE 1: Running under memory debuggers such as Purify, valgrind, or Third Degree greatly slows down the execution: seconds become minutes, minutes become hours. For example as of Perl 5.8.1, the ext/Encode/t/Unicode.t takes extraordinarily long to complete under e.g. Purify, Third Degree, and valgrind. Under valgrind it takes more than six hours, even on a snappy computer– the said test must be doing something that is quite unfriendly for memory debuggers. If you don't feel like waiting, that you can simply kill away the perl process.

NOTE 2: To minimize the number of memory leak false alarms (see PERL_DESTRUCT_LEVEL for more information), you have to have environment variable PERL_DESTRUCT_LEVEL set to 2. The *TEST* and harness scripts do that automatically. But if you are running some of the tests manually– for csh-like shells:

```
setenv PERL_DESTRUCT_LEVEL 2
```

and for Bourne-type shells:

```
PERL_DESTRUCT_LEVEL=2
export PERL_DESTRUCT_LEVEL
```

or in UNIXy environments you can also use the `env` command:

```
env PERL_DESTRUCT_LEVEL=2 valgrind ./perl -Ilib ...
```

NOTE 3: There are known memory leaks when there are compile-time errors within eval or require, seeing `S_doeval` in the call stack is a good sign of these. Fixing these leaks is non-trivial, unfortunately, but they must be fixed eventually.

76.2.1 Rational Software's Purify

Purify is a commercial tool that is helpful in identifying memory overruns, wild pointers, memory leaks and other such badness. Perl must be compiled in a specific way for optimal testing with Purify. Purify is available under Windows NT, Solaris, HP-UX, SGI, and Siemens Unix.

76.2.2 Purify on Unix

On Unix, Purify creates a new Perl binary. To get the most benefit out of Purify, you should create the perl to Purify using:

```
sh Configure -Accflags=-DPURIFY -Doptimize='-g' \
 -Uusemymalloc -Dusemultiplicity
```

where these arguments mean:

-Accflags=-DPURIFY

Disables Perl's arena memory allocation functions, as well as forcing use of memory allocation functions derived from the system malloc.

-Doptimize='-g'

Adds debugging information so that you see the exact source statements where the problem occurs. Without this flag, all you will see is the source filename of where the error occurred.

-Uusemymalloc

Disable Perl's malloc so that Purify can more closely monitor allocations and leaks. Using Perl's malloc will make Purify report most leaks in the "potential" leaks category.

-Dusemultiplicity

Enabling the multiplicity option allows perl to clean up thoroughly when the interpreter shuts down, which reduces the number of bogus leak reports from Purify.

Once you've compiled a perl suitable for Purify'ing, then you can just:

```
make pureperl
```

which creates a binary named 'pureperl' that has been Purify'ed. This binary is used in place of the standard 'perl' binary when you want to debug Perl memory problems.

As an example, to show any memory leaks produced during the standard Perl testset you would create and run the Purify'ed perl as:

```
make pureperl
cd t
../pureperl -I../lib harness
```

which would run Perl on test.pl and report any memory problems.

Purify outputs messages in "Viewer" windows by default. If you don't have a windowing environment or if you simply want the Purify output to unobtrusively go to a log file instead of to the interactive window, use these following options to output to the log file "perl.log":

```
setenv PURIFYOPTIONS "-chain-length=25 -windows=no \
 -log-file=perl.log -append-logfile=yes"
```

If you plan to use the "Viewer" windows, then you only need this option:

```
setenv PURIFYOPTIONS "-chain-length=25"
```

In Bourne-type shells:

```
PURIFYOPTIONS="..."
export PURIFYOPTIONS
```

or if you have the "env" utility:

```
env PURIFYOPTIONS="..." ../pureperl ...
```

76.2.3 Purify on NT

Purify on Windows NT instruments the Perl binary 'perl.exe' on the fly. There are several options in the makefile you should change to get the most use out of Purify:

DEFINES

You should add -DPURIFY to the DEFINES line so the DEFINES line looks something like:

```
DEFINES = -DWIN32 -D_CONSOLE -DNO_STRICT $(CRYPT_FLAG) -DPURIFY=1
```

to disable Perl's arena memory allocation functions, as well as to force use of memory allocation functions derived from the system malloc.

USE_MULTI = define

Enabling the multiplicity option allows perl to clean up thoroughly when the interpreter shuts down, which reduces the number of bogus leak reports from Purify.

#PERL_MALLOC = define

Disable Perl's malloc so that Purify can more closely monitor allocations and leaks. Using Perl's malloc will make Purify report most leaks in the "potential" leaks category.

CFG = Debug

Adds debugging information so that you see the exact source statements where the problem occurs. Without this flag, all you will see is the source filename of where the error occurred.

As an example, to show any memory leaks produced during the standard Perl testset you would create and run Purify as:

```
cd win32
make
cd ../t
purify ../perl -I../lib harness
```

which would instrument Perl in memory, run Perl on test.pl, then finally report any memory problems.

76.2.4 valgrind

The excellent valgrind tool can be used to find out both memory leaks and illegal memory accesses. As of August 2003 it unfortunately works only on x86 (ELF) Linux. The special "test.valgrind" target can be used to run the tests under valgrind. Found errors and memory leaks are logged in files named *test.valgrind*.

As system libraries (most notably glibc) are also triggering errors, valgrind allows to suppress such errors using suppression files. The default suppression file that comes with valgrind already catches a lot of them. Some additional suppressions are defined in *t/perl.supp*.

To get valgrind and for more information see

```
http://developer.kde.org/~sewardj/
```

76.2.5 Compaq's/Digital's/HP's Third Degree

Third Degree is a tool for memory leak detection and memory access checks. It is one of the many tools in the ATOM toolkit. The toolkit is only available on Tru64 (formerly known as Digital UNIX formerly known as DEC OSF/1).

When building Perl, you must first run Configure with -Doptimize=-g and -Uusemymalloc flags, after that you can use the make targets "perl.third" and "test.third". (What is required is that Perl must be compiled using the `-g` flag, you may need to re-Configure.)

The short story is that with "atom" you can instrument the Perl executable to create a new executable called *perl.third*. When the instrumented executable is run, it creates a log of dubious memory traffic in file called *perl.3log*. See the manual pages of atom and third for more information. The most extensive Third Degree documentation is available in the Compaq "Tru64 UNIX Programmer's Guide", chapter "Debugging Programs with Third Degree".

The "test.third" leaves a lot of files named *foo_bar.3log* in the t/ subdirectory. There is a problem with these files: Third Degree is so effective that it finds problems also in the system libraries. Therefore you should used the Porting/thirdclean script to cleanup the **.3log* files.

There are also leaks that for given certain definition of a leak, aren't. See PERL_DESTRUCT_LEVEL for more information.

76.2.6 PERL_DESTRUCT_LEVEL

If you want to run any of the tests yourself manually using e.g. valgrind, or the pureperl or perl.third executables, please note that by default perl **does not** explicitly cleanup all the memory it has allocated (such as global memory arenas) but instead lets the exit() of the whole program "take care" of such allocations, also known as "global destruction of objects".

There is a way to tell perl to do complete cleanup: set the environment variable PERL_DESTRUCT_LEVEL to a non-zero value. The t/TEST wrapper does set this to 2, and this is what you need to do too, if you don't want to see the "global leaks": For example, for "third-degreed" Perl:

```
    env PERL_DESTRUCT_LEVEL=2 ./perl.third -Ilib t/foo/bar.t
```

(Note: the mod_perl apache module uses also this environment variable for its own purposes and extended its semantics. Refer to the mod_perl documentation for more information. Also, spawned threads do the equivalent of setting this variable to the value 1.)

If, at the end of a run you get the message *N scalars leaked*, you can recompile with `-DDEBUG_LEAKING_SCALARS`, which will cause the addresses of all those leaked SVs to be dumped; it also converts `new_SV()` from a macro into a real function, so you can use your favourite debugger to discover where those pesky SVs were allocated.

76.2.7 Profiling

Depending on your platform there are various of profiling Perl.

There are two commonly used techniques of profiling executables: *statistical time-sampling* and *basic-block counting*.

The first method takes periodically samples of the CPU program counter, and since the program counter can be correlated with the code generated for functions, we get a statistical view of in which functions the program is spending its time. The caveats are that very small/fast functions have lower probability of showing up in the profile, and that periodically interrupting the program (this is usually done rather frequently, in the scale of milliseconds) imposes an additional overhead that may skew the results. The first problem can be alleviated by running the code for longer (in general this is a good idea for profiling), the second problem is usually kept in guard by the profiling tools themselves.

The second method divides up the generated code into *basic blocks*. Basic blocks are sections of code that are entered only in the beginning and exited only at the end. For example, a conditional jump starts a basic block. Basic block profiling usually works by *instrumenting* the code by adding *enter basic block #nnnn* book-keeping code to the generated code. During the execution of the code the basic block counters are then updated appropriately. The caveat is that the added extra code can skew the results: again, the profiling tools usually try to factor their own effects out of the results.

76.2.8 Gprof Profiling

gprof is a profiling tool available in many UNIX platforms, it uses *statistical time-sampling*.

You can build a profiled version of perl called "perl.gprof" by invoking the make target "perl.gprof" (What is required is that Perl must be compiled using the `-pg` flag, you may need to re-Configure). Running the profiled version of Perl will create an output file called *gmon.out* is created which contains the profiling data collected during the execution.

The gprof tool can then display the collected data in various ways. Usually gprof understands the following options:

-a

Suppress statically defined functions from the profile.

-b

Suppress the verbose descriptions in the profile.

-e routine

Exclude the given routine and its descendants from the profile.

-f routine

Display only the given routine and its descendants in the profile.

-s

Generate a summary file called *gmon.sum* which then may be given to subsequent gprof runs to accumulate data over several runs.

-z

Display routines that have zero usage.

For more detailed explanation of the available commands and output formats, see your own local documentation of gprof.

76.2.9 GCC gcov Profiling

Starting from GCC 3.0 *basic block profiling* is officially available for the GNU CC.

You can build a profiled version of perl called *perl.gcov* by invoking the make target "perl.gcov" (what is required that Perl must be compiled using gcc with the flags `-fprofile-arcs -ftest-coverage`, you may need to re-Configure).

Running the profiled version of Perl will cause profile output to be generated. For each source file an accompanying ".da" file will be created.

To display the results you use the "gcov" utility (which should be installed if you have gcc 3.0 or newer installed). *gcov* is run on source code files, like this

```
    gcov sv.c
```

which will cause *sv.c.gcov* to be created. The *.gcov* files contain the source code annotated with relative frequencies of execution indicated by "#" markers.

Useful options of *gcov* include `-b` which will summarise the basic block, branch, and function call coverage, and `-c` which instead of relative frequencies will use the actual counts. For more information on the use of *gcov* and basic block profiling with gcc, see the latest GNU CC manual, as of GCC 3.0 see

```
    http://gcc.gnu.org/onlinedocs/gcc-3.0/gcc.html
```

and its section titled "8. gcov: a Test Coverage Program"

```
    http://gcc.gnu.org/onlinedocs/gcc-3.0/gcc_8.html#SEC132
```

76.2.10 Pixie Profiling

Pixie is a profiling tool available on IRIX and Tru64 (aka Digital UNIX aka DEC OSF/1) platforms. Pixie does its profiling using *basic-block counting*.

You can build a profiled version of perl called *perl.pixie* by invoking the make target "perl.pixie" (what is required is that Perl must be compiled using the `-g` flag, you may need to re-Configure).

In Tru64 a file called *perl.Addrs* will also be silently created, this file contains the addresses of the basic blocks. Running the profiled version of Perl will create a new file called "perl.Counts" which contains the counts for the basic block for that particular program execution.

To display the results you use the *prof* utility. The exact incantation depends on your operating system, "prof perl.Counts" in IRIX, and "prof -pixie -all -L. perl" in Tru64.

In IRIX the following prof options are available:

-h

Reports the most heavily used lines in descending order of use. Useful for finding the hotspot lines.

-l

Groups lines by procedure, with procedures sorted in descending order of use. Within a procedure, lines are listed in source order. Useful for finding the hotspots of procedures.

In Tru64 the following options are available:

-p[rocedures]

Procedures sorted in descending order by the number of cycles executed in each procedure. Useful for finding the hotspot procedures. (This is the default option.)

-h[eavy]

Lines sorted in descending order by the number of cycles executed in each line. Useful for finding the hotspot lines.

-i[nvocations]

The called procedures are sorted in descending order by number of calls made to the procedures. Useful for finding the most used procedures.

-l[ines]

Grouped by procedure, sorted by cycles executed per procedure. Useful for finding the hotspots of procedures.

-testcoverage

The compiler emitted code for these lines, but the code was unexecuted.

-z[ero]

Unexecuted procedures.

For further information, see your system's manual pages for pixie and prof.

76.2.11 Miscellaneous tricks

- Those debugging perl with the DDD frontend over gdb may find the following useful:

  You can extend the data conversion shortcuts menu, so for example you can display an SV's IV value with one click, without doing any typing. To do that simply edit ˜/.ddd/init file and add after:

```
! Display shortcuts.
Ddd*gdbDisplayShortcuts: \
/t ()   // Convert to Bin\n\
/d ()   // Convert to Dec\n\
/x ()   // Convert to Hex\n\
/o ()   // Convert to Oct(\n\
```

the following two lines:

```
((XPV*) (())->sv_any )->xpv_pv  // 2pvx\n\
((XPVIV*) (())->sv_any )->xiv_iv // 2ivx
```

so now you can do ivx and pvx lookups or you can plug there the sv_peek "conversion":

```
Perl_sv_peek(my_perl, (SV*)()) // sv_peek
```

(The my_perl is for threaded builds.) Just remember that every line, but the last one, should end with \n\

Alternatively edit the init file interactively via: 3rd mouse button -> New Display -> Edit Menu

Note: you can define up to 20 conversion shortcuts in the gdb section.

- If you see in a debugger a memory area mysteriously full of 0xabababab, you may be seeing the effect of the Poison() macro, see *perlclib*.

76.2.12 CONCLUSION

We've had a brief look around the Perl source, an overview of the stages *perl* goes through when it's running your code, and how to use a debugger to poke at the Perl guts. We took a very simple problem and demonstrated how to solve it fully - with documentation, regression tests, and finally a patch for submission to p5p. Finally, we talked about how to use external tools to debug and test Perl.

I'd now suggest you read over those references again, and then, as soon as possible, get your hands dirty. The best way to learn is by doing, so:

- Subscribe to perl5-porters, follow the patches and try and understand them; don't be afraid to ask if there's a portion you're not clear on - who knows, you may unearth a bug in the patch...
- Keep up to date with the bleeding edge Perl distributions and get familiar with the changes. Try and get an idea of what areas people are working on and the changes they're making.
- Do read the README associated with your operating system, e.g. README.aix on the IBM AIX OS. Don't hesitate to supply patches to that README if you find anything missing or changed over a new OS release.
- Find an area of Perl that seems interesting to you, and see if you can work out how it works. Scan through the source, and step over it in the debugger. Play, poke, investigate, fiddle! You'll probably get to understand not just your chosen area but a much wider range of *perl*'s activity as well, and probably sooner than you'd think.

The Road goes ever on and on, down from the door where it began.

If you can do these things, you've started on the long road to Perl porting. Thanks for wanting to help make Perl better - and happy hacking!

76.3 AUTHOR

This document was written by Nathan Torkington, and is maintained by the perl5-porters mailing list.

Part V

Miscellaneous

Chapter 77

perlbook

Perl book information

77.1 DESCRIPTION

The Camel Book, officially known as *Programming Perl, Third Edition*, by Larry Wall et al, is the definitive reference work covering nearly all of Perl. You can order it and other Perl books from O'Reilly & Associates, 1-800-998-9938. Local/overseas is +1 707 829 0515. If you can locate an O'Reilly order form, you can also fax to +1 707 829 0104. If you're web-connected, you can even mosey on over to http://www.oreilly.com/ for an online order form.

Other Perl books from various publishers and authors can be found listed in *perlfaq2*.

Chapter 78

perltodo

Perl TO-DO List

78.1 DESCRIPTION

This is a list of wishes for Perl. Send updates to *perl5-porters@perl.org*. If you want to work on any of these projects, be sure to check the perl5-porters archives for past ideas, flames, and propaganda. This will save you time and also prevent you from implementing something that Larry has already vetoed. One set of archives may be found at:

```
    http://www.xray.mpe.mpg.de/mailing-lists/perl5-porters/
```

78.2 assertions

Clean up and finish support for assertions. See *assertions*.

78.3 iCOW

Sarathy and Arthur have a proposal for an improved Copy On Write which specifically will be able to COW new ithreads. If this can be implemented it would be a good thing.

78.4 (?{...}) closures in regexps

Fix (or rewrite) the implementation of the `/(?{...})/` closures.

78.5 A re-entrant regexp engine

This will allow the use of a regex from inside (?{ }), (??{ }) and (?(?{ })|) constructs.

78.6 pragmata

78.6.1 lexical pragmas

Reimplement the mechanism of lexical pragmas to be more extensible. Fix current pragmas that don't work well (or at all) with lexical scopes or in run-time eval(STRING) (`sort`, `re`, `encoding` for example). MJD has a preliminary patch that implements this.

78.6.2 use less 'memory'

Investigate trade offs to switch out perl's choices on memory usage. Particularly perl should be able to give memory back.

78.7 prototypes and functions

78.7.1 _ prototype character

Study the possibility of adding a new prototype character, _, meaning "this argument defaults to $_".

78.7.2 inlining autoloaded constants

Currently the optimiser can inline constants when expressed as subroutines with prototype ($) that return a constant. Likewise, many packages wrapping C libraries export lots of constants as subroutines which are AUTOLOADed on demand. However, these have no prototypes, so can't be seen as constants by the optimiser. Some way of cheaply (low syntax, low memory overhead) to the perl compiler that a name is a constant would be great, so that it knows to call the AUTOLOAD routine at compile time, and then inline the constant.

78.7.3 Finish off lvalue functions

The old perltodo notes "They don't work in the debugger, and they don't work for list or hash slices."

78.8 Unicode and UTF8

78.8.1 Implicit Latin 1 => Unicode translation

Conversions from byte strings to UTF-8 currently map high bit characters to Unicode without translation (or, depending on how you look at it, by implicitly assuming that the byte strings are in Latin-1). As perl assumes the C locale by default, upgrading a string to UTF-8 may change the meaning of its contents regarding character classes, case mapping, etc. This should probably emit a warning (at least).

78.8.2 UTF8 caching code

The string position/offset cache is not optional. It should be.

78.8.3 Unicode in Filenames

chdir, chmod, chown, chroot, exec, glob, link, lstat, mkdir, open, opendir, qx, readdir, readlink, rename, rmdir, stat, symlink, sysopen, system, truncate, unlink, utime, -X. All these could potentially accept Unicode filenames either as input or output (and in the case of system and qx Unicode in general, as input or output to/from the shell). Whether a filesystem - an operating system pair understands Unicode in filenames varies.

Known combinations that have some level of understanding include Microsoft NTFS, Apple HFS+ (In Mac OS 9 and X) and Apple UFS (in Mac OS X), NFS v4 is rumored to be Unicode, and of course Plan 9. How to create Unicode filenames, what forms of Unicode are accepted and used (UCS-2, UTF-16, UTF-8), what (if any) is the normalization form used, and so on, varies. Finding the right level of interfacing to Perl requires some thought. Remember that an OS does not implicate a filesystem.

(The Windows -C command flag "wide API support" has been at least temporarily retired in 5.8.1, and the -C has been repurposed, see *perlrun*.)

78.8.4 Unicode in %ENV

Currently the %ENV entries are always byte strings.

78.9 Regexps

78.9.1 regexp optimiser optional

The regexp optimiser is not optional. It should configurable to be, to allow its performance to be measured, and its bugs to be easily demonstrated.

78.9.2 common suffices/prefices in regexps (trie optimization)

Currently, the user has to optimize `foo|far` and `foo|goo` into `f(?:oo|ar)` and `[fg]oo` by hand; this could be done automatically.

78.10 POD

78.10.1 POD -> HTML conversion still sucks

Which is crazy given just how simple POD purports to be, and how simple HTML can be.

78.11 Misc medium sized projects

78.11.1 UNITCHECK

Introduce a new special block, UNITCHECK, which is run at the end of a compilation unit (module, file, eval(STRING) block). This will correspond to the Perl 6 CHECK. Perl 5's CHECK cannot be changed or removed because the O.pm/B.pm backend framework depends on it.

78.11.2 optional optimizer

Make the peephole optimizer optional.

78.11.3 You WANT *how* many

Currently contexts are void, scalar and list. split has a special mechanism in place to pass in the number of return values wanted. It would be useful to have a general mechanism for this, backwards compatible and little speed hit. This would allow proposals such as short circuiting sort to be implemented as a module on CPAN.

78.11.4 lexical aliases

Allow lexical aliases (maybe via the syntax `my \$alias = \$foo`.

78.11.5 no 6

Make `no 6` and `no v6` work (opposite of `use 5.005`, etc.).

78.11.6 IPv6

Clean this up. Check everything in core works

78.11.7 entersub XS vs Perl

At the moment pp_entersub is huge, and has code to deal with entering both perl and and XS subroutines. Subroutine implementations rarely change between perl and XS at run time, so investigate using 2 ops to enter subs (one for XS, one for perl) and swap between if a sub is redefined.

78.11.8 @INC source filter to Filter::Simple

The second return value from a sub in @INC can be a source filter. This isn't documented. It should be changed to use Filter::Simple, tested and documented.

78.11.9 bincompat functions

There are lots of functions which are retained for binary compatibility. Clean these up. Move them to mathom.c, and don't compile for blead?

78.11.10 Use fchown/fchmod internally

The old perltodo notes "This has been done in places, but needs a thorough code review. Also fchdir is available in some platforms."

78.12 Tests

78.12.1 Make Schwern poorer

Tests for everything, At which point Schwern coughs up $500 to TPF.

78.12.2 test B

A test suite for the B module would be nice.

78.12.3 Improve tests for Config.pm

Config.pm doesn't appear to be well tested.

78.12.4 common test code for timed bailout

Write portable self destruct code for tests to stop them burning CPU in infinite loops. Needs to avoid using alarm, as some of the tests are testing alarm/sleep or timers.

78.13 Installation

78.13.1 compressed man pages

Be able to install them

78.13.2 Make Config.pm cope with differences between build and installed perl

78.13.3 Relocatable perl

Make it possible to create a relocatable perl binary. Will need some collusion with Config.pm. We could use a syntax of ... for location of current binary?

78.13.4 make HTML install work

78.13.5 put patchlevel in -v

Currently perl from p4/rsync ships with a patchlevel.h file that usually defines one local patch, of the form "MAINT12345" or "RC1". The output of perl -v doesn't report that a perl isn't an official release, and this information can get lost in bugs reports. Because of this, the minor version isn't bumped up util RC time, to minimise the possibility of versions of perl escaping that believe themselves to be newer than they actually are.

It would be useful to find an elegant way to have the "this is an interim maintenance release" or "this is a release candidate" in the terse -v output, and have it so that it's easy for the pumpking to remove this just as the release tarball is rolled up. This way the version pulled out of rsync would always say "I'm a development release" and it would be safe to bump the reported minor version as soon as a release ships, which would aid perl developers.

78.14 Incremental things

Some tasks that don't need to get done in one big hit.

78.14.1 autovivification

Make all autovivification consistent w.r.t LVALUE/RVALUE and strict/no strict;

78.14.2 fix tainting bugs

Fix the bugs revealed by running the test suite with the `-t` switch (via `make test.taintwarn`).

78.14.3 Make tainting consistent

Tainting would be easier to use if it didn't take documented shortcuts and allow taint to "leak" everywhere within an expression.

78.14.4 Dual life everything

As part of the "dists" plan, anything that doesn't belong in the smallest perl distribution needs to be dual lifed. Anything else can be too.

78.15 Vague things

Some more nebulous ideas

78.15.1 threads

Make threads more robust.

78.15.2 POSIX memory footprint

Ilya observed that use POSIX; eats memory like there's no tomorrow, and at various times worked to cut it down. There is probably still fat to cut out - for example POSIX passes Exporter some very memory hungry data structures.

78.15.3 Optimize away @_

The old perltodo notes "Look at the "reification" code in `av.c`"

78.15.4 switch ops

The old perltodo notes "Although we have `Switch.pm` in core, Larry points to the dormant `nswitch` and `cswitch` ops in *pp.c*; using these opcodes would be much faster."

78.15.5 Attach/detach debugger from running program

The old perltodo notes "With `gdb`, you can attach the debugger to a running program if you pass the process ID. It would be good to do this with the Perl debugger on a running Perl program, although I'm not sure how it would be done." ssh and screen do this with named pipes in tmp. Maybe we can too.

78.15.6 A decent benchmark

perlbench seems impervious to any recent changes made to the perl core. It would be useful to have a reasonable general benchmarking suite that roughly represented what current perl programs do, and measurably reported whether tweaks to the core improve, degrade or don't really affect performance, to guide people attempting to optimise the guts of perl.

Chapter 79

perldoc

Look up Perl documentation in Pod format.

79.1 SYNOPSIS

perldoc [**-h**] [**-v**] [**-t**] [**-u**] [**-m**] [**-l**] [**-F**] [**-i**] [**-V**] [**-T**] [**-r**] [**-d*destination_file***] [**-o*formatname***] [**-M*FormatterClassName***] [**-w*formatteroption:value***] [**-n***nroff-replacement*] [**-X**] PageName|ModuleName|ProgramName

perldoc -f BuiltinFunction

perldoc -q FAQ Keyword

See below for more description of the switches.

79.2 DESCRIPTION

perldoc looks up a piece of documentation in .pod format that is embedded in the perl installation tree or in a perl script, and displays it via `pod2man | nroff -man | $PAGER`. (In addition, if running under HP-UX, `col -x` will be used.) This is primarily used for the documentation for the perl library modules.

Your system may also have man pages installed for those modules, in which case you can probably just use the man(1) command.

If you are looking for a table of contents to the Perl library modules documentation, see the *perltoc* page.

79.3 OPTIONS

-h

Prints out a brief **h**elp message.

-v

Describes search for the item in detail (**v**erbosely).

-t

Display docs using plain **t**ext converter, instead of nroff. This may be faster, but it probably won't look as nice.

-u

Skip the real Pod formatting, and just show the raw Pod source (**U**nformatted)

-m *module*

Display the entire module: both code and unformatted pod documentation. This may be useful if the docs don't explain a function in the detail you need, and you'd like to inspect the code directly; perldoc will find the file for you and simply hand it off for display.

-l

Display on**l**y the file name of the module found.

-F

Consider arguments as file names; no search in directories will be performed.

-f *perlfunc*

The **-f** option followed by the name of a perl built in function will extract the documentation of this function from *perlfunc*.

Example:

```
    perldoc -f sprintf
```

-q *perlfaq-search-regexp*

The **-q** option takes a regular expression as an argument. It will search the **q**uestion headings in perlfaq[1-9] and print the entries matching the regular expression. Example: `perldoc -q shuffle`

-T

This specifies that the output is not to be sent to a pager, but is to be sent right to STDOUT.

-d *destination-filename*

This specifies that the output is to be sent neither to a pager nor to STDOUT, but is to be saved to the specified filename. Example: `perldoc -oLaTeX -dtextwrapdocs.tex Text::Wrap`

-o *output-formatname*

This specifies that you want Perldoc to try using a Pod-formatting class for the output format that you specify. For example: `-oman`. This is actually just a wrapper around the `-M` switch; using `-o`*`formatname`* just looks for a loadable class by adding that format name (with different capitalizations) to the end of different classname prefixes.

For example, `-oLaTeX` currently tries all of the following classes: Pod::Perldoc::ToLaTeX Pod::Perldoc::Tolatex Pod::Perldoc::ToLatex Pod::Perldoc::ToLATEX Pod::Simple::LaTeX Pod::Simple::latex Pod::Simple::Latex Pod::Simple::LATEX Pod::LaTeX Pod::latex Pod::Latex Pod::LATEX.

-M *module-name*

This specifies the module that you want to try using for formatting the pod. The class must must at least provide a `parse_from_file` method. For example: `perldoc -MPod::Perldoc::ToChecker`.

You can specify several classes to try by joining them with commas or semicolons, as in `-MTk::SuperPod;Tk::Pod`.

-w *option:value* or -w *option*

This specifies an option to call the formatter **w**ith. For example, `-w textsize:15` will call `$formatter->textsize(15)` on the formatter object before it is used to format the object. For this to be valid, the formatter class must provide such a method, and the value you pass should be valid. (So if `textsize` expects an integer, and you do `-w textsize:big`, expect trouble.)

You can use `-w optionname` (without a value) as shorthand for `-w optionname:`*`TRUE`*. This is presumably useful in cases of on/off features like: `-w page_numbering`.

You can use a "=" instead of the ":", as in: `-w textsize=15`. This might be more (or less) convenient, depending on what shell you use.

-X

Use an index if it is present – the **-X** option looks for an entry whose basename matches the name given on the command line in the file `$Config{archlib}/pod.idx`. The *pod.idx* file should contain fully qualified filenames, one per line.

PageName|ModuleName|ProgramName

The item you want to look up. Nested modules (such as `File::Basename`) are specified either as `File::Basename` or `File/Basename`. You may also give a descriptive name of a page, such as `perlfunc`.

-n *some-formatter*

Specify replacement for nroff

-r

Recursive search.

-i

Ignore case.

-V

Displays the version of perldoc you're running.

79.4 SECURITY

Because **perldoc** does not run properly tainted, and is known to have security issues, when run as the superuser it will attempt to drop privileges by setting the effective and real IDs to nobody's or nouser's account, or -2 if unavailable. If it cannot relinquish its privileges, it will not run.

79.5 ENVIRONMENT

Any switches in the `PERLDOC` environment variable will be used before the command line arguments.

Useful values for `PERLDOC` include `-oman`, `-otext`, `-otk`, `-ortf`, `-oxml`, and so on, depending on what modules you have on hand; or exactly specify the formatter class with `-MPod::Perldoc::ToMan` or the like.

`perldoc` also searches directories specified by the `PERL5LIB` (or `PERLLIB` if `PERL5LIB` is not defined) and `PATH` environment variables. (The latter is so that embedded pods for executables, such as `perldoc` itself, are available.)

`perldoc` will use, in order of preference, the pager defined in `PERLDOC_PAGER`, `MANPAGER`, or `PAGER` before trying to find a pager on its own. (`MANPAGER` is not used if `perldoc` was told to display plain text or unformatted pod.)

One useful value for `PERLDOC_PAGER` is `less -+C -E`.

Having PERLDOCDEBUG set to a positive integer will make perldoc emit even more descriptive output than the `-v` switch does – the higher the number, the more it emits.

79.6 AUTHOR

Current maintainer: Sean M. Burke, <sburke@cpan.org>

Past contributors are: Kenneth Albanowski <kjahds@kjahds.com>, Andy Dougherty <doughera@lafcol.lafayette.edu>, and many others.

Chapter 80

perlhist

The Perl history records

80.1 DESCRIPTION

This document aims to record the Perl source code releases.

80.2 INTRODUCTION

Perl history in brief, by Larry Wall:

```
    Perl 0 introduced Perl to my officemates.
    Perl 1 introduced Perl to the world, and changed /\(...\|...\)/ to
        /(...|...)/.  \(Dan Faigin still hasn't forgiven me. :-\)
    Perl 2 introduced Henry Spencer's regular expression package.
    Perl 3 introduced the ability to handle binary data (embedded nulls).
    Perl 4 introduced the first Camel book.  Really.  We mostly just
        switched version numbers so the book could refer to 4.000.
    Perl 5 introduced everything else, including the ability to
        introduce everything else.
```

80.3 THE KEEPERS OF THE PUMPKIN

Larry Wall, Andy Dougherty, Tom Christiansen, Charles Bailey, Nick Ing-Simmons, Chip Salzenberg, Tim Bunce, Malcolm Beattie, Gurusamy Sarathy, Graham Barr, Jarkko Hietaniemi, Hugo van der Sanden, Michael Schwern, Rafael Garcia-Suarez, Nicholas Clark, Richard Clamp, Leon Brocard.

80.3.1 PUMPKIN?

[from Porting/pumpkin.pod in the Perl source code distribution]

Chip Salzenberg gets credit for that, with a nod to his cow orker, David Croy. We had passed around various names (baton, token, hot potato) but none caught on. Then, Chip asked:

[begin quote]

```
   Who has the patch pumpkin?
```

To explain: David Croy once told me once that at a previous job, there was one tape drive and multiple systems that used it for backups. But instead of some high-tech exclusion software, they used a low-tech method to prevent multiple simultaneous backups: a stuffed pumpkin. No one was allowed to make backups unless they had the "backup pumpkin".

[end quote]

The name has stuck. The holder of the pumpkin is sometimes called the pumpking (keeping the source afloat?) or the pumpkineer (pulling the strings?).

80.4 THE RECORDS

```
Pump-  Release         Date            Notes
king                                   (by no means
                                        comprehensive,
                                        see Changes*
                                        for details)
===========================================================================

80.4.1 SELECTED RELEASE SIZES

For example the notation "core: 212 29" in the release 1.000 means that it had in the core 212 kilobytes, in 29 files. The "core".."doc" are explained below.

```
 release        core       lib         ext        t         doc
 ======================================================================

 1.000           212  29        -   -        -   -     38  51      62    3
 1.014           219  29        -   -        -   -     39  52      68    4

```

The "core"..."doc" mean the following files from the Perl source code distribution. The glob notation ** means recursively, (.) means regular files.

```
core   *.[hcy]
lib    lib/**/*.p[ml]
ext    ext/**/*.{[hcyt],xs,pm}
t      t/**/*(.) (for 1-5.005_56) or **/*.t (for 5.6.0-5.7.3)
doc    {README*,INSTALL,*[_.]man{,.?},pod/**/*.pod}
```

Here are some statistics for the other subdirectories and one file in the Perl source distribution for somewhat more selected releases.

```

80.4.2 SELECTED PATCH SIZES

The "diff lines kb" means that for example the patch 5.003_08, to be applied on top of the 5.003_07 (or whatever was before the 5.003_08) added lines for 110 kilobytes, it removed lines for 19 kilobytes, and changed lines for 424 kilobytes. Just the lines themselves are counted, not their context. The "+ - !" become from the diff(1) context diff output format.

```

80.5 THE KEEPERS OF THE RECORDS

Jarkko Hietaniemi <*jhi@iki.fi*>.

Thanks to the collective memory of the Perlfolk. In addition to the Keepers of the Pumpkin also Alan Champion, Mark Dominus, Andreas König, John Macdonald, Matthias Neeracher, Jeff Okamoto, Michael Peppler, Randal Schwartz, and Paul D. Smith sent corrections and additions.

Chapter 81

perldelta

What is new for perl v5.8.5

81.1 DESCRIPTION

This document describes differences between the 5.8.4 release and the 5.8.5 release.

81.2 Incompatible Changes

There are no changes incompatible with 5.8.4.

81.3 Core Enhancements

Perl's regular expression engine now contains support for matching on the intersection of two Unicode character classes. You can also now refer to user-defined character classes from within other user defined character classes.

81.4 Modules and Pragmata

- Carp improved to work nicely with Safe. Carp's message reporting should now be anomaly free - it will always print out line number information.
- CGI upgraded to version 3.05
- charnames now avoids clobbering $_
- Digest upgraded to version 1.08
- Encode upgraded to version 2.01
- FileCache upgraded to version 1.04
- libnet upgraded to version 1.19
- Pod::Parser upgraded to version 1.28
- Pod::Perldoc upgraded to version 3.13
- Pod::LaTeX upgraded to version 0.57
- Safe now works properly with Carp

- Scalar-List-Utils upgraded to version 1.14
- Shell's documentation has been re-written, and its historical partial auto-quoting of command arguments can now be disabled.
- Test upgraded to version 1.25
- Test::Harness upgraded to version 2.42
- Time::Local upgraded to version 1.10
- Unicode::Collate upgraded to version 0.40
- Unicode::Normalize upgraded to version 0.30

81.5 Utility Changes

81.5.1 Perl's debugger

The debugger can now emulate stepping backwards, by restarting and rerunning all bar the last command from a saved command history.

81.5.2 h2ph

h2ph is now able to understand a very limited set of C inline functions – basically, the inline functions that look like CPP macros. This has been introduced to deal with some of the headers of the newest versions of the glibc. The standard warning still applies; to quote *h2ph*'s documentation, *you may need to dicker with the files produced*.

81.6 Installation and Configuration Improvements

Perl 5.8.5 should build cleanly from source on LynxOS.

81.7 Selected Bug Fixes

- The in-place sort optimisation introduced in 5.8.4 had a bug. For example, in code such as

  ```
  @a = sort ($b, @a)
  ```

  the result would omit the value $b. This is now fixed.
- The optimisation for unnecessary assignments introduced in 5.8.4 could give spurious warnings. This has been fixed.
- Perl should now correctly detect and read BOM-marked and (BOMless) UTF-16 scripts of either endianness.
- Creating a new thread when weak references exist was buggy, and would often cause warnings at interpreter destruction time. The known bug is now fixed.
- Several obscure bugs involving manipulating Unicode strings with `substr` have been fixed.
- Previously if Perl's file globbing function encountered a directory that it did not have permission to open it would return immediately, leading to unexpected truncation of the list of results. This has been fixed, to be consistent with Unix shells' globbing behaviour.
- Thread creation time could vary wildly between identical runs. This was caused by a poor hashing algorithm in the thread cloning routines, which has now been fixed.
- The internals of the ithreads implementation were not checking if OS-level thread creation had failed. threads->create() now returns `undef` in if thead creation fails instead of crashing perl.

81.8 New or Changed Diagnostics

- Perl -V has several improvements
  - correctly outputs local patch names that contain embedded code snippets or other characters that used to confuse it.
  - arguments to -V that look like regexps will give multiple lines of output.
  - a trailing colon suppresses the linefeed and ';' terminator, allowing embedding of queries into shell commands.
  - a leading colon removes the 'name=' part of the response, allowing mapping to any name.
- When perl fails to find the specified script, it now outputs a second line suggesting that the user use the `-S` flag:

```
$ perl5.8.5 missing.pl
Can't open perl script "missing.pl": No such file or directory.
Use -S to search $PATH for it.
```

81.9 Changed Internals

The Unicode character class files used by the regular expression engine are now built at build time from the supplied Unicode consortium data files, instead of being shipped prebuilt. This makes the compressed Perl source tarball about 200K smaller. A side effect is that the layout of files inside lib/unicore has changed.

81.10 Known Problems

The regression test *t/uni/class.t* is now performing considerably more tests, and can take several minutes to run even on a fast machine.

81.11 Platform Specific Problems

This release is known not to build on Windows 95.

81.12 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org. There may also be information at http://www.perl.org, the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team. You can browse and search the Perl 5 bugs at http://bugs.perl.org/

81.13 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

Chapter 82

perl584delta

What is new for perl v5.8.4

82.1 DESCRIPTION

This document describes differences between the 5.8.3 release and the 5.8.4 release.

82.2 Incompatible Changes

Many minor bugs have been fixed. Scripts which happen to rely on previously erroneous behaviour will consider these fixes as incompatible changes :-) You are advised to perform sufficient acceptance testing on this release to satisfy yourself that this does not affect you, before putting this release into production.

The diagnostic output of Carp has been changed slightly, to add a space after the comma between arguments. This makes it much easier for tools such as web browsers to wrap it, but might confuse any automatic tools which perform detailed parsing of Carp output.

The internal dump output has been improved, so that non-printable characters such as newline and backspace are output in `\x` notation, rather than octal. This might just confuse non-robust tools which parse the output of modules such as Devel::Peek.

82.3 Core Enhancements

82.3.1 Malloc wrapping

Perl can now be built to detect attempts to assign pathologically large chunks of memory. Previously such assignments would suffer from integer wrap-around during size calculations causing a misallocation, which would crash perl, and could theoretically be used for "stack smashing" attacks. The wrapping defaults to enabled on platforms where we know it works (most AIX configurations, BSDi, Darwin, DEC OSF/1, FreeBSD, HP/UX, GNU Linux, OpenBSD, Solaris, VMS and most Win32 compilers) and defaults to disabled on other platforms.

82.3.2 Unicode Character Database 4.0.1

The copy of the Unicode Character Database included in Perl 5.8 has been updated to 4.0.1 from 4.0.0.

82.3.3 suidperl less insecure

Paul Szabo has analysed and patched `suidperl` to remove existing known insecurities. Currently there are no known holes in `suidperl`, but previous experience shows that we cannot be confident that these were the last. You may no longer invoke the set uid perl directly, so to preserve backwards compatibility with scripts that invoke #!/usr/bin/suidperl the only set uid binary is now `sperl5.8.`*n* (`sperl5.8.4` for this release). `suidperl` is installed as a hard link to `perl`; both `suidperl` and `perl` will invoke `sperl5.8.4` automatically the set uid binary, so this change should be completely transparent.

For new projects the core perl team would strongly recommend that you use dedicated, single purpose security tools such as `sudo` in preference to `suidperl`.

82.3.4 format

In addition to bug fixes, `format`'s features have been enhanced. See *perlform*

82.4 Modules and Pragmata

The (mis)use of `/tmp` in core modules and documentation has been tidied up. Some modules available both within the perl core and independently from CPAN ("dual-life modules") have not yet had these changes applied; the changes will be integrated into future stable perl releases as the modules are updated on CPAN.

82.4.1 Updated modules

Attribute::Handlers

B

Benchmark

CGI

Carp

Cwd

Exporter

File::Find

IO

IPC::Open3

Local::Maketext

Math::BigFloat

Math::BigInt

Math::BigRat

MIME::Base64

ODBM_File

POSIX

Shell

Socket

There is experimental support for Linux abstract Unix domain sockets.

Storable

Switch

Synced with its CPAN version 2.10

Sys::Syslog

`syslog()` can now use numeric constants for facility names and priorities, in addition to strings.

Term::ANSIColor

Time::HiRes

Unicode::UCD

Win32

Win32.pm/Win32.xs has moved from the libwin32 module to core Perl

base

open

threads

Detached threads are now also supported on Windows.

utf8

82.5 Performance Enhancements

- Accelerated Unicode case mappings (`/i`, `lc`, `uc`, etc).
- In place sort optimised (eg `@a = sort @a`)
- Unnecessary assignment optimised away in

```
my $s = undef;
my @a = ();
my %h = ();
```

- Optimised `map` in scalar context

82.6 Utility Changes

The Perl debugger (*lib/perl5db.pl*) can now save all debugger commands for sourcing later, and can display the parent inheritance tree of a given class.

82.7 Installation and Configuration Improvements

The build process on both VMS and Windows has had several minor improvements made. On Windows Borland's C compiler can now compile perl with PerlIO and/or USE_LARGE_FILES enabled.

`perl.exe` on Windows now has a "Camel" logo icon. The use of a camel with the topic of Perl is a trademark of O'Reilly and Associates Inc., and is used with their permission (ie distribution of the source, compiling a Windows executable from it, and using that executable locally). Use of the supplied camel for anything other than a perl executable's icon is specifically not covered, and anyone wishing to redistribute perl binaries *with* the icon should check directly with O'Reilly beforehand.

Perl should build cleanly on Stratus VOS once more.

82.8 Selected Bug Fixes

More utf8 bugs fixed, notably in how `chomp`, `chop`, `send`, and `syswrite` and interact with utf8 data. Concatenation now works correctly when `use bytes;` is in scope.

Pragmata are now correctly propagated into (?{...}) constructions in regexps. Code such as

```
   my $x = qr{ ... (??{ $x }) ... };
```

will now (correctly) fail under use strict. (As the inner `$x` is and has always referred to `$::x`)

The "const in void context" warning has been suppressed for a constant in an optimised-away boolean expression such as `5 || print;`

`perl -i` could `fchmod(stdin)` by mistake. This is serious if stdin is attached to a terminal, and perl is running as root. Now fixed.

82.9 New or Changed Diagnostics

`Carp` and the internal diagnostic routines used by `Devel::Peek` have been made clearer, as described in Incompatible Changes

82.10 Changed Internals

Some bugs have been fixed in the hash internals. Restricted hashes and their place holders are now allocated and deleted at slightly different times, but this should not be visible to user code.

82.11 Future Directions

Code freeze for the next maintenance release (5.8.5) will be on 30th June 2004, with release by mid July.

82.12 Platform Specific Problems

This release is known not to build on Windows 95.

82.13 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org. There may also be information at http://www.perl.org, the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team. You can browse and search the Perl 5 bugs at http://bugs.perl.org/

82.14 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

Chapter 83

perl583delta

What is new for perl v5.8.3

83.1 DESCRIPTION

This document describes differences between the 5.8.2 release and the 5.8.3 release.

If you are upgrading from an earlier release such as 5.6.1, first read the *perl58delta*, which describes differences between 5.6.0 and 5.8.0, and the *perl581delta* and *perl582delta*, which describe differences between 5.8.0, 5.8.1 and 5.8.2

83.2 Incompatible Changes

There are no changes incompatible with 5.8.2.

83.3 Core Enhancements

A `SCALAR` method is now available for tied hashes. This is called when a tied hash is used in scalar context, such as

```
    if (%tied_hash) {
        ...
    }
```

The old behaviour was that %tied_hash would return whatever would have been returned for that hash before the hash was tied (so usually 0). The new behaviour in the absence of a SCALAR method is to return TRUE if in the middle of an `each` iteration, and otherwise call FIRSTKEY to check if the hash is empty (making sure that a subsequent `each` will also begin by calling FIRSTKEY). Please see SCALAR in *perltie* for the full details and caveats.

83.4 Modules and Pragmata

CGI

Cwd

Digest

Digest::MD5

Encode

File::Spec

FindBin

A function `again` is provided to resolve problems where modules in different directories wish to use FindBin.

List::Util

You can now weaken references to read only values.

Math::BigInt

PodParser

Pod::Perldoc

POSIX

Unicode::Collate

Unicode::Normalize

Test::Harness

threads::shared

`cond_wait` has a new two argument form. `cond_timedwait` has been added.

83.5 Utility Changes

`find2perl` now assumes `-print` as a default action. Previously, it needed to be specified explicitly.

A new utility, `prove`, makes it easy to run an individual regression test at the command line. `prove` is part of Test::Harness, which users of earlier Perl versions can install from CPAN.

83.6 New Documentation

The documentation has been revised in places to produce more standard manpages.

The documentation for the special code blocks (BEGIN, CHECK, INIT, END) has been improved.

83.7 Installation and Configuration Improvements

Perl now builds on OpenVMS I64

83.8 Selected Bug Fixes

Using substr() on a UTF8 string could cause subsequent accesses on that string to return garbage. This was due to incorrect UTF8 offsets being cached, and is now fixed.

join() could return garbage when the same join() statement was used to process 8 bit data having earlier processed UTF8 data, due to the flags on that statement's temporary workspace not being reset correctly. This is now fixed.

`$a .. $b` will now work as expected when either $a or $b is `undef`

Using Unicode keys with tied hashes should now work correctly.

Reading $ˆE now preserves $!. Previously, the C code implementing $ˆE did not preserve `errno`, so reading $ˆE could cause `errno` and therefore `$!` to change unexpectedly.

Reentrant functions will (once more) work with C++. 5.8.2 introduced a bugfix which accidentally broke the compilation of Perl extensions written in C++

83.9 New or Changed Diagnostics

The fatal error "DESTROY created new reference to dead object" is now documented in *perldiag*.

83.10 Changed Internals

The hash code has been refactored to reduce source duplication. The external interface is unchanged, and aside from the bug fixes described above, there should be no change in behaviour.

`hv_clear_placeholders` is now part of the perl API

Some C macros have been tidied. In particular macros which create temporary local variables now name these variables more defensively, which should avoid bugs where names clash.

<signal.h> is now always included.

83.11 Configuration and Building

`Configure` now invokes callbacks regardless of the value of the variable they are called for. Previously callbacks were only invoked in the `case $variable $define)` branch. This change should only affect platform maintainers writing configuration hints files.

83.12 Platform Specific Problems

The regression test ext/threads/shared/t/wait.t fails on early RedHat 9 and HP-UX 10.20 due to bugs in their threading implementations. RedHat users should see https://rhn.redhat.com/errata/RHBA-2003-136.html and consider upgrading their glibc.

83.13 Known Problems

Detached threads aren't supported on Windows yet, as they may lead to memory access violation problems.

There is a known race condition opening scripts in `suidperl`. `suidperl` is neither built nor installed by default, and has been deprecated since perl 5.8.0. You are advised to replace use of suidperl with tools such as sudo (http://www.courtesan.com/sudo/)

We have a backlog of unresolved bugs. Dealing with bugs and bug reports is unglamorous work; not something ideally suited to volunteer labour, but that is all that we have.

The perl5 development team are implementing changes to help address this problem, which should go live in early 2004.

83.14 Future Directions

Code freeze for the next maintenance release (5.8.4) is on March 31st 2004, with release expected by mid April. Similarly 5.8.5's freeze will be at the end of June, with release by mid July.

83.15 Obituary

Iain 'Spoon' Truskett, Perl hacker, author of *perlreref* and contributor to CPAN, died suddenly on 29th December 2003, aged 24. He will be missed.

83.16 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org. There may also be information at http://www.perl.org, the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team. You can browse and search the Perl 5 bugs at http://bugs.perl.org/

83.17 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

Chapter 84

perl582delta

What is new for perl v5.8.2

84.1 DESCRIPTION

This document describes differences between the 5.8.1 release and the 5.8.2 release.

If you are upgrading from an earlier release such as 5.6.1, first read the *perl58delta*, which describes differences between 5.6.0 and 5.8.0, and the *perl581delta*, which describes differences between 5.8.0 and 5.8.1.

84.2 Incompatible Changes

For threaded builds for modules calling certain re-entrant system calls, binary compatibility was accidentally lost between 5.8.0 and 5.8.1. Binary compatibility with 5.8.0 has been restored in 5.8.2, which necessitates breaking compatibility with 5.8.1. We see this as the lesser of two evils.

This will only affect people who have a threaded perl 5.8.1, and compiled modules which use these calls, and now attempt to run the compiled modules with 5.8.2. The fix is to re-compile and re-install the modules using 5.8.2.

84.3 Core Enhancements

84.3.1 Hash Randomisation

The hash randomisation introduced with 5.8.1 has been amended. It transpired that although the implementation introduced in 5.8.1 was source compatible with 5.8.0, it was not binary compatible in certain cases. 5.8.2 contains an improved implementation which is both source and binary compatible with both 5.8.0 and 5.8.1, and remains robust against the form of attack which prompted the change for 5.8.1.

We are grateful to the Debian project for their input in this area. See Algorithmic Complexity Attacks in *perlsec* for the original rationale behind this change.

84.3.2 Threading

Several memory leaks associated with variables shared between threads have been fixed.

84.4 Modules and Pragmata

84.4.1 Updated Modules And Pragmata

The following modules and pragmata have been updated since Perl 5.8.1:

Devel::PPPort

Digest::MD5

I18N::LangTags

libnet

MIME::Base64

Pod::Perldoc

84.5 Selected Bug Fixes

Some syntax errors involving unrecognized filetest operators are now handled correctly by the parser.

84.6 Changed Internals

Interpreter initialization is more complete when -DMULTIPLICITY is off. This should resolve problems with initializing and destroying the Perl interpreter more than once in a single process.

84.7 Platform Specific Problems

Dynamic linker flags have been tweaked for Solaris and OS X, which should solve problems seen while building some XS modules.

Bugs in OS/2 sockets and tmpfile have been fixed.

In OS X `setreuid` and friends are troublesome - perl will now work around their problems as best possible.

84.8 Future Directions

Starting with 5.8.3 we intend to make more frequent maintenance releases, with a smaller number of changes in each. The intent is to propagate bug fixes out to stable releases more rapidly and make upgrading stable releases less of an upheaval. This should give end users more flexibility in their choice of upgrade timing, and allow them easier assessment of the impact of upgrades. The current plan is for code freezes as follows

- 5.8.3 23:59:59 GMT, Wednesday December 31st 2003
- 5.8.4 23:59:59 GMT, Wednesday March 31st 2004
- 5.8.5 23:59:59 GMT, Wednesday June 30th 2004

with the release following soon after, when testing is complete.

See Future Directions in *perl581delta* for more soothsaying.

84.9 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org/. There may also be information at http://www.perl.com/, the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team. You can browse and search the Perl 5 bugs at http://bugs.perl.org/

84.10 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

Chapter 85

perl581delta

What is new for perl v5.8.1

85.1 DESCRIPTION

This document describes differences between the 5.8.0 release and the 5.8.1 release.

If you are upgrading from an earlier release such as 5.6.1, first read the *perl58delta*, which describes differences between 5.6.0 and 5.8.0.

In case you are wondering about 5.6.1, it was bug-fix-wise rather identical to the development release 5.7.1. Confused? This timeline hopefully helps a bit: it lists the new major releases, their maintenance releases, and the development releases.

```
          New     Maintenance  Development

          5.6.0                             2000-Mar-22
                               5.7.0        2000-Sep-02
                  5.6.1                     2001-Apr-08
                               5.7.1        2001-Apr-09
                               5.7.2        2001-Jul-13
                               5.7.3        2002-Mar-05
          5.8.0                             2002-Jul-18
                  5.8.1                     2003-Sep-25
```

85.2 Incompatible Changes

85.2.1 Hash Randomisation

Mainly due to security reasons, the "random ordering" of hashes has been made even more random. Previously while the order of hash elements from keys(), values(), and each() was essentially random, it was still repeatable. Now, however, the order varies between different runs of Perl.

Perl has never guaranteed any ordering of the hash keys, and the ordering has already changed several times during the lifetime of Perl 5. Also, the ordering of hash keys has always been, and continues to be, affected by the insertion order.

The added randomness may affect applications.

One possible scenario is when output of an application has included hash data. For example, if you have used the Data::Dumper module to dump data into different files, and then compared the files to see whether the data has changed, now you will have false positives since the order in which hashes are dumped will vary. In general the cure is to sort the keys (or the values); in particular for Data::Dumper to use the `Sortkeys` option. If some particular order is really important, use tied hashes: for example the Tie::IxHash module which by default preserves the order in which the hash elements were added.

More subtle problem is reliance on the order of "global destruction". That is what happens at the end of execution: Perl destroys all data structures, including user data. If your destructors (the DESTROY subroutines) have assumed any particular ordering to the global destruction, there might be problems ahead. For example, in a destructor of one object you cannot assume that objects of any other class are still available, unless you hold a reference to them. If the environment variable PERL_DESTRUCT_LEVEL is set to a non-zero value, or if Perl is exiting a spawned thread, it will also destruct the ordinary references and the symbol tables that are no longer in use. You can't call a class method or an ordinary function on a class that has been collected that way.

The hash randomisation is certain to reveal hidden assumptions about some particular ordering of hash elements, and outright bugs: it revealed a few bugs in the Perl core and core modules.

To disable the hash randomisation in runtime, set the environment variable PERL_HASH_SEED to 0 (zero) before running Perl (for more information see PERL_HASH_SEED in *perlrun*), or to disable the feature completely in compile time, compile with `-DNO_HASH_SEED` (see *INSTALL*).

See Algorithmic Complexity Attacks in *perlsec* for the original rationale behind this change.

85.2.2 UTF-8 On Filehandles No Longer Activated By Locale

In Perl 5.8.0 all filehandles, including the standard filehandles, were implicitly set to be in Unicode UTF-8 if the locale settings indicated the use of UTF-8. This feature caused too many problems, so the feature was turned off and redesigned: see §85.3.

85.2.3 Single-number v-strings are no longer v-strings before "=>"

The version strings or v-strings (see Version Strings in *perldata*) feature introduced in Perl 5.6.0 has been a source of some confusion– especially when the user did not want to use it, but Perl thought it knew better. Especially troublesome has been the feature that before a "=>" a version string (a "v" followed by digits) has been interpreted as a v-string instead of a string literal. In other words:

```
    %h = ( v65 => 42 );
```

has meant since Perl 5.6.0

```
    %h = ( 'A' => 42 );
```

(at least in platforms of ASCII progeny) Perl 5.8.1 restores the more natural interpretation

```
    %h = ( 'v65' => 42 );
```

The multi-number v-strings like v65.66 and 65.66.67 still continue to be v-strings in Perl 5.8.

85.2.4 (Win32) The -C Switch Has Been Repurposed

The -C switch has changed in an incompatible way. The old semantics of this switch only made sense in Win32 and only in the "use utf8" universe in 5.6.x releases, and do not make sense for the Unicode implementation in 5.8.0. Since this switch could not have been used by anyone, it has been repurposed. The behavior that this switch enabled in 5.6.x releases may be supported in a transparent, data-dependent fashion in a future release.

For the new life of this switch, see §85.3.1, and -C in *perlrun*.

85.2.5 (Win32) The /d Switch Of cmd.exe

Perl 5.8.1 uses the /d switch when running the cmd.exe shell internally for system(), backticks, and when opening pipes to external programs. The extra switch disables the execution of AutoRun commands from the registry, which is generally considered undesirable when running external programs. If you wish to retain compatibility with the older behavior, set PERL5SHELL in your environment to `cmd /x/c`.

85.3 Core Enhancements

85.3.1 UTF-8 no longer default under UTF-8 locales

In Perl 5.8.0 many Unicode features were introduced. One of them was found to be of more nuisance than benefit: the automagic (and silent) "UTF-8-ification" of filehandles, including the standard filehandles, if the user's locale settings indicated use of UTF-8.

For example, if you had `en_US.UTF-8` as your locale, your STDIN and STDOUT were automatically "UTF-8", in other words an implicit binmode(..., ":utf8") was made. This meant that trying to print, say, chr(0xff), ended up printing the bytes 0xc3 0xbf. Hardly what you had in mind unless you were aware of this feature of Perl 5.8.0. The problem is that the vast majority of people weren't: for example in RedHat releases 8 and 9 the **default** locale setting is UTF-8, so all RedHat users got UTF-8 filehandles, whether they wanted it or not. The pain was intensified by the Unicode implementation of Perl 5.8.0 (still) having nasty bugs, especially related to the use of s/// and tr///. (Bugs that have been fixed in 5.8.1)

Therefore a decision was made to backtrack the feature and change it from implicit silent default to explicit conscious option. The new Perl command line option `-C` and its counterpart environment variable PERL_UNICODE can now be used to control how Perl and Unicode interact at interfaces like I/O and for example the command line arguments. See -C in *perlrun* and PERL_UNICODE in *perlrun* for more information.

85.3.2 Unsafe signals again available

In Perl 5.8.0 the so-called "safe signals" were introduced. This means that Perl no longer handles signals immediately but instead "between opcodes", when it is safe to do so. The earlier immediate handling easily could corrupt the internal state of Perl, resulting in mysterious crashes.

However, the new safer model has its problems too. Because now an opcode, a basic unit of Perl execution, is never interrupted but instead let to run to completion, certain operations that can take a long time now really do take a long time. For example, certain network operations have their own blocking and timeout mechanisms, and being able to interrupt them immediately would be nice.

Therefore perl 5.8.1 introduces a "backdoor" to restore the pre-5.8.0 (pre-5.7.3, really) signal behaviour. Just set the environment variable PERL_SIGNALS to `unsafe`, and the old immediate (and unsafe) signal handling behaviour returns. See PERL_SIGNALS in *perlrun* and Deferred Signals (Safe Signals) in *perlipc*.

In completely unrelated news, you can now use safe signals with POSIX::SigAction. See POSIX::SigAction in *POSIX*.

85.3.3 Tied Arrays with Negative Array Indices

Formerly, the indices passed to `FETCH`, `STORE`, `EXISTS`, and `DELETE` methods in tied array class were always non-negative. If the actual argument was negative, Perl would call FETCHSIZE implicitly and add the result to the index before passing the result to the tied array method. This behaviour is now optional. If the tied array class contains a package variable named `$NEGATIVE_INDICES` which is set to a true value, negative values will be passed to `FETCH`, `STORE`, `EXISTS`, and `DELETE` unchanged.

85.3.4 local $ {$ x}

The syntaxes

```
        local ${$x}
        local @{$x}
        local %{$x}
```

now do localise variables, given that the $x is a valid variable name.

85.3.5 Unicode Character Database 4.0.0

The copy of the Unicode Character Database included in Perl 5.8 has been updated to 4.0.0 from 3.2.0. This means for example that the Unicode character properties are as in Unicode 4.0.0.

85.3.6 Deprecation Warnings

There is one new feature deprecation. Perl 5.8.0 forgot to add some deprecation warnings, these warnings have now been added. Finally, a reminder of an impending feature removal.

(Reminder) Pseudo-hashes are deprecated (really)

Pseudo-hashes were deprecated in Perl 5.8.0 and will be removed in Perl 5.10.0, see *perl58delta* for details. Each attempt to access pseudo-hashes will trigger the warning `Pseudo-hashes are deprecated`. If you really want to continue using pseudo-hashes but not to see the deprecation warnings, use:

```
    no warnings 'deprecated';
```

Or you can continue to use the *fields* pragma, but please don't expect the data structures to be pseudohashes any more.

(Reminder) 5.005-style threads are deprecated (really)

5.005-style threads (activated by `use Thread;`) were deprecated in Perl 5.8.0 and will be removed after Perl 5.8, see *perl58delta* for details. Each 5.005-style thread creation will trigger the warning `5.005 threads are deprecated`. If you really want to continue using the 5.005 threads but not to see the deprecation warnings, use:

```
    no warnings 'deprecated';
```

(Reminder) The $ * variable is deprecated (really)

The `$*` variable controlling multi-line matching has been deprecated and will be removed after 5.8. The variable has been deprecated for a long time, and a deprecation warning `Use of $* is deprecated` is given, now the variable will just finally be removed. The functionality has been supplanted by the `/s` and `/m` modifiers on pattern matching. If you really want to continue using the `$*`-variable but not to see the deprecation warnings, use:

```
    no warnings 'deprecated';
```

85.3.7 Miscellaneous Enhancements

`map` in void context is no longer expensive. `map` is now context aware, and will not construct a list if called in void context.

If a socket gets closed by the server while printing to it, the client now gets a SIGPIPE. While this new feature was not planned, it fell naturally out of PerlIO changes, and is to be considered an accidental feature.

PerlIO::get_layers(FH) returns the names of the PerlIO layers active on a filehandle.

PerlIO::via layers can now have an optional UTF8 method to indicate whether the layer wants to "auto-:utf8" the stream.

utf8::is_utf8() has been added as a quick way to test whether a scalar is encoded internally in UTF-8 (Unicode).

85.4 Modules and Pragmata

85.4.1 Updated Modules And Pragmata

The following modules and pragmata have been updated since Perl 5.8.0:

base

B::Bytecode

In much better shape than it used to be. Still far from perfect, but maybe worth a try.

B::Concise

B::Deparse

Benchmark

An optional feature, `:hireswallclock`, now allows for high resolution wall clock times (uses Time::HiRes).

ByteLoader

See B::Bytecode.

bytes

Now has bytes::substr.

CGI

charnames

One can now have custom character name aliases.

CPAN

There is now a simple command line frontend to the CPAN.pm module called *cpan*.

Data::Dumper

A new option, Pair, allows choosing the separator between hash keys and values.

DB_File

Devel::PPPort

Digest::MD5

Encode

Significant updates on the encoding pragma functionality (tr/// and the DATA filehandle, formats).

If a filehandle has been marked as to have an encoding, unmappable characters are detected already during input, not later (when the corrupted data is being used).

The ISO 8859-6 conversion table has been corrected (the 0x30..0x39 erroneously mapped to U+0660..U+0669, instead of U+0030..U+0039). The GSM 03.38 conversion did not handle escape sequences correctly. The UTF-7 encoding has been added (making Encode feature-complete with Unicode::String).

fields

libnet

Math::BigInt

A lot of bugs have been fixed since v1.60, the version included in Perl v5.8.0. Especially noteworthy are the bug in Calc that caused div and mod to fail for some large values, and the fixes to the handling of bad inputs.

Some new features were added, e.g. the broot() method, you can now pass parameters to config() to change some settings at runtime, and it is now possible to trap the creation of NaN and infinity.

As usual, some optimizations took place and made the math overall a tad faster. In some cases, quite a lot faster, actually. Especially alternative libraries like Math::BigInt::GMP benefit from this. In addition, a lot of the quite clunky routines like fsqrt() and flog() are now much much faster.

MIME::Base64

NEXT

Diamond inheritance now works.

Net::Ping

PerlIO::scalar

Reading from non-string scalars (like the special variables, see *perlvar*) now works.

podlators

Pod::LaTeX

PodParsers

Pod::Perldoc

Complete rewrite. As a side-effect, no longer refuses to startup when run by root.

Scalar::Util

New utilities: refaddr, isvstring, looks_like_number, set_prototype.

Storable

Can now store code references (via B::Deparse, so not foolproof).

strict

Earlier versions of the strict pragma did not check the parameters implicitly passed to its "import" (use) and "unimport" (no) routine. This caused the false idiom such as:

```
    use strict qw(@ISA);
    @ISA = qw(Foo);
```

This however (probably) raised the false expectation that the strict refs, vars and subs were being enforced (and that @ISA was somehow "declared"). But the strict refs, vars, and subs are **not** enforced when using this false idiom.

Starting from Perl 5.8.1, the above **will** cause an error to be raised. This may cause programs which used to execute seemingly correctly without warnings and errors to fail when run under 5.8.1. This happens because

```
    use strict qw(@ISA);
```

will now fail with the error:

```
    Unknown 'strict' tag(s) '@ISA'
```

The remedy to this problem is to replace this code with the correct idiom:

```
    use strict;
    use vars qw(@ISA);
    @ISA = qw(Foo);
```

Term::ANSIcolor

Test::Harness

Now much more picky about extra or missing output from test scripts.

Test::More

Test::Simple

Text::Balanced

Time::HiRes

Use of nanosleep(), if available, allows mixing subsecond sleeps with alarms.

threads

Several fixes, for example for join() problems and memory leaks. In some platforms (like Linux) that use glibc the minimum memory footprint of one ithread has been reduced by several hundred kilobytes.

threads::shared

Many memory leaks have been fixed.

Unicode::Collate

Unicode::Normalize

Win32::GetFolderPath

Win32::GetOSVersion

Now returns extra information.

85.5 Utility Changes

The `h2xs` utility now produces a more modern layout: *Foo-Bar/lib/Foo/Bar.pm* instead of *Foo/Bar/Bar.pm*. Also, the boilerplate test is now called *t/Foo-Bar.t* instead of *t/1.t*.

The Perl debugger (*lib/perl5db.pl*) has now been extensively documented and bugs found while documenting have been fixed.

`perldoc` has been rewritten from scratch to be more robust and featureful.

`perlcc -B` works now at least somewhat better, while `perlcc -c` is rather more broken. (The Perl compiler suite as a whole continues to be experimental.)

85.6 New Documentation

perl573delta has been added to list the differences between the (now quite obsolete) development releases 5.7.2 and 5.7.3.

perl58delta has been added: it is the perldelta of 5.8.0, detailing the differences between 5.6.0 and 5.8.0.

perlartistic has been added: it is the Artistic License in pod format, making it easier for modules to refer to it.

perlcheat has been added: it is a Perl cheat sheet.

perlgpl has been added: it is the GNU General Public License in pod format, making it easier for modules to refer to it.

perlmacosx has been added to tell about the installation and use of Perl in Mac OS X.

perlos400 has been added to tell about the installation and use of Perl in OS/400 PASE.

perlreref has been added: it is a regular expressions quick reference.

85.7 Installation and Configuration Improvements

The UNIX standard Perl location, */usr/bin/perl*, is no longer overwritten by default if it exists. This change was very prudent because so many UNIX vendors already provide a */usr/bin/perl*, but simultaneously many system utilities may depend on that exact version of Perl, so better not to overwrite it.

One can now specify installation directories for site and vendor man and HTML pages, and site and vendor scripts. See *INSTALL*.

One can now specify a destination directory for Perl installation by specifying the DESTDIR variable for `make install`. (This feature is slightly different from the previous `Configure -Dinstallprefix=...`.) See *INSTALL*.

gcc versions 3.x introduced a new warning that caused a lot of noise during Perl compilation: `gcc -Ialreadyknowndirectory (warning:  changing search order)`. This warning has now been avoided by Configure weeding out such directories before the compilation.

One can now build subsets of Perl core modules by using the Configure flags `-Dnoextensions=...` and `-Donlyextensions=...`, see *INSTALL*.

85.7.1 Platform-specific enhancements

In Cygwin Perl can now be built with threads (`Configure -Duseithreads`). This works with both Cygwin 1.3.22 and Cygwin 1.5.3.

In newer FreeBSD releases Perl 5.8.0 compilation failed because of trying to use *malloc.h*, which in FreeBSD is just a dummy file, and a fatal error to even try to use. Now *malloc.h* is not used.

Perl is now known to build also in Hitachi HI-UXMPP.

Perl is now known to build again in LynxOS.

Mac OS X now installs with Perl version number embedded in installation directory names for easier upgrading of user-compiled Perl, and the installation directories in general are more standard. In other words, the default installation no longer breaks the Apple-provided Perl. On the other hand, with `Configure -Dprefix=/usr` you can now really replace the Apple-supplied Perl (**please be careful**).

Mac OS X now builds Perl statically by default. This change was done mainly for faster startup times. The Apple-provided Perl is still dynamically linked and shared, and you can enable the sharedness for your own Perl builds by `Configure -Duseshrplib`.

Perl has been ported to IBM's OS/400 PASE environment. The best way to build a Perl for PASE is to use an AIX host as a cross-compilation environment. See README.os400.

Yet another cross-compilation option has been added: now Perl builds on OpenZaurus, an Linux distribution based on Mandrake + Embedix for the Sharp Zaurus PDA. See the Cross/README file.

Tru64 when using gcc 3 drops the optimisation for *toke.c* to `-O2` because of gigantic memory use with the default `-O3`.

Tru64 can now build Perl with the newer Berkeley DBs.

Building Perl on WinCE has been much enhanced, see *README.ce* and *README.perlce*.

85.8 Selected Bug Fixes

85.8.1 Closures, eval and lexicals

There have been many fixes in the area of anonymous subs, lexicals and closures. Although this means that Perl is now more "correct", it is possible that some existing code will break that happens to rely on the faulty behaviour. In practice this is unlikely unless your code contains a very complex nesting of anonymous subs, evals and lexicals.

85.8.2 Generic fixes

If an input filehandle is marked `:utf8` and Perl sees illegal UTF-8 coming in when doing `<FH>`, if warnings are enabled a warning is immediately given - instead of being silent about it and Perl being unhappy about the broken data later. (The `:encoding(utf8)` layer also works the same way.)

binmode(SOCKET, ":utf8") only worked on the input side, not on the output side of the socket. Now it works both ways.

For threaded Perls certain system database functions like getpwent() and getgrent() now grow their result buffer dynamically, instead of failing. This means that at sites with lots of users and groups the functions no longer fail by returning only partial results.

Perl 5.8.0 had accidentally broken the capability for users to define their own uppercase<->lowercase Unicode mappings (as advertised by the Camel). This feature has been fixed and is also documented better.

In 5.8.0 this

```
    $some_unicode .= <FH>;
```

didn't work correctly but instead corrupted the data. This has now been fixed.

Tied methods like FETCH etc. may now safely access tied values, i.e. resulting in a recursive call to FETCH etc. Remember to break the recursion, though.

At startup Perl blocks the SIGFPE signal away since there isn't much Perl can do about it. Previously this blocking was in effect also for programs executed from within Perl. Now Perl restores the original SIGFPE handling routine, whatever it was, before running external programs.

Linenumbers in Perl scripts may now be greater than 65536, or 2**16. (Perl scripts have always been able to be larger than that, it's just that the linenumber for reported errors and warnings have "wrapped around".) While scripts that large usually indicate a need to rethink your code a bit, such Perl scripts do exist, for example as results from generated code. Now linenumbers can go all the way to 4294967296, or 2**32.

85.8.3 Platform-specific fixes

Linux

- Setting $0 works again (with certain limitations that Perl cannot do much about: see `$0` in *perlvar*)

HP-UX

- Setting $0 now works.

VMS

- Configuration now tests for the presence of `poll()`, and IO::Poll now uses the vendor-supplied function if detected.
- A rare access violation at Perl start-up could occur if the Perl image was installed with privileges or if there was an identifier with the subsystem attribute set in the process's rightslist. Either of these circumstances triggered tainting code that contained a pointer bug. The faulty pointer arithmetic has been fixed.
- The length limit on values (not keys) in the %ENV hash has been raised from 255 bytes to 32640 bytes (except when the PERL_ENV_TABLES setting overrides the default use of logical names for %ENV). If it is necessary to access these long values from outside Perl, be aware that they are implemented using search list logical names that store the value in pieces, each 255-byte piece (up to 128 of them) being an element in the search list. When doing a lookup in %ENV from within Perl, the elements are combined into a single value. The existing VMS-specific ability to access individual elements of a search list logical name via the $ENV{'foo;N'} syntax (where N is the search list index) is unimpaired.
- The piping implementation now uses local rather than global DCL symbols for inter-process communication.

- File::Find could become confused when navigating to a relative directory whose name collided with a logical name. This problem has been corrected by adding directory syntax to relative path names, thus preventing logical name translation.

Win32

- A memory leak in the fork() emulation has been fixed.
- The return value of the ioctl() built-in function was accidentally broken in 5.8.0. This has been corrected.
- The internal message loop executed by perl during blocking operations sometimes interfered with messages that were external to Perl. This often resulted in blocking operations terminating prematurely or returning incorrect results, when Perl was executing under environments that could generate Windows messages. This has been corrected.
- Pipes and sockets are now automatically in binary mode.
- The four-argument form of select() did not preserve $! (errno) properly when there were errors in the underlying call. This is now fixed.
- The "CR CR LF" problem of has been fixed, binmode(FH, ":crlf") is now effectively a no-op.

85.9 New or Changed Diagnostics

All the warnings related to pack() and unpack() were made more informative and consistent.

85.9.1 Changed "A thread exited while %d threads were running"

The old version

```
    A thread exited while %d other threads were still running
```

was misleading because the "other" included also the thread giving the warning.

85.9.2 Removed "Attempt to clear a restricted hash"

It is not illegal to clear a restricted hash, so the warning was removed.

85.9.3 New "Illegal declaration of anonymous subroutine"

You must specify the block of code for `sub`.

85.9.4 Changed "Invalid range "%s" in transliteration operator"

The old version

```
    Invalid [] range "%s" in transliteration operator
```

was simply wrong because there are no "[] ranges" in tr///.

85.9.5 New "Missing control char name in \c"

Self-explanatory.

85.9.6 New "Newline in left-justified string for %s"

The padding spaces would appear after the newline, which is probably not what you had in mind.

85.9.7 New "Possible precedence problem on bitwise %c operator"

If you think this

```
    $x & $y == 0
```

tests whether the bitwise AND of $x and $y is zero, you will like this warning.

85.9.8 New "Pseudo-hashes are deprecated"

This warning should have been already in 5.8.0, since they are.

85.9.9 New "read() on %s filehandle %s"

You cannot read() (or sysread()) from a closed or unopened filehandle.

85.9.10 New "5.005 threads are deprecated"

This warning should have been already in 5.8.0, since they are.

85.9.11 New "Tied variable freed while still in use"

Something pulled the plug on a live tied variable, Perl plays safe by bailing out.

85.9.12 New "To%s: illegal mapping '%s'"

An illegal user-defined Unicode casemapping was specified.

85.9.13 New "Use of freed value in iteration"

Something modified the values being iterated over. This is not good.

85.10 Changed Internals

These news matter to you only if you either write XS code or like to know about or hack Perl internals (using Devel::Peek or any of the `B::` modules counts), or like to run Perl with the `-D` option.

The embedding examples of *perlembed* have been reviewed to be uptodate and consistent: for example, the correct use of PERL_SYS_INIT3() and PERL_SYS_TERM().

Extensive reworking of the pad code (the code responsible for lexical variables) has been conducted by Dave Mitchell.

Extensive work on the v-strings by John Peacock.

UTF-8 length and position cache: to speed up the handling of Unicode (UTF-8) scalars, a cache was introduced. Potential problems exist if an extension bypasses the official APIs and directly modifies the PV of an SV: the UTF-8 cache does not get cleared as it should.

APIs obsoleted in Perl 5.8.0, like sv_2pv, sv_catpvn, sv_catsv, sv_setsv, are again available.

Certain Perl core C APIs like cxinc and regatom are no longer available at all to code outside the Perl core of the Perl core extensions. This is intentional. They never should have been available with the shorter names, and if you application depends on them, you should (be ashamed and) contact perl5-porters to discuss what are the proper APIs.

Certain Perl core C APIs like `Perl_list` are no longer available without their `Perl_` prefix. If your XS module stops working because some functions cannot be found, in many cases a simple fix is to add the `Perl_` prefix to the function and the thread context `aTHX_` as the first argument of the function call. This is also how it should always have been done: letting the Perl_-less forms to leak from the core was an accident. For cleaner embedding you can also force this for all APIs by defining at compile time the cpp define PERL_NO_SHORT_NAMES.

Perl_save_bool() has been added.

Regexp objects (those created with `qr`) now have S-magic rather than R-magic. This fixed regexps of the form /...(??{...;$x})/ to no longer ignore changes made to $x. The S-magic avoids dropping the caching optimization and making (??{...}) constructs obscenely slow (and consequently useless). See also Magic Variables in *perlguts*. Regexp::Copy was affected by this change.

The Perl internal debugging macros DEBUG() and DEB() have been renamed to PERL_DEBUG() and PERL_DEB() to avoid namespace conflicts.

`-DL` removed (the leaktest had been broken and unsupported for years, use alternative debugging mallocs or tools like valgrind and Purify).

Verbose modifier `v` added for `-DXv` and `-Dsv`, see *perlrun*.

85.11 New Tests

In Perl 5.8.0 there were about 69000 separate tests in about 700 test files, in Perl 5.8.1 there are about 77000 separate tests in about 780 test files. The exact numbers depend on the Perl configuration and on the operating system platform.

85.12 Known Problems

The hash randomisation mentioned in Incompatible Changes is definitely problematic: it will wake dormant bugs and shake out bad assumptions.

If you want to use mod_perl 2.x with Perl 5.8.1, you will need mod_perl-1.99_10 or higher. Earlier versions of mod_perl 2.x do not work with the randomised hashes. (mod_perl 1.x works fine.) You will also need Apache::Test 1.04 or higher.

Many of the rarer platforms that worked 100% or pretty close to it with perl 5.8.0 have been left a little bit untended since their maintainers have been otherwise busy lately, and therefore there will be more failures on those platforms. Such platforms include Mac OS Classic, IBM z/OS (and other EBCDIC platforms), and NetWare. The most common Perl platforms (Unix and Unix-like, Microsoft platforms, and VMS) have large enough testing and expert population that they are doing well.

85.12.1 Tied hashes in scalar context

Tied hashes do not currently return anything useful in scalar context, for example when used as boolean tests:

```
        if (%tied_hash) { ... }
```

The current nonsensical behaviour is always to return false, regardless of whether the hash is empty or has elements.

The root cause is that there is no interface for the implementors of tied hashes to implement the behaviour of a hash in scalar context.

85.12.2 Net::Ping 450_service and 510_ping_udp failures

The subtests 9 and 18 of lib/Net/Ping/t/450_service.t, and the subtest 2 of lib/Net/Ping/t/510_ping_udp.t might fail if you have an unusual networking setup. For example in the latter case the test is trying to send a UDP ping to the IP address 127.0.0.1.

85.12.3 B::C

The C-generating compiler backend B::C (the frontend being `perlcc -c`) is even more broken than it used to be because of the extensive lexical variable changes. (The good news is that B::Bytecode and ByteLoader are better than they used to be.)

85.13 Platform Specific Problems

85.13.1 EBCDIC Platforms

IBM z/OS and other EBCDIC platforms continue to be problematic regarding Unicode support. Many Unicode tests are skipped when they really should be fixed.

85.13.2 Cygwin 1.5 problems

In Cygwin 1.5 the *io/tell* and *op/sysio* tests have failures for some yet unknown reason. In 1.5.5 the threads tests stress_cv, stress_re, and stress_string are failing unless the environment variable PERLIO is set to "perlio" (which makes also the io/tell failure go away).

Perl 5.8.1 does build and work well with Cygwin 1.3: with (uname -a) `CYGWIN_NT-5.0 ... 1.3.22(0.78/3/2) 2003-03-18 09:20 i686 ...` a 100% "make test" was achieved with `Configure -des -Duseithreads`.

85.13.3 HP-UX: HP cc warnings about sendfile and sendpath

With certain HP C compiler releases (e.g. B.11.11.02) you will get many warnings like this (lines wrapped for easier reading):

```
  cc: "/usr/include/sys/socket.h", line 504: warning 562:
    Redeclaration of "sendfile" with a different storage class specifier:
      "sendfile" will have internal linkage.
  cc: "/usr/include/sys/socket.h", line 505: warning 562:
    Redeclaration of "sendpath" with a different storage class specifier:
      "sendpath" will have internal linkage.
```

The warnings show up both during the build of Perl and during certain lib/ExtUtils tests that invoke the C compiler. The warning, however, is not serious and can be ignored.

85.13.4 IRIX: t/uni/tr_7jis.t falsely failing

The test t/uni/tr_7jis.t is known to report failure under 'make test' or the test harness with certain releases of IRIX (at least IRIX 6.5 and MIPSpro Compilers Version 7.3.1.1m), but if run manually the test fully passes.

85.13.5 Mac OS X: no usemymalloc

The Perl malloc (`-Dusemymalloc`) does not work at all in Mac OS X. This is not that serious, though, since the native malloc works just fine.

85.13.6 Tru64: No threaded builds with GNU cc (gcc)

In the latest Tru64 releases (e.g. v5.1B or later) gcc cannot be used to compile a threaded Perl (-Duseithreads) because the system <`pthread.h`> file doesn't know about gcc.

85.13.7 Win32: sysopen, sysread, syswrite

As of the 5.8.0 release, sysopen()/sysread()/syswrite() do not behave like they used to in 5.6.1 and earlier with respect to "text" mode. These built-ins now always operate in "binary" mode (even if sysopen() was passed the O_TEXT flag, or if binmode() was used on the file handle). Note that this issue should only make a difference for disk files, as sockets and pipes have always been in "binary" mode in the Windows port. As this behavior is currently considered a bug, compatible behavior may be re-introduced in a future release. Until then, the use of sysopen(), sysread() and syswrite() is not supported for "text" mode operations.

85.14 Future Directions

The following things **might** happen in future. The first publicly available releases having these characteristics will be the developer releases Perl 5.9.x, culminating in the Perl 5.10.0 release. These are our best guesses at the moment: we reserve the right to rethink.

- PerlIO will become The Default. Currently (in Perl 5.8.x) the stdio library is still used if Perl thinks it can use certain tricks to make stdio go **really** fast. For future releases our goal is to make PerlIO go even faster.
- A new feature called *assertions* will be available. This means that one can have code called assertions sprinkled in the code: usually they are optimised away, but they can be enabled with the `-A` option.
- A new operator `//` (defined-or) will be available. This means that one will be able to say

  ```
   $a // $b
  ```

  instead of

  ```
  defined $a ? $a : $b
  ```

  and

  ```
  $c //= $d;
  ```

  instead of

  ```
  $c = $d unless defined $c;
  ```

  The operator will have the same precedence and associativity as ||. A source code patch against the Perl 5.8.1 sources will be available in CPAN as *authors/id/H/HM/HMBRAND/dor-5.8.1.diff*.
- `unpack()` will default to unpacking the `$_`.
- Various Copy-On-Write techniques will be investigated in hopes of speeding up Perl.
- CPANPLUS, Inline, and Module::Build will become core modules.
- The ability to write true lexically scoped pragmas will be introduced.
- Work will continue on the bytecompiler and byteloader.
- v-strings as they currently exist are scheduled to be deprecated. The v-less form (1.2.3) will become a "version object" when used with `use`, `require`, and `$VERSION`. $^V will also be a "version object" so the printf("%vd",...) construct will no longer be needed. The v-ful version (v1.2.3) will become obsolete. The equivalence of strings and v-strings (e.g. that currently 5.8.0 is equal to "\5\8\0") will go away. **There may be no deprecation warning for v-strings**, though: it is quite hard to detect when v-strings are being used safely, and when they are not.
- 5.005 Threads Will Be Removed
- The `$*` Variable Will Be Removed (it was deprecated a long time ago)
- Pseudohashes Will Be Removed

85.15 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org/ . There may also be information at http://www.perl.com/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team. You can browse and search the Perl 5 bugs at http://bugs.perl.org/

85.16 SEE ALSO

Chapter 86

perl58delta

What is new for perl v5.8.0

86.1 DESCRIPTION

This document describes differences between the 5.6.0 release and the 5.8.0 release.

Many of the bug fixes in 5.8.0 were already seen in the 5.6.1 maintenance release since the two releases were kept closely coordinated (while 5.8.0 was still called 5.7.something).

Changes that were integrated into the 5.6.1 release are marked `[561]`. Many of these changes have been further developed since 5.6.1 was released, those are marked `[561+]`.

You can see the list of changes in the 5.6.1 release (both from the 5.005_03 release and the 5.6.0 release) by reading *perl561delta*.

86.2 Highlights In 5.8.0

- Better Unicode support
- New IO Implementation
- New Thread Implementation
- Better Numeric Accuracy
- Safe Signals
- Many New Modules
- More Extensive Regression Testing

86.3 Incompatible Changes

86.3.1 Binary Incompatibility

Perl 5.8 is not binary compatible with earlier releases of Perl.

You have to recompile your XS modules.

(Pure Perl modules should continue to work.)

The major reason for the discontinuity is the new IO architecture called PerlIO. PerlIO is the default configuration because without it many new features of Perl 5.8 cannot be used. In other words: you just have to recompile your modules containing XS code, sorry about that.

In future releases of Perl, non-PerlIO aware XS modules may become completely unsupported. This shouldn't be too difficult for module authors, however: PerlIO has been designed as a drop-in replacement (at the source code level) for the stdio interface.

Depending on your platform, there are also other reasons why we decided to break binary compatibility, please read on.

86.3.2 64-bit platforms and malloc

If your pointers are 64 bits wide, the Perl malloc is no longer being used because it does not work well with 8-byte pointers. Also, usually the system mallocs on such platforms are much better optimized for such large memory models than the Perl malloc. Some memory-hungry Perl applications like the PDL don't work well with Perl's malloc. Finally, other applications than Perl (such as mod_perl) tend to prefer the system malloc. Such platforms include Alpha and 64-bit HPPA, MIPS, PPC, and Sparc.

86.3.3 AIX Dynaloading

The AIX dynaloading now uses in AIX releases 4.3 and newer the native dlopen interface of AIX instead of the old emulated interface. This change will probably break backward compatibility with compiled modules. The change was made to make Perl more compliant with other applications like mod_perl which are using the AIX native interface.

86.3.4 Attributes for `my` variables now handled at run-time

The `my EXPR : ATTRS` syntax now applies variable attributes at run-time. (Subroutine and `our` variables still get attributes applied at compile-time.) See *attributes* for additional details. In particular, however, this allows variable attributes to be useful for `tie` interfaces, which was a deficiency of earlier releases. Note that the new semantics doesn't work with the Attribute::Handlers module (as of version 0.76).

86.3.5 Socket Extension Dynamic in VMS

The Socket extension is now dynamically loaded instead of being statically built in. This may or may not be a problem with ancient TCP/IP stacks of VMS: we do not know since we weren't able to test Perl in such configurations.

86.3.6 IEEE-format Floating Point Default on OpenVMS Alpha

Perl now uses IEEE format (T_FLOAT) as the default internal floating point format on OpenVMS Alpha, potentially breaking binary compatibility with external libraries or existing data. G_FLOAT is still available as a configuration option. The default on VAX (D_FLOAT) has not changed.

86.3.7 New Unicode Semantics (no more `use utf8`, almost)

Previously in Perl 5.6 to use Unicode one would say "use utf8" and then the operations (like string concatenation) were Unicode-aware in that lexical scope.

This was found to be an inconvenient interface, and in Perl 5.8 the Unicode model has completely changed: now the "Unicodeness" is bound to the data itself, and for most of the time "use utf8" is not needed at all. The only remaining use of "use utf8" is when the Perl script itself has been written in the UTF-8 encoding of Unicode. (UTF-8 has not been made the default since there are many Perl scripts out there that are using various national eight-bit character sets, which would be illegal in UTF-8.)

See *perluniintro* for the explanation of the current model, and *utf8* for the current use of the utf8 pragma.

86.3.8 New Unicode Properties

Unicode *scripts* are now supported. Scripts are similar to (and superior to) Unicode *blocks*. The difference between scripts and blocks is that scripts are the glyphs used by a language or a group of languages, while the blocks are more artificial groupings of (mostly) 256 characters based on the Unicode numbering.

In general, scripts are more inclusive, but not universally so. For example, while the script `Latin` includes all the Latin characters and their various diacritic-adorned versions, it does not include the various punctuation or digits (since they are not solely `Latin`).

A number of other properties are now supported, including `\p{L&}`, `\p{Any}` `\p{Assigned}`, `\p{Unassigned}`, `\p{Blank}` [561] and `\p{SpacePerl}` [561] (along with their `\P{...}` versions, of course). See *perlunicode* for details, and more additions.

The `In` or `Is` prefix to names used with the `\p{...}` and `\P{...}` are now almost always optional. The only exception is that a `In` prefix is required to signify a Unicode block when a block name conflicts with a script name. For example, `\p{Tibetan}` refers to the script, while `\p{InTibetan}` refers to the block. When there is no name conflict, you can omit the `In` from the block name (e.g. `\p{BraillePatterns}`), but to be safe, it's probably best to always use the `In`).

86.3.9 REF(...) Instead Of SCALAR(...)

A reference to a reference now stringifies as "REF(0x81485ec)" instead of "SCALAR(0x81485ec)" in order to be more consistent with the return value of ref().

86.3.10 pack/unpack D/F recycled

The undocumented pack/unpack template letters D/F have been recycled for better use: now they stand for long double (if supported by the platform) and NV (Perl internal floating point type). (They used to be aliases for d/f, but you never knew that.)

86.3.11 glob() now returns filenames in alphabetical order

The list of filenames from glob() (or <...>) is now by default sorted alphabetically to be csh-compliant (which is what happened before in most UNIX platforms). (bsd_glob() does still sort platform natively, ASCII or EBCDIC, unless GLOB_ALPHASORT is specified.) [561]

86.3.12 Deprecations

- The semantics of bless(REF, REF) were unclear and until someone proves it to make some sense, it is forbidden.
- The obsolete chat2 library that should never have been allowed to escape the laboratory has been decommissioned.
- Using chdir("") or chdir(undef) instead of explicit chdir() is doubtful. A failure (think chdir(some_function()) can lead into unintended chdir() to the home directory, therefore this behaviour is deprecated.
- The builtin dump() function has probably outlived most of its usefulness. The core-dumping functionality will remain in future available as an explicit call to `CORE::dump()`, but in future releases the behaviour of an unqualified `dump()` call may change.
- The very dusty examples in the eg/ directory have been removed. Suggestions for new shiny examples welcome but the main issue is that the examples need to be documented, tested and (most importantly) maintained.
- The (bogus) escape sequences \8 and \9 now give an optional warning ("Unrecognized escape passed through"). There is no need to \-escape any `\w` character.
- The *glob{FILEHANDLE} is deprecated, use *glob{IO} instead.

- The `package;` syntax (`package` without an argument) has been deprecated. Its semantics were never that clear and its implementation even less so. If you have used that feature to disallow all but fully qualified variables, `use strict;` instead.

- The unimplemented POSIX regex features [[.cc.]] and [[=c=]] are still recognised but now cause fatal errors. The previous behaviour of ignoring them by default and warning if requested was unacceptable since it, in a way, falsely promised that the features could be used.

- In future releases, non-PerlIO aware XS modules may become completely unsupported. Since PerlIO is a drop-in replacement for stdio at the source code level, this shouldn't be that drastic a change.

- Previous versions of perl and some readings of some sections of Camel III implied that the `:raw` "discipline" was the inverse of `:crlf`. Turning off "clrfness" is no longer enough to make a stream truly binary. So the PerlIO `:raw` layer (or "discipline", to use the Camel book's older terminology) is now formally defined as being equivalent to binmode(FH) - which is in turn defined as doing whatever is necessary to pass each byte as-is without any translation. In particular binmode(FH) - and hence `:raw` - will now turn off both CRLF and UTF-8 translation and remove other layers (e.g. :encoding()) which would modify byte stream.

- The current user-visible implementation of pseudo-hashes (the weird use of the first array element) is deprecated starting from Perl 5.8.0 and will be removed in Perl 5.10.0, and the feature will be implemented differently. Not only is the current interface rather ugly, but the current implementation slows down normal array and hash use quite noticeably. The `fields` pragma interface will remain available. The *restricted hashes* interface is expected to be the replacement interface (see *Hash::Util*). If your existing programs depends on the underlying implementation, consider using *Class::PseudoHash* from CPAN.

- The syntaxes `@a->[...]` and `%h->{...}` have now been deprecated.

- After years of trying, suidperl is considered to be too complex to ever be considered truly secure. The suidperl functionality is likely to be removed in a future release.

- The 5.005 threads model (module `Thread`) is deprecated and expected to be removed in Perl 5.10. Multithreaded code should be migrated to the new ithreads model (see *threads*, *threads::shared* and *perlthrtut*).

- The long deprecated uppercase aliases for the string comparison operators (EQ, NE, LT, LE, GE, GT) have now been removed.

- The tr///C and tr///U features have been removed and will not return; the interface was a mistake. Sorry about that. For similar functionality, see pack('U0', ...) and pack('C0', ...). [561]

- Earlier Perls treated "sub foo (@bar)" as equivalent to "sub foo (@)". The prototypes are now checked better at compile-time for invalid syntax. An optional warning is generated ("Illegal character in prototype...") but this may be upgraded to a fatal error in a future release.

- The `exec LIST` and `system LIST` operations now produce warnings on tainted data and in some future release they will produce fatal errors.

- The existing behaviour when localising tied arrays and hashes is wrong, and will be changed in a future release, so do not rely on the existing behaviour. See §86.15.2.

86.4 Core Enhancements

86.4.1 Unicode Overhaul

Unicode in general should be now much more usable than in Perl 5.6.0 (or even in 5.6.1). Unicode can be used in hash keys, Unicode in regular expressions should work now, Unicode in tr/// should work now, Unicode in I/O should work now. See *perluniintro* for introduction and *perlunicode* for details.

- The Unicode Character Database coming with Perl has been upgraded to Unicode 3.2.0. For more information, see http://www.unicode.org/ . [561+] (5.6.1 has UCD 3.0.1.)

- For developers interested in enhancing Perl's Unicode capabilities: almost all the UCD files are included with the Perl distribution in the *lib/unicore* subdirectory. The most notable omission, for space considerations, is the Unihan database.
- The properties \p{Blank} and \p{SpacePerl} have been added. "Blank" is like C isblank(), that is, it contains only "horizontal whitespace" (the space character is, the newline isn't), and the "SpacePerl" is the Unicode equivalent of `\s` (`\p{Space}` isn't, since that includes the vertical tabulator character, whereas `\s` doesn't.)

  See "New Unicode Properties" earlier in this document for additional information on changes with Unicode properties.

86.4.2 PerlIO is Now The Default

- IO is now by default done via PerlIO rather than system's "stdio". PerlIO allows "layers" to be "pushed" onto a file handle to alter the handle's behaviour. Layers can be specified at open time via 3-arg form of open:

  ```
  open($fh,'>:crlf :utf8', $path) || ...
  ```

  or on already opened handles via extended `binmode`:

  ```
  binmode($fh,':encoding(iso-8859-7)');
  ```

  The built-in layers are: unix (low level read/write), stdio (as in previous Perls), perlio (re-implementation of stdio buffering in a portable manner), crlf (does CRLF <=> "\n" translation as on Win32, but available on any platform). A mmap layer may be available if platform supports it (mostly UNIXes).

  Layers to be applied by default may be specified via the 'open' pragma.

  See §86.9 for the effects of PerlIO on your architecture name.
- If your platform supports fork(), you can use the list form of `open` for pipes. For example:

  ```
   open KID_PS, "-|", "ps", "aux" or die $!;
  ```

  forks the ps(1) command (without spawning a shell, as there are more than three arguments to open()), and reads its standard output via the `KID_PS` filehandle. See *perlipc*.
- File handles can be marked as accepting Perl's internal encoding of Unicode (UTF-8 or UTF-EBCDIC depending on platform) by a pseudo layer ":utf8" :

  ```
  open($fh,">:utf8","Uni.txt");
  ```

  Note for EBCDIC users: the pseudo layer ":utf8" is erroneously named for you since it's not UTF-8 what you will be getting but instead UTF-EBCDIC. See *perlunicode*, *utf8*, and http://www.unicode.org/unicode/reports/tr16/ for more information. In future releases this naming may change. See *perluniintro* for more information about UTF-8.
- If your environment variables (LC_ALL, LC_CTYPE, LANG) look like you want to use UTF-8 (any of the the variables match `/utf-?8/i`), your STDIN, STDOUT, STDERR handles and the default open layer (see *open*) are marked as UTF-8. (This feature, like other new features that combine Unicode and I/O, work only if you are using PerlIO, but that's the default.)

  Note that after this Perl really does assume that everything is UTF-8: for example if some input handle is not, Perl will probably very soon complain about the input data like this "Malformed UTF-8 ..." since any old eight-bit data is not legal UTF-8.

  Note for code authors: if you want to enable your users to use UTF-8 as their default encoding but in your code still have eight-bit I/O streams (such as images or zip files), you need to explicitly open() or binmode() with `:bytes` (see open in *perlfunc* and binmode in *perlfunc*), or you can just use `binmode(FH)` (nice for pre-5.8.0 backward compatibility).

- File handles can translate character encodings from/to Perl's internal Unicode form on read/write via the ":encoding()" layer.
- File handles can be opened to "in memory" files held in Perl scalars via:

  ```
  open($fh,'>', \$variable) || ...
  ```

- Anonymous temporary files are available without need to 'use FileHandle' or other module via

  ```
  open($fh,"+>", undef) || ...
  ```

  That is a literal undef, not an undefined value.

86.4.3 ithreads

The new interpreter threads ("ithreads" for short) implementation of multithreading, by Arthur Bergman, replaces the old "5.005 threads" implementation. In the ithreads model any data sharing between threads must be explicit, as opposed to the model where data sharing was implicit. See *threads* and *threads::shared*, and *perlthrtut*.

As a part of the ithreads implementation Perl will also use any necessary and detectable reentrant libc interfaces.

86.4.4 Restricted Hashes

A restricted hash is restricted to a certain set of keys, no keys outside the set can be added. Also individual keys can be restricted so that the key cannot be deleted and the value cannot be changed. No new syntax is involved: the Hash::Util module is the interface.

86.4.5 Safe Signals

Perl used to be fragile in that signals arriving at inopportune moments could corrupt Perl's internal state. Now Perl postpones handling of signals until it's safe (between opcodes).

This change may have surprising side effects because signals no longer interrupt Perl instantly. Perl will now first finish whatever it was doing, like finishing an internal operation (like sort()) or an external operation (like an I/O operation), and only then look at any arrived signals (and before starting the next operation). No more corrupt internal state since the current operation is always finished first, but the signal may take more time to get heard. Note that breaking out from potentially blocking operations should still work, though.

86.4.6 Understanding of Numbers

In general a lot of fixing has happened in the area of Perl's understanding of numbers, both integer and floating point. Since in many systems the standard number parsing functions like `strtoul()` and `atof()` seem to have bugs, Perl tries to work around their deficiencies. This results hopefully in more accurate numbers.

Perl now tries internally to use integer values in numeric conversions and basic arithmetics (+ - * /) if the arguments are integers, and tries also to keep the results stored internally as integers. This change leads to often slightly faster and always less lossy arithmetics. (Previously Perl always preferred floating point numbers in its math.)

86.4.7 Arrays now always interpolate into double-quoted strings [561]

In double-quoted strings, arrays now interpolate, no matter what. The behavior in earlier versions of perl 5 was that arrays would interpolate into strings if the array had been mentioned before the string was compiled, and otherwise Perl would raise a fatal compile-time error. In versions 5.000 through 5.003, the error was

```
        Literal @example now requires backslash
```

In versions 5.004_01 through 5.6.0, the error was

```
        In string, @example now must be written as \@example
```

The idea here was to get people into the habit of writing `"fred\@example.com"` when they wanted a literal `@` sign, just as they have always written `"Give me back my \$5"` when they wanted a literal `$` sign.

Starting with 5.6.1, when Perl now sees an `@` sign in a double-quoted string, it *always* attempts to interpolate an array, regardless of whether or not the array has been used or declared already. The fatal error has been downgraded to an optional warning:

```
        Possible unintended interpolation of @example in string
```

This warns you that `"fred@example.com"` is going to turn into `fred.com` if you don't backslash the `@`. See http://www.plover.com/˜mjd/perl/at-error.html for more details about the history here.

86.4.8 Miscellaneous Changes

- AUTOLOAD is now lvaluable, meaning that you can add the :lvalue attribute to AUTOLOAD subroutines and you can assign to the AUTOLOAD return value.
- The $Config{byteorder} (and corresponding BYTEORDER in config.h) was previously wrong in platforms if sizeof(long) was 4, but sizeof(IV) was 8. The byteorder was only sizeof(long) bytes long (1234 or 4321), but now it is correctly sizeof(IV) bytes long, (12345678 or 87654321). (This problem didn't affect Windows platforms.)

  Also, $Config{byteorder} is now computed dynamically–this is more robust with "fat binaries" where an executable image contains binaries for more than one binary platform, and when cross-compiling.
- `perl -d:Module=arg,arg,arg` now works (previously one couldn't pass in multiple arguments.)
- do followed by a bareword now ensures that this bareword isn't a keyword (to avoid a bug where `do q(foo.pl)` tried to call a subroutine called `q`). This means that for example instead of `do format()` you must write `do &format()`.
- The builtin dump() now gives an optional warning `dump() better written as CORE::dump()`, meaning that by default `dump(...)` is resolved as the builtin dump() which dumps core and aborts, not as (possibly) user-defined `sub dump`. To call the latter, qualify the call as `&dump(...)`. (The whole dump() feature is to considered deprecated, and possibly removed/changed in future releases.)
- chomp() and chop() are now overridable. Note, however, that their prototype (as given by `prototype("CORE::chomp")` is undefined, because it cannot be expressed and therefore one cannot really write replacements to override these builtins.
- END blocks are now run even if you exit/die in a BEGIN block. Internally, the execution of END blocks is now controlled by PL_exit_flags & PERL_EXIT_DESTRUCT_END. This enables the new behaviour for Perl embedders. This will default in 5.10. See *perlembed*.
- Formats now support zero-padded decimal fields.
- Although "you shouldn't do that", it was possible to write code that depends on Perl's hashed key order (Data::Dumper does this). The new algorithm "One-at-a-Time" produces a different hashed key order. More details are in §86.8.

- lstat(FILEHANDLE) now gives a warning because the operation makes no sense. In future releases this may become a fatal error.
- Spurious syntax errors generated in certain situations, when glob() caused File::Glob to be loaded for the first time, have been fixed. [561]
- Lvalue subroutines can now return `undef` in list context. However, the lvalue subroutine feature still remains experimental. [561+]
- A lost warning "Can't declare ... dereference in my" has been restored (Perl had it earlier but it became lost in later releases.)
- A new special regular expression variable has been introduced: `$^N`, which contains the most-recently closed group (submatch).
- `no Module;` does not produce an error even if Module does not have an unimport() method. This parallels the behavior of `use` vis-a-vis `import`. [561]
- The numerical comparison operators return `undef` if either operand is a NaN. Previously the behaviour was unspecified.
- `our` can now have an experimental optional attribute `unique` that affects how global variables are shared among multiple interpreters, see `our` in *perlfunc*.
- The following builtin functions are now overridable: each(), keys(), pop(), push(), shift(), splice(), unshift(). [561]
- `pack() / unpack()` can now group template letters with `()` and then apply repetition/count modifiers on the groups.
- `pack() / unpack()` can now process the Perl internal numeric types: IVs, UVs, NVs– and also long doubles, if supported by the platform. The template letters are `j`, `J`, `F`, and `D`.
- `pack('U0a*', ...)` can now be used to force a string to UTF-8.
- my __PACKAGE__ $obj now works. [561]
- POSIX::sleep() now returns the number of *unslept* seconds (as the POSIX standard says), as opposed to CORE::sleep() which returns the number of slept seconds.
- printf() and sprintf() now support parameter reordering using the `%\d+\$` and `*\d+\$` syntaxes. For example

  ```
  printf "%2\$s %1\$s\n", "foo", "bar";
  ```

  will print "bar foo\n". This feature helps in writing internationalised software, and in general when the order of the parameters can vary.
- The (\&) prototype now works properly. [561]
- prototype(\[$@%&]) is now available to implicitly create references (useful for example if you want to emulate the tie() interface).
- A new command-line option, `-t` is available. It is the little brother of `-T`: instead of dying on taint violations, lexical warnings are given. **This is only meant as a temporary debugging aid while securing the code of old legacy applications. This is not a substitute for -T.**
- In other taint news, the `exec LIST` and `system LIST` have now been considered too risky (think `exec @ARGV`: it can start any program with any arguments), and now the said forms cause a warning under lexical warnings. You should carefully launder the arguments to guarantee their validity. In future releases of Perl the forms will become fatal errors so consider starting laundering now.
- Tied hash interfaces are now required to have the EXISTS and DELETE methods (either own or inherited).
- If tr/// is just counting characters, it doesn't attempt to modify its target.

- untie() will now call an UNTIE() hook if it exists. See *perltie* for details. [561]
- *utime* now supports `utime undef, undef, @files` to change the file timestamps to the current time.
- The rules for allowing underscores (underbars) in numeric constants have been relaxed and simplified: now you can have an underscore simply **between digits**.
- Rather than relying on C's argv[0] (which may not contain a full pathname) where possible $ˆX is now set by asking the operating system. (eg by reading */proc/self/exe* on Linux, */proc/curproc/file* on FreeBSD)
- A new variable, `${ˆTAINT}`, indicates whether taint mode is enabled.
- You can now override the readline() builtin, and this overrides also the <FILEHANDLE> angle bracket operator.
- The command-line options -s and -F are now recognized on the shebang (#!) line.
- Use of the `/c` match modifier without an accompanying `/g` modifier elicits a new warning: `Use of /c modifier is meaningless without /g`.

  Use of `/c` in substitutions, even with `/g`, elicits `Use of /c modifier is meaningless in s///`.

  Use of `/g` with `split` elicits `Use of /g modifier is meaningless in split`.
- Support for the `CLONE` special subroutine had been added. With ithreads, when a new thread is created, all Perl data is cloned, however non-Perl data cannot be cloned automatically. In `CLONE` you can do whatever you need to do, like for example handle the cloning of non-Perl data, if necessary. `CLONE` will be executed once for every package that has it defined or inherited. It will be called in the context of the new thread, so all modifications are made in the new area.

  See *perlmod*

86.5 Modules and Pragmata

86.5.1 New Modules and Pragmata

- `Attribute::Handlers`, originally by Damian Conway and now maintained by Arthur Bergman, allows a class to define attribute handlers.

```
package MyPack;
use Attribute::Handlers;
sub Wolf :ATTR(SCALAR) { print "howl!\n" }

# later, in some package using or inheriting from MyPack...

my MyPack $Fluffy : Wolf; # the attribute handler Wolf will be called
```

  Both variables and routines can have attribute handlers. Handlers can be specific to type (SCALAR, ARRAY, HASH, or CODE), or specific to the exact compilation phase (BEGIN, CHECK, INIT, or END). See *Attribute::Handlers*.
- `B::Concise`, by Stephen McCamant, is a new compiler backend for walking the Perl syntax tree, printing concise info about ops. The output is highly customisable. See *B::Concise*. [561+]
- The new bignum, bigint, and bigrat pragmas, by Tels, implement transparent bignum support (using the Math::BigInt, Math::BigFloat, and Math::BigRat backends).
- `Class::ISA`, by Sean Burke, is a module for reporting the search path for a class's ISA tree. See *Class::ISA*.
- `Cwd` now has a split personality: if possible, an XS extension is used, (this will hopefully be faster, more secure, and more robust) but if not possible, the familiar Perl implementation is used.

- `Devel::PPPort`, originally by Kenneth Albanowski and now maintained by Paul Marquess, has been added. It is primarily used by `h2xs` to enhance portability of XS modules between different versions of Perl. See *Devel::PPPort*.
- `Digest`, frontend module for calculating digests (checksums), from Gisle Aas, has been added. See *Digest*.
- `Digest::MD5` for calculating MD5 digests (checksums) as defined in RFC 1321, from Gisle Aas, has been added. See *Digest::MD5*.

  ```
  use Digest::MD5 'md5_hex';

  $digest = md5_hex("Thirsty Camel");

  print $digest, "\n"; # 01d19d9d2045e005c3f1b80e8b164de1
  ```

  NOTE: the `MD5` backward compatibility module is deliberately not included since its further use is discouraged.

  See also *PerlIO::via::QuotedPrint*.
- `Encode`, originally by Nick Ing-Simmons and now maintained by Dan Kogai, provides a mechanism to translate between different character encodings. Support for Unicode, ISO-8859-1, and ASCII are compiled in to the module. Several other encodings (like the rest of the ISO-8859, CP*/Win*, Mac, KOI8-R, three variants EBCDIC, Chinese, Japanese, and Korean encodings) are included and can be loaded at runtime. (For space considerations, the largest Chinese encodings have been separated into their own CPAN module, Encode::HanExtra, which Encode will use if available). See *Encode*.

  Any encoding supported by Encode module is also available to the ":encoding()" layer if PerlIO is used.
- `Hash::Util` is the interface to the new *restricted hashes* feature. (Implemented by Jeffrey Friedl, Nick Ing-Simmons, and Michael Schwern.) See *Hash::Util*.
- `I18N::Langinfo` can be used to query locale information. See *I18N::Langinfo*.
- `I18N::LangTags`, by Sean Burke, has functions for dealing with RFC3066-style language tags. See *I18N::LangTags*.
- `ExtUtils::Constant`, by Nicholas Clark, is a new tool for extension writers for generating XS code to import C header constants. See *ExtUtils::Constant*.
- `Filter::Simple`, by Damian Conway, is an easy-to-use frontend to Filter::Util::Call. See *Filter::Simple*.

  ```
  # in MyFilter.pm:

  package MyFilter;

  use Filter::Simple sub {
      while (my ($from, $to) = splice @_, 0, 2) {
              s/$from/$to/g;
      }
  };

  1;

  # in user's code:

  use MyFilter qr/red/ => 'green';

  print "red\n";   # this code is filtered, will print "green\n"
  print "bored\n"; # this code is filtered, will print "bogreen\n"
  ```

```
    no MyFilter;

    print "red\n";   # this code is not filtered, will print "red\n"
```

- `File::Temp`, by Tim Jenness, allows one to create temporary files and directories in an easy, portable, and secure way. See *File::Temp*. [561+]
- `Filter::Util::Call`, by Paul Marquess, provides you with the framework to write *source filters* in Perl. For most uses, the frontend Filter::Simple is to be preferred. See *Filter::Util::Call*.
- `if`, by Ilya Zakharevich, is a new pragma for conditional inclusion of modules.
- *libnet*, by Graham Barr, is a collection of perl5 modules related to network programming. See *Net::FTP*, *Net::NNTP*, *Net::Ping* (not part of libnet, but related), *Net::POP3*, *Net::SMTP*, and *Net::Time*.

  Perl installation leaves libnet unconfigured; use *libnetcfg* to configure it.
- `List::Util`, by Graham Barr, is a selection of general-utility list subroutines, such as sum(), min(), first(), and shuffle(). See *List::Util*.
- `Locale::Constants`, `Locale::Country`, `Locale::Currency` `Locale::Language`, and *Locale::Script*, by Neil Bowers, have been added. They provide the codes for various locale standards, such as "fr" for France, "usd" for US Dollar, and "ja" for Japanese.

  ```
  use Locale::Country;

  $country = code2country('jp');               # $country gets 'Japan'
  $code    = country2code('Norway');           # $code gets 'no'
  ```

  See *Locale::Constants*, *Locale::Country*, *Locale::Currency*, and *Locale::Language*.
- `Locale::Maketext`, by Sean Burke, is a localization framework. See *Locale::Maketext*, and *Locale::Maketext::TPJ13*. The latter is an article about software localization, originally published in The Perl Journal #13, and republished here with kind permission.
- `Math::BigRat` for big rational numbers, to accompany Math::BigInt and Math::BigFloat, from Tels. See *Math::BigRat*.
- `Memoize` can make your functions faster by trading space for time, from Mark-Jason Dominus. See *Memoize*.
- `MIME::Base64`, by Gisle Aas, allows you to encode data in base64, as defined in RFC 2045 - *MIME (Multipurpose Internet Mail Extensions)*.

  ```
  use MIME::Base64;

  $encoded = encode_base64('Aladdin:open sesame');
  $decoded = decode_base64($encoded);

  print $encoded, "\n"; # "QWxhZGRpbjpvcGVuIHNlc2FtZQ=="
  ```

  See *MIME::Base64*.
- `MIME::QuotedPrint`, by Gisle Aas, allows you to encode data in quoted-printable encoding, as defined in RFC 2045 - *MIME (Multipurpose Internet Mail Extensions)*.

  ```
  use MIME::QuotedPrint;

  $encoded = encode_qp("\xDE\xAD\xBE\xEF");
  $decoded = decode_qp($encoded);
  ```

```
    print $encoded, "\n"; # "=DE=AD=BE=EF\n"
    print $decoded, "\n"; # "\xDE\xAD\xBE\xEF\n"
```

See also *PerlIO::via::QuotedPrint*.

- `NEXT`, by Damian Conway, is a pseudo-class for method redispatch. See *NEXT*.
- `open` is a new pragma for setting the default I/O layers for open().
- `PerlIO::scalar`, by Nick Ing-Simmons, provides the implementation of IO to "in memory" Perl scalars as discussed above. It also serves as an example of a loadable PerlIO layer. Other future possibilities include PerlIO::Array and PerlIO::Code. See *PerlIO::scalar*.
- `PerlIO::via`, by Nick Ing-Simmons, acts as a PerlIO layer and wraps PerlIO layer functionality provided by a class (typically implemented in Perl code).
- `PerlIO::via::QuotedPrint`, by Elizabeth Mattijsen, is an example of a `PerlIO::via` class:

```
    use PerlIO::via::QuotedPrint;
    open($fh,">:via(QuotedPrint)",$path);
```

  This will automatically convert everything output to `$fh` to Quoted-Printable. See *PerlIO::via* and *PerlIO::via::QuotedPrint*.

- `Pod::ParseLink`, by Russ Allbery, has been added, to parse L<> links in pods as described in the new perlpodspec.
- `Pod::Text::Overstrike`, by Joe Smith, has been added. It converts POD data to formatted overstrike text. See *Pod::Text::Overstrike*. [561+]
- `Scalar::Util` is a selection of general-utility scalar subroutines, such as blessed(), reftype(), and tainted(). See *Scalar::Util*.
- `sort` is a new pragma for controlling the behaviour of sort().
- `Storable` gives persistence to Perl data structures by allowing the storage and retrieval of Perl data to and from files in a fast and compact binary format. Because in effect Storable does serialisation of Perl data structures, with it you can also clone deep, hierarchical datastructures. Storable was originally created by Raphael Manfredi, but it is now maintained by Abhijit Menon-Sen. Storable has been enhanced to understand the two new hash features, Unicode keys and restricted hashes. See *Storable*.
- `Switch`, by Damian Conway, has been added. Just by saying

```
    use Switch;
```

  you have `switch` and `case` available in Perl.

```
    use Switch;

    switch ($val) {

                case 1          { print "number 1" }
                case "a"        { print "string a" }
                case [1..10,42] { print "number in list" }
                case (@array)   { print "number in list" }
                case /\w+/      { print "pattern" }
                case qr/\w+/    { print "pattern" }
                case (%hash)    { print "entry in hash" }
                case (\%hash)   { print "entry in hash" }
                case (\&sub)    { print "arg to subroutine" }
                else            { print "previous case not true" }
    }
```

See *Switch*.

- `Test::More`, by Michael Schwern, is yet another framework for writing test scripts, more extensive than Test::Simple. See *Test::More*.
- `Test::Simple`, by Michael Schwern, has basic utilities for writing tests. See *Test::Simple*.
- `Text::Balanced`, by Damian Conway, has been added, for extracting delimited text sequences from strings.

```
    use Text::Balanced 'extract_delimited';

    ($a, $b) = extract_delimited("'never say never', he never said", "'", '');
```

  $a will be "'never say never'", $b will be ', he never said'.

  In addition to extract_delimited(), there are also extract_bracketed(), extract_quotelike(), extract_codeblock(), extract_variable(), extract_tagged(), extract_multiple(), gen_delimited_pat(), and gen_extract_tagged(). With these, you can implement rather advanced parsing algorithms. See *Text::Balanced*.
- `threads`, by Arthur Bergman, is an interface to interpreter threads. Interpreter threads (ithreads) is the new thread model introduced in Perl 5.6 but only available as an internal interface for extension writers (and for Win32 Perl for `fork()` emulation). See *threads*, *threads::shared*, and *perlthrtut*.
- `threads::shared`, by Arthur Bergman, allows data sharing for interpreter threads. See *threads::shared*.
- `Tie::File`, by Mark-Jason Dominus, associates a Perl array with the lines of a file. See *Tie::File*.
- `Tie::Memoize`, by Ilya Zakharevich, provides on-demand loaded hashes. See *Tie::Memoize*.
- `Tie::RefHash::Nestable`, by Edward Avis, allows storing hash references (unlike the standard Tie::RefHash) The module is contained within Tie::RefHash. See *Tie::RefHash*.
- `Time::HiRes`, by Douglas E. Wegscheid, provides high resolution timing (ualarm, usleep, and gettimeofday). See *Time::HiRes*.
- `Unicode::UCD` offers a querying interface to the Unicode Character Database. See *Unicode::UCD*.
- `Unicode::Collate`, by SADAHIRO Tomoyuki, implements the UCA (Unicode Collation Algorithm) for sorting Unicode strings. See *Unicode::Collate*.
- `Unicode::Normalize`, by SADAHIRO Tomoyuki, implements the various Unicode normalization forms. See *Unicode::Normalize*.
- `XS::APItest`, by Tim Jenness, is a test extension that exercises XS APIs. Currently only `printf()` is tested: how to output various basic data types from XS.
- `XS::Typemap`, by Tim Jenness, is a test extension that exercises XS typemaps. Nothing gets installed, but the code is worth studying for extension writers.

86.5.2 Updated And Improved Modules and Pragmata

- The following independently supported modules have been updated to the newest versions from CPAN: CGI, CPAN, DB_File, File::Spec, File::Temp, Getopt::Long, Math::BigFloat, Math::BigInt, the podlators bundle (Pod::Man, Pod::Text), Pod::LaTeX [561+], Pod::Parser, Storable, Term::ANSIColor, Test, Text-Tabs+Wrap.
- attributes::reftype() now works on tied arguments.
- AutoLoader can now be disabled with `no AutoLoader;`.
- B::Deparse has been significantly enhanced by Robin Houston. It can now deparse almost all of the standard test suite (so that the tests still succeed). There is a make target "test.deparse" for trying this out.

- Carp now has better interface documentation, and the @CARP_NOT interface has been added to get optional control over where errors are reported independently of @ISA, by Ben Tilly.
- Class::Struct can now define the classes in compile time.
- Class::Struct now assigns the array/hash element if the accessor is called with an array/hash element as the **sole** argument.
- The return value of Cwd::fastcwd() is now tainted.
- Data::Dumper now has an option to sort hashes.
- Data::Dumper now has an option to dump code references using B::Deparse.
- DB_File now supports newer Berkeley DB versions, among other improvements.
- Devel::Peek now has an interface for the Perl memory statistics (this works only if you are using perl's malloc, and if you have compiled with debugging).
- The English module can now be used without the infamous performance hit by saying

  ```
          use English '-no_match_vars';
  ```

  (Assuming, of course, that you don't need the troublesome variables `` $` ``, `$&`, or `$'`.) Also, introduced `@LAST_MATCH_START` and `@LAST_MATCH_END` English aliases for `@-` and `@+`.
- ExtUtils::MakeMaker has been significantly cleaned up and fixed. The enhanced version has also been backported to earlier releases of Perl and submitted to CPAN so that the earlier releases can enjoy the fixes.
- The arguments of WriteMakefile() in Makefile.PL are now checked for sanity much more carefully than before. This may cause new warnings when modules are being installed. See *ExtUtils::MakeMaker* for more details.
- ExtUtils::MakeMaker now uses File::Spec internally, which hopefully leads to better portability.
- Fcntl, Socket, and Sys::Syslog have been rewritten by Nicholas Clark to use the new-style constant dispatch section (see *ExtUtils::Constant*). This means that they will be more robust and hopefully faster.
- File::Find now chdir()s correctly when chasing symbolic links. [561]
- File::Find now has pre- and post-processing callbacks. It also correctly changes directories when chasing symbolic links. Callbacks (naughtily) exiting with "next;" instead of "return;" now work.
- File::Find is now (again) reentrant. It also has been made more portable.
- The warnings issued by File::Find now belong to their own category. You can enable/disable them with `use/no warnings 'File::Find';`.
- File::Glob::glob() has been renamed to File::Glob::bsd_glob() because the name clashes with the builtin glob(). The older name is still available for compatibility, but is deprecated. [561]
- File::Glob now supports `GLOB_LIMIT` constant to limit the size of the returned list of filenames.
- IPC::Open3 now allows the use of numeric file descriptors.
- IO::Socket now has an atmark() method, which returns true if the socket is positioned at the out-of-band mark. The method is also exportable as a sockatmark() function.
- IO::Socket::INET failed to open the specified port if the service name was not known. It now correctly uses the supplied port number as is. [561]
- IO::Socket::INET has support for the ReusePort option (if your platform supports it). The Reuse option now has an alias, ReuseAddr. For clarity, you may want to prefer ReuseAddr.
- IO::Socket::INET now supports a value of zero for `LocalPort` (usually meaning that the operating system will make one up.)

- ’use lib’ now works identically to @INC. Removing directories with ’no lib’ now works.
- Math::BigFloat and Math::BigInt have undergone a full rewrite by Tels. They are now magnitudes faster, and they support various bignum libraries such as GMP and PARI as their backends.
- Math::Complex handles inf, NaN etc., better.
- Net::Ping has been considerably enhanced by Rob Brown: multihoming is now supported, Win32 functionality is better, there is now time measuring functionality (optionally high-resolution using Time::HiRes), and there is now "external" protocol which uses Net::Ping::External module which runs your external ping utility and parses the output. A version of Net::Ping::External is available in CPAN.

  Note that some of the Net::Ping tests are disabled when running under the Perl distribution since one cannot assume one or more of the following: enabled echo port at localhost, full Internet connectivity, or sympathetic firewalls. You can set the environment variable PERL_TEST_Net_Ping to "1" (one) before running the Perl test suite to enable all the Net::Ping tests.
- POSIX::sigaction() is now much more flexible and robust. You can now install coderef handlers, ’DEFAULT’, and ’IGNORE’ handlers, installing new handlers was not atomic.
- In Safe, `%INC` is now localised in a Safe compartment so that use/require work.
- In SDBM_File on dosish platforms, some keys went missing because of lack of support for files with "holes". A workaround for the problem has been added.
- In Search::Dict one can now have a pre-processing hook for the lines being searched.
- The Shell module now has an OO interface.
- In Sys::Syslog there is now a failover mechanism that will go through alternative connection mechanisms until the message is successfully logged.
- The Test module has been significantly enhanced.
- Time::Local::timelocal() does not handle fractional seconds anymore. The rationale is that neither does localtime(), and timelocal() and localtime() are supposed to be inverses of each other.
- The vars pragma now supports declaring fully qualified variables. (Something that `our()` does not and will not support.)
- The `utf8::` name space (as in the pragma) provides various Perl-callable functions to provide low level access to Perl’s internal Unicode representation. At the moment only length() has been implemented.

86.6 Utility Changes

- Emacs perl mode (emacs/cperl-mode.el) has been updated to version 4.31.
- *emacs/e2ctags.pl* is now much faster.
- `enc2xs` is a tool for people adding their own encodings to the Encode module.
- `h2ph` now supports C trigraphs.
- `h2xs` now produces a template README.
- `h2xs` now uses `Devel::PPPort` for better portability between different versions of Perl.
- `h2xs` uses the new ExtUtils::Constant module which will affect newly created extensions that define constants. Since the new code is more correct (if you have two constants where the first one is a prefix of the second one, the first constant **never** got defined), less lossy (it uses integers for integer constant, as opposed to the old code that used floating point numbers even for integer constants), and slightly faster, you might want to consider regenerating your extension code (the new scheme makes regenerating easy). *h2xs* now also supports C trigraphs.

- `libnetcfg` has been added to configure libnet.
- `perlbug` is now much more robust. It also sends the bug report to perl.org, not perl.com.
- `perlcc` has been rewritten and its user interface (that is, command line) is much more like that of the UNIX C compiler, cc. (The perlbc tools has been removed. Use `perlcc -B` instead.) **Note that perlcc is still considered very experimental and unsupported.** [561]
- `perlivp` is a new Installation Verification Procedure utility for running any time after installing Perl.
- `piconv` is an implementation of the character conversion utility `iconv`, demonstrating the new Encode module.
- `pod2html` now allows specifying a cache directory.
- `pod2html` now produces XHTML 1.0.
- `pod2html` now understands POD written using different line endings (PC-like CRLF versus UNIX-like LF versus MacClassic-like CR).
- `s2p` has been completely rewritten in Perl. (It is in fact a full implementation of sed in Perl: you can use the sed functionality by using the `psed` utility.)
- `xsubpp` now understands POD documentation embedded in the *.xs files. [561]
- `xsubpp` now supports the OUT keyword.

86.7 New Documentation

- perl56delta details the changes between the 5.005 release and the 5.6.0 release.
- perlclib documents the internal replacements for standard C library functions. (Interesting only for extension writers and Perl core hackers.) [561+]
- perldebtut is a Perl debugging tutorial. [561+]
- perlebcdic contains considerations for running Perl on EBCDIC platforms. [561+]
- perlintro is a gentle introduction to Perl.
- perliol documents the internals of PerlIO with layers.
- perlmodstyle is a style guide for writing modules.
- perlnewmod tells about writing and submitting a new module. [561+]
- perlpacktut is a pack() tutorial.
- perlpod has been rewritten to be clearer and to record the best practices gathered over the years.
- perlpodspec is a more formal specification of the pod format, mainly of interest for writers of pod applications, not to people writing in pod.
- perlretut is a regular expression tutorial. [561+]
- perlrequick is a regular expressions quick-start guide. Yes, much quicker than perlretut. [561]
- perltodo has been updated.
- perltootc has been renamed as perltooc (to not to conflict with perltoot in filesystems restricted to "8.3" names).
- perluniintro is an introduction to using Unicode in Perl. (perlunicode is more of a detailed reference and background information)
- perlutil explains the command line utilities packaged with the Perl distribution. [561+]

The following platform-specific documents are available before the installation as README.*platform*, and after the installation as perl*platform*:

```
    perlaix perlamiga perlapollo perlbeos perlbs2000
    perlce perlcygwin perldgux perldos perlepoc perlfreebsd perlhpux
    perlhurd perlirix perlmachten perlmacos perlmint perlmpeix
    perlnetware perlos2 perlos390 perlplan9 perlqnx perlsolaris
    perltru64 perluts perlvmesa perlvms perlvos perlwin32
```

These documents usually detail one or more of the following subjects: configuring, building, testing, installing, and sometimes also using Perl on the said platform.

Eastern Asian Perl users are now welcomed in their own languages: README.jp (Japanese), README.ko (Korean), README.cn (simplified Chinese) and README.tw (traditional Chinese), which are written in normal pod but encoded in EUC-JP, EUC-KR, EUC-CN and Big5. These will get installed as

```
   perljp perlko perlcn perltw
```

- The documentation for the POSIX-BC platform is called "BS2000", to avoid confusion with the Perl POSIX module.
- The documentation for the WinCE platform is called perlce (README.ce in the source code kit), to avoid confusion with the perlwin32 documentation on 8.3-restricted filesystems.

86.8 Performance Enhancements

- map() could get pathologically slow when the result list it generates is larger than the source list. The performance has been improved for common scenarios. [561]
- sort() is also fully reentrant, in the sense that the sort function can itself call sort(). This did not work reliably in previous releases. [561]
- sort() has been changed to use primarily mergesort internally as opposed to the earlier quicksort. For very small lists this may result in slightly slower sorting times, but in general the speedup should be at least 20%. Additional bonuses are that the worst case behaviour of sort() is now better (in computer science terms it now runs in time O(N log N), as opposed to quicksort's Theta(N**2) worst-case run time behaviour), and that sort() is now stable (meaning that elements with identical keys will stay ordered as they were before the sort). See the `sort` pragma for information.

  The story in more detail: suppose you want to serve yourself a little slice of Pi.

  ```
      @digits = ( 3,1,4,1,5,9 );
  ```

  A numerical sort of the digits will yield (1,1,3,4,5,9), as expected. Which 1 comes first is hard to know, since one 1 looks pretty much like any other. You can regard this as totally trivial, or somewhat profound. However, if you just want to sort the even digits ahead of the odd ones, then what will

  ```
      sort { ($a % 2) <=> ($b % 2) } @digits;
  ```

  yield? The only even digit, 4, will come first. But how about the odd numbers, which all compare equal? With the quicksort algorithm used to implement Perl 5.6 and earlier, the order of ties is left up to the sort. So, as you add more and more digits of Pi, the order in which the sorted even and odd digits appear will change. and, for sufficiently large slices of Pi, the quicksort algorithm in Perl 5.8 won't return the same results even if reinvoked with the same input. The justification for this rests with quicksort's worst case behavior. If you run

  ```
     sort { $a <=> $b } ( 1 .. $N , 1 .. $N );
  ```

(something you might approximate if you wanted to merge two sorted arrays using sort), doubling $N doesn't just double the quicksort time, it *quadruples* it. Quicksort has a worst case run time that can grow like N**2, so-called *quadratic* behaviour, and it can happen on patterns that may well arise in normal use. You won't notice this for small arrays, but you *will* notice it with larger arrays, and you may not live long enough for the sort to complete on arrays of a million elements. So the 5.8 quicksort scrambles large arrays before sorting them, as a statistical defence against quadratic behaviour. But that means if you sort the same large array twice, ties may be broken in different ways.

Because of the unpredictability of tie-breaking order, and the quadratic worst-case behaviour, quicksort was *almost* replaced completely with a stable mergesort. *Stable* means that ties are broken to preserve the original order of appearance in the input array. So

```
    sort { ($a % 2) <=> ($b % 2) } (3,1,4,1,5,9);
```

will yield (4,3,1,1,5,9), guaranteed. The even and odd numbers appear in the output in the same order they appeared in the input. Mergesort has worst case O(N log N) behaviour, the best value attainable. And, ironically, this mergesort does particularly well where quicksort goes quadratic: mergesort sorts (1..$N, 1..$N) in O(N) time. But quicksort was rescued at the last moment because it is faster than mergesort on certain inputs and platforms. For example, if you really *don't* care about the order of even and odd digits, quicksort will run in O(N) time; it's very good at sorting many repetitions of a small number of distinct elements. The quicksort divide and conquer strategy works well on platforms with relatively small, very fast, caches. Eventually, the problem gets whittled down to one that fits in the cache, from which point it benefits from the increased memory speed.

Quicksort was rescued by implementing a sort pragma to control aspects of the sort. The **stable** subpragma forces stable behaviour, regardless of algorithm. The **_quicksort** and **_mergesort** subpragmas are heavy-handed ways to select the underlying implementation. The leading **_** is a reminder that these subpragmas may not survive beyond 5.8. More appropriate mechanisms for selecting the implementation exist, but they wouldn't have arrived in time to save quicksort.

- Hashes now use Bob Jenkins "One-at-a-Time" hashing key algorithm (http://burtleburtle.net/bob/hash/doobs.html). This algorithm is reasonably fast while producing a much better spread of values than the old hashing algorithm (originally by Chris Torek, later tweaked by Ilya Zakharevich). Hash values output from the algorithm on a hash of all 3-char printable ASCII keys comes much closer to passing the DIEHARD random number generation tests. According to perlbench, this change has not affected the overall speed of Perl.

- unshift() should now be noticeably faster.

86.9 Installation and Configuration Improvements

86.9.1 Generic Improvements

- INSTALL now explains how you can configure Perl to use 64-bit integers even on non-64-bit platforms.

- Policy.sh policy change: if you are reusing a Policy.sh file (see INSTALL) and you use Configure -Dprefix=/foo/bar and in the old Policy $prefix eq $siteprefix and $prefix eq $vendorprefix, all of them will now be changed to the new prefix, /foo/bar. (Previously only $prefix changed.) If you do not like this new behaviour, specify prefix, siteprefix, and vendorprefix explicitly.

- A new optional location for Perl libraries, otherlibdirs, is available. It can be used for example for vendor add-ons without disturbing Perl's own library directories.

- In many platforms, the vendor-supplied 'cc' is too stripped-down to build Perl (basically, 'cc' doesn't do ANSI C). If this seems to be the case and 'cc' does not seem to be the GNU C compiler 'gcc', an automatic attempt is made to find and use 'gcc' instead.

- gcc needs to closely track the operating system release to avoid build problems. If Configure finds that gcc was built for a different operating system release than is running, it now gives a clearly visible warning that there may be trouble ahead.

- Since Perl 5.8 is not binary-compatible with previous releases of Perl, Configure no longer suggests including the 5.005 modules in @INC.
- Configure `-S` can now run non-interactively. [561]
- Configure support for pdp11-style memory models has been removed due to obsolescence. [561]
- configure.gnu now works with options with whitespace in them.
- installperl now outputs everything to STDERR.
- Because PerlIO is now the default on most platforms, "-perlio" doesn't get appended to the $Config{archname} (also known as $^O) anymore. Instead, if you explicitly choose not to use perlio (Configure command line option -Uuseperlio), you will get "-stdio" appended.
- Another change related to the architecture name is that "-64all" (-Duse64bitall, or "maximally 64-bit") is appended only if your pointers are 64 bits wide. (To be exact, the use64bitall is ignored.)
- In AFS installations, one can configure the root of the AFS to be somewhere else than the default */afs* by using the Configure parameter `-Dafsroot=/some/where/else`.
- APPLLIB_EXP, a lesser-known configuration-time definition, has been documented. It can be used to prepend site-specific directories to Perl's default search path (@INC); see INSTALL for information.
- The version of Berkeley DB used when the Perl (and, presumably, the DB_File extension) was built is now available as `@Config{qw(db_version_major db_version_minor db_version_patch)}` from Perl and as `DB_VERSION_MAJOR_CFG DB_VERSION_MINOR_CFG DB_VERSION_PATCH_CFG` from C.
- Building Berkeley DB3 for compatibility modes for DB, NDBM, and ODBM has been documented in INSTALL.
- If you have CPAN access (either network or a local copy such as a CD-ROM) you can during specify extra modules to Configure to build and install with Perl using the -Dextras=... option. See INSTALL for more details.
- In addition to config.over, a new override file, config.arch, is available. This file is supposed to be used by hints file writers for architecture-wide changes (as opposed to config.over which is for site-wide changes).
- If your file system supports symbolic links, you can build Perl outside of the source directory by

  ```
  mkdir perl/build/directory
  cd perl/build/directory
  sh /path/to/perl/source/Configure -Dmksymlinks ...
  ```

  This will create in perl/build/directory a tree of symbolic links pointing to files in /path/to/perl/source. The original files are left unaffected. After Configure has finished, you can just say

  ```
  make all test
  ```

  and Perl will be built and tested, all in perl/build/directory. [561]
- For Perl developers, several new make targets for profiling and debugging have been added; see *perlhack*.
  - Use of the *gprof* tool to profile Perl has been documented in *perlhack*. There is a make target called "perl.gprof" for generating a gprofiled Perl executable.
  - If you have GCC 3, there is a make target called "perl.gcov" for creating a gcoved Perl executable for coverage analysis. See *perlhack*.
  - If you are on IRIX or Tru64 platforms, new profiling/debugging options have been added; see *perlhack* for more information about pixie and Third Degree.
- Guidelines of how to construct minimal Perl installations have been added to INSTALL.

- The Thread extension is now not built at all under ithreads (`Configure -Duseithreads`) because it wouldn't work anyway (the Thread extension requires being Configured with `-Duse5005threads`).

  Note that the 5.005 threads are unsupported and deprecated: if you have code written for the old threads you should migrate it to the new ithreads model.

- The Gconvert macro ($Config{d_Gconvert}) used by perl for stringifying floating-point numbers is now more picky about using sprintf %.*g rules for the conversion. Some platforms that used to use gcvt may now resort to the slower sprintf.

- The obsolete method of making a special (e.g., debugging) flavor of perl by saying

  ```
      make LIBPERL=libperld.a
  ```

  has been removed. Use -DDEBUGGING instead.

86.9.2 New Or Improved Platforms

For the list of platforms known to support Perl, see Supported Platforms in *perlport*.

- AIX dynamic loading should be now better supported.
- AIX should now work better with gcc, threads, and 64-bitness. Also the long doubles support in AIX should be better now. See *perlaix*.
- AtheOS (http://www.atheos.cx/) is a new platform.
- BeOS has been reclaimed.
- The DG/UX platform now supports 5.005-style threads. See *perldgux*.
- The DYNIX/ptx platform (also known as dynixptx) is supported at or near osvers 4.5.2.
- EBCDIC platforms (z/OS (also known as OS/390), POSIX-BC, and VM/ESA) have been regained. Many test suite tests still fail and the co-existence of Unicode and EBCDIC isn't quite settled, but the situation is much better than with Perl 5.6. See *perlos390*, *perlbs2000* (for POSIX-BC), and *perlvmesa* for more information.
- Building perl with -Duseithreads or -Duse5005threads now works under HP-UX 10.20 (previously it only worked under 10.30 or later). You will need a thread library package installed. See README.hpux. [561]
- Mac OS Classic is now supported in the mainstream source package (MacPerl has of course been available since perl 5.004 but now the source code bases of standard Perl and MacPerl have been synchronised) [561]
- Mac OS X (or Darwin) should now be able to build Perl even on HFS+ filesystems. (The case-insensitivity used to confuse the Perl build process.)
- NCR MP-RAS is now supported. [561]
- All the NetBSD specific patches (except for the installation specific ones) have been merged back to the main distribution.
- NetWare from Novell is now supported. See *perlnetware*.
- NonStop-UX is now supported. [561]
- NEC SUPER-UX is now supported.
- All the OpenBSD specific patches (except for the installation specific ones) have been merged back to the main distribution.

- Perl has been tested with the GNU pth userlevel thread package (http://www.gnu.org/software/pth/pth.html). All thread tests of Perl now work, but not without adding some yield()s to the tests, so while pth (and other userlevel thread implementations) can be considered to be "working" with Perl ithreads, keep in mind the possible non-preemptability of the underlying thread implementation.
- Stratus VOS is now supported using Perl's native build method (Configure). This is the recommended method to build Perl on VOS. The older methods, which build miniperl, are still available. See *perlvos*. [561+]
- The Amdahl UTS UNIX mainframe platform is now supported. [561]
- WinCE is now supported. See *perlce*.
- z/OS (formerly known as OS/390, formerly known as MVS OE) now has support for dynamic loading. This is not selected by default, however, you must specify -Dusedl in the arguments of Configure. [561]

86.10 Selected Bug Fixes

Numerous memory leaks and uninitialized memory accesses have been hunted down. Most importantly, anonymous subs used to leak quite a bit. [561]

- The autouse pragma didn't work for Multi::Part::Function::Names.
- caller() could cause core dumps in certain situations. Carp was sometimes affected by this problem. In particular, caller() now returns a subroutine name of `(unknown)` for subroutines that have been removed from the symbol table.
- chop(@list) in list context returned the characters chopped in reverse order. This has been reversed to be in the right order. [561]
- Configure no longer includes the DBM libraries (dbm, gdbm, db, ndbm) when building the Perl binary. The only exception to this is SunOS 4.x, which needs them. [561]
- The behaviour of non-decimal but numeric string constants such as "0x23" was platform-dependent: in some platforms that was seen as 35, in some as 0, in some as a floating point number (don't ask). This was caused by Perl's using the operating system libraries in a situation where the result of the string to number conversion is undefined: now Perl consistently handles such strings as zero in numeric contexts.
- Several debugger fixes: exit code now reflects the script exit code, condition `"0"` now treated correctly, the `d` command now checks line number, `$.` no longer gets corrupted, and all debugger output now goes correctly to the socket if RemotePort is set. [561]
- The debugger (perl5db.pl) has been modified to present a more consistent commands interface, via (CommandSet=580). perl5db.t was also added to test the changes, and as a placeholder for further tests.

  See *perldebug*.
- The debugger has a new `dumpDepth` option to control the maximum depth to which nested structures are dumped. The `x` command has been extended so that `x N EXPR` dumps out the value of *EXPR* to a depth of at most *N* levels.
- The debugger can now show lexical variables if you have the CPAN module PadWalker installed.
- The order of DESTROYs has been made more predictable.
- Perl 5.6.0 could emit spurious warnings about redefinition of dl_error() when statically building extensions into perl. This has been corrected. [561]
- *dprofpp* -R didn't work.
- `*foo{FORMAT}` now works.
- Infinity is now recognized as a number.

- UNIVERSAL::isa no longer caches methods incorrectly. (This broke the Tk extension with 5.6.0.) [561]
- Lexicals I: lexicals outside an eval "" weren't resolved correctly inside a subroutine definition inside the eval "" if they were not already referenced in the top level of the eval""ed code.
- Lexicals II: lexicals leaked at file scope into subroutines that were declared before the lexicals.
- Lexical warnings now propagating correctly between scopes and into `eval "..."`.
- `use warnings qw(FATAL all)` did not work as intended. This has been corrected. [561]
- warnings::enabled() now reports the state of $ˆW correctly if the caller isn't using lexical warnings. [561]
- Line renumbering with eval and `#line` now works. [561]
- Fixed numerous memory leaks, especially in eval "".
- Localised tied variables no longer leak memory

  ```
  use Tie::Hash;
  tie my %tied_hash => 'Tie::StdHash';

  ...

  # Used to leak memory every time local() was called;
  # in a loop, this added up.
  local($tied_hash{Foo}) = 1;
  ```

- Localised hash elements (and %ENV) are correctly unlocalised to not exist, if they didn't before they were localised.

  ```
  use Tie::Hash;
  tie my %tied_hash => 'Tie::StdHash';

  ...

  # Nothing has set the FOO element so far

  { local $tied_hash{FOO} = 'Bar' }

  # This used to print, but not now.
  print "exists!\n" if exists $tied_hash{FOO};
  ```

  As a side effect of this fix, tied hash interfaces **must** define the EXISTS and DELETE methods.

- mkdir() now ignores trailing slashes in the directory name, as mandated by POSIX.
- Some versions of glibc have a broken modfl(). This affects builds with `-Duselongdouble`. This version of Perl detects this brokenness and has a workaround for it. The glibc release 2.2.2 is known to have fixed the modfl() bug.
- Modulus of unsigned numbers now works (4063328477 % 65535 used to return 27406, instead of 27047). [561]
- Some "not a number" warnings introduced in 5.6.0 eliminated to be more compatible with 5.005. Infinity is now recognised as a number. [561]
- Numeric conversions did not recognize changes in the string value properly in certain circumstances. [561]
- Attributes (such as :shared) didn't work with our().
- our() variables will not cause bogus "Variable will not stay shared" warnings. [561]

- "our" variables of the same name declared in two sibling blocks resulted in bogus warnings about "redeclaration" of the variables. The problem has been corrected. [561]
- pack "Z" now correctly terminates the string with "\0".
- Fix password routines which in some shadow password platforms (e.g. HP-UX) caused getpwent() to return every other entry.
- The PERL5OPT environment variable (for passing command line arguments to Perl) didn't work for more than a single group of options. [561]
- PERL5OPT with embedded spaces didn't work.
- printf() no longer resets the numeric locale to "C".
- `qw(a\\b)` now parses correctly as `'a\\b'`: that is, as three characters, not four. [561]
- pos() did not return the correct value within s///ge in earlier versions. This is now handled correctly. [561]
- Printing quads (64-bit integers) with printf/sprintf now works without the q L ll prefixes (assuming you are on a quad-capable platform).
- Regular expressions on references and overloaded scalars now work. [561+]
- Right-hand side magic (GMAGIC) could in many cases such as string concatenation be invoked too many times.
- scalar() now forces scalar context even when used in void context.
- SOCKS support is now much more robust.
- sort() arguments are now compiled in the right wantarray context (they were accidentally using the context of the sort() itself). The comparison block is now run in scalar context, and the arguments to be sorted are always provided list context. [561]
- Changed the POSIX character class `[[:space:]]` to include the (very rarely used) vertical tab character. Added a new POSIX-ish character class `[[:blank:]]` which stands for horizontal whitespace (currently, the space and the tab).
- The tainting behaviour of sprintf() has been rationalized. It does not taint the result of floating point formats anymore, making the behaviour consistent with that of string interpolation. [561]
- Some cases of inconsistent taint propagation (such as within hash values) have been fixed.
- The RE engine found in Perl 5.6.0 accidentally pessimised certain kinds of simple pattern matches. These are now handled better. [561]
- Regular expression debug output (whether through `use re 'debug'` or via `-Dr`) now looks better. [561]
- Multi-line matches like `"a\nxb\n" =~ /(?!\A)x/m` were flawed. The bug has been fixed. [561]
- Use of $& could trigger a core dump under some situations. This is now avoided. [561]
- The regular expression captured submatches ($1, $2, ...) are now more consistently unset if the match fails, instead of leaving false data lying around in them. [561]
- readline() on files opened in "slurp" mode could return an extra "" (blank line) at the end in certain situations. This has been corrected. [561]
- Autovivification of symbolic references of special variables described in *perlvar* (as in `${$num}`) was accidentally disabled. This works again now. [561]
- Sys::Syslog ignored the `LOG_AUTH` constant.
- $AUTOLOAD, sort(), lock(), and spawning subprocesses in multiple threads simultaneously are now thread-safe.

- Tie::Array's SPLICE method was broken.
- Allow a read-only string on the left-hand side of a non-modifying tr///.
- If `STDERR` is tied, warnings caused by `warn` and `die` now correctly pass to it.
- Several Unicode fixes.
  - BOMs (byte order marks) at the beginning of Perl files (scripts, modules) should now be transparently skipped. UTF-16 and UCS-2 encoded Perl files should now be read correctly.
  - The character tables have been updated to Unicode 3.2.0.
  - Comparing with utf8 data does not magically upgrade non-utf8 data into utf8. (This was a problem for example if you were mixing data from I/O and Unicode data: your output might have got magically encoded as UTF-8.)
  - Generating illegal Unicode code points such as U+FFFE, or the UTF-16 surrogates, now also generates an optional warning.
  - `IsAlnum`, `IsAlpha`, and `IsWord` now match titlecase.
  - Concatenation with the `.` operator or via variable interpolation, `eq`, `substr`, `reverse`, `quotemeta`, the `x` operator, substitution with `s///`, single-quoted UTF-8, should now work.
  - The `tr///` operator now works. Note that the `tr///CU` functionality has been removed (but see pack('U0', ...)).
  - `eval "v200"` now works.
  - Perl 5.6.0 parsed m/\x{ab}/ incorrectly, leading to spurious warnings. This has been corrected. [561]
  - Zero entries were missing from the Unicode classes such as `IsDigit`.
- Large unsigned numbers (those above 2**31) could sometimes lose their unsignedness, causing bogus results in arithmetic operations. [561]
- The Perl parser has been stress tested using both random input and Markov chain input and the few found crashes and lockups have been fixed.

86.10.1 Platform Specific Changes and Fixes

- BSDI 4.*

  Perl now works on post-4.0 BSD/OSes.
- All BSDs

  Setting `$0` now works (as much as possible; see *perlvar* for details).
- Cygwin

  Numerous updates; currently synchronised with Cygwin 1.3.10.
- Previously DYNIX/ptx had problems in its Configure probe for non-blocking I/O.
- EPOC

  EPOC now better supported. See README.epoc. [561]
- FreeBSD 3.*

  Perl now works on post-3.0 FreeBSDs.
- HP-UX

  README.hpux updated; `Configure -Duse64bitall` now works; now uses HP-UX malloc instead of Perl malloc.

- IRIX

  Numerous compilation flag and hint enhancements; accidental mixing of 32-bit and 64-bit libraries (a doomed attempt) made much harder.

- Linux

  - Long doubles should now work (see INSTALL). [561]
  - Linux previously had problems related to sockaddrlen when using accept(), recvfrom() (in Perl: recv()), getpeername(), and getsockname().

- Mac OS Classic

  Compilation of the standard Perl distribution in Mac OS Classic should now work if you have the Metrowerks development environment and the missing Mac-specific toolkit bits. Contact the macperl mailing list for details.

- MPE/iX

  MPE/iX update after Perl 5.6.0. See README.mpeix. [561]

- NetBSD/threads: try installing the GNU pth (should be in the packages collection, or http://www.gnu.org/software/pth/), and Configure with -Duseithreads.

- NetBSD/sparc

  Perl now works on NetBSD/sparc.

- OS/2

  Now works with usethreads (see INSTALL). [561]

- Solaris

  64-bitness using the Sun Workshop compiler now works.

- Stratus VOS

  The native build method requires at least VOS Release 14.5.0 and GNU C++/GNU Tools 2.0.1 or later. The Perl pack function now maps overflowed values to +infinity and underflowed values to -infinity.

- Tru64 (aka Digital UNIX, aka DEC OSF/1)

  The operating system version letter now recorded in $Config{osvers}. Allow compiling with gcc (previously explicitly forbidden). Compiling with gcc still not recommended because buggy code results, even with gcc 2.95.2.

- Unicos

  Fixed various alignment problems that lead into core dumps either during build or later; no longer dies on math errors at runtime; now using full quad integers (64 bits), previously was using only 46 bit integers for speed.

- VMS

  See §86.3.5 and §86.3.6 for important changes not otherwise listed here.

  chdir() now works better despite a CRT bug; now works with MULTIPLICITY (see INSTALL); now works with Perl's malloc.

  The tainting of `%ENV` elements via `keys` or `values` was previously unimplemented. It now works as documented.

  The `waitpid` emulation has been improved. The worst bug (now fixed) was that a pid of -1 would cause a wildcard search of all processes on the system.

  POSIX-style signals are now emulated much better on VMS versions prior to 7.0.

  The `system` function and backticks operator have improved functionality and better error handling. [561]

  File access tests now use current process privileges rather than the user's default privileges, which could sometimes result in a mismatch between reported access and actual access. This improvement is only available on VMS v6.0 and later.

There is a new `kill` implementation based on `sys$sigprc` that allows older VMS systems (pre-7.0) to use `kill` to send signals rather than simply force exit. This implementation also allows later systems to call `kill` from within a signal handler.

Iterative logical name translations are now limited to 10 iterations in imitation of SHOW LOGICAL and other OpenVMS facilities.

- Windows
  - Signal handling now works better than it used to. It is now implemented using a Windows message loop, and is therefore less prone to random crashes.
  - fork() emulation is now more robust, but still continues to have a few esoteric bugs and caveats. See *perlfork* for details. [561+]
  - A failed (pseudo)fork now returns undef and sets errno to EAGAIN. [561]
  - The following modules now work on Windows:

    ```
    ExtUtils::Embed         [561]
    IO::Pipe
    IO::Poll
    Net::Ping
    ```

  - IO::File::new_tmpfile() is no longer limited to 32767 invocations per-process.
  - Better chdir() return value for a non-existent directory.
  - Compiling perl using the 64-bit Platform SDK tools is now supported.
  - The Win32::SetChildShowWindow() builtin can be used to control the visibility of windows created by child processes. See *Win32* for details.
  - Non-blocking waits for child processes (or pseudo-processes) are supported via `waitpid($pid, &POSIX::WNOHANG)`.
  - The behavior of system() with multiple arguments has been rationalized. Each unquoted argument will be automatically quoted to protect whitespace, and any existing whitespace in the arguments will be preserved. This improves the portability of system(@args) by avoiding the need for Windows `cmd` shell specific quoting in perl programs.

    Note that this means that some scripts that may have relied on earlier buggy behavior may no longer work correctly. For example, `system("nmake /nologo", @args)` will now attempt to run the file `nmake /nologo` and will fail when such a file isn't found. On the other hand, perl will now execute code such as `system("c:/Program Files/MyApp/foo.exe", @args)` correctly.
  - The perl header files no longer suppress common warnings from the Microsoft Visual C++ compiler. This means that additional warnings may now show up when compiling XS code.
  - Borland C++ v5.5 is now a supported compiler that can build Perl. However, the generated binaries continue to be incompatible with those generated by the other supported compilers (GCC and Visual C++). [561]
  - Duping socket handles with open(F, ">&MYSOCK") now works under Windows 9x. [561]
  - Current directory entries in %ENV are now correctly propagated to child processes. [561]
  - New %ENV entries now propagate to subprocesses. [561]
  - Win32::GetCwd() correctly returns C:\ instead of C: when at the drive root. Other bugs in chdir() and Cwd::cwd() have also been fixed. [561]
  - The makefiles now default to the features enabled in ActiveState ActivePerl (a popular Win32 binary distribution). [561]
  - HTML files will now be installed in c:\perl\html instead of c:\perl\lib\pod\html
  - REG_EXPAND_SZ keys are now allowed in registry settings used by perl. [561]
  - Can now send() from all threads, not just the first one. [561]
  - ExtUtils::MakeMaker now uses $ENV{LIB} to search for libraries. [561]
  - Less stack reserved per thread so that more threads can run concurrently. (Still 16M per thread.) [561]

- `File::Spec->tmpdir()` now prefers C:/temp over /tmp (works better when perl is running as service).
- Better UNC path handling under ithreads. [561]
- wait(), waitpid(), and backticks now return the correct exit status under Windows 9x. [561]
- A socket handle leak in accept() has been fixed. [561]

86.11 New or Changed Diagnostics

Please see *perldiag* for more details.

- Ambiguous range in the transliteration operator (like a-z-9) now gives a warning.
- chdir("") and chdir(undef) now give a deprecation warning because they cause a possible unintentional chdir to the home directory. Say chdir() if you really mean that.
- Two new debugging options have been added: if you have compiled your Perl with debugging, you can use the -DT [561] and -DR options to trace tokenising and to add reference counts to displaying variables, respectively.
- The lexical warnings category "deprecated" is no longer a sub-category of the "syntax" category. It is now a top-level category in its own right.
- Unadorned dump() will now give a warning suggesting to use explicit CORE::dump() if that's what really is meant.
- The "Unrecognized escape" warning has been extended to include `\8`, `\9`, and `\_`. There is no need to escape any of the `\w` characters.
- All regular expression compilation error messages are now hopefully easier to understand both because the error message now comes before the failed regex and because the point of failure is now clearly marked by a `<- HERE` marker.
- Various I/O (and socket) functions like binmode(), close(), and so forth now more consistently warn if they are used illogically either on a yet unopened or on an already closed filehandle (or socket).
- Using lstat() on a filehandle now gives a warning. (It's a non-sensical thing to do.)
- The `-M` and `-m` options now warn if you didn't supply the module name.
- If you in `use` specify a required minimum version, modules matching the name and but not defining a $VERSION will cause a fatal failure.
- Using negative offset for vec() in lvalue context is now a warnable offense.
- Odd number of arguments to overload::constant now elicits a warning.
- Odd number of elements in anonymous hash now elicits a warning.
- The various "opened only for", "on closed", "never opened" warnings drop the `main::` prefix for filehandles in the `main` package, for example `STDIN` instead of `main::STDIN`.
- Subroutine prototypes are now checked more carefully, you may get warnings for example if you have used non-prototype characters.
- If an attempt to use a (non-blessed) reference as an array index is made, a warning is given.
- `push @a;` and `unshift @a;` (with no values to push or unshift) now give a warning. This may be a problem for generated and evaled code.
- If you try to `pack` in *perlfunc* a number less than 0 or larger than 255 using the `"C"` format you will get an optional warning. Similarly for the `"c"` format and a number less than -128 or more than 127.
- pack `P` format now demands an explicit size.

- unpack `w` now warns of unterminated compressed integers.
- Warnings relating to the use of PerlIO have been added.
- Certain regex modifiers such as `(?o)` make sense only if applied to the entire regex. You will get an optional warning if you try to do otherwise.
- Variable length lookbehind has not yet been implemented, trying to use it will tell that.
- Using arrays or hashes as references (e.g. `%foo->{bar}` has been deprecated for a while. Now you will get an optional warning.
- Warnings relating to the use of the new restricted hashes feature have been added.
- Self-ties of arrays and hashes are not supported and fatal errors will happen even at an attempt to do so.
- Using `sort` in scalar context now issues an optional warning. This didn't do anything useful, as the sort was not performed.
- Using the /g modifier in split() is meaningless and will cause a warning.
- Using splice() past the end of an array now causes a warning.
- Malformed Unicode encodings (UTF-8 and UTF-16) cause a lot of warnings, ad doestrying to use UTF-16 surrogates (which are unimplemented).
- Trying to use Unicode characters on an I/O stream without marking the stream's encoding (using open() or binmode()) will cause "Wide character" warnings.
- Use of v-strings in use/require causes a (backward) portability warning.
- Warnings relating to the use interpreter threads and their shared data have been added.

86.12 Changed Internals

- PerlIO is now the default.
- perlapi.pod (a companion to perlguts) now attempts to document the internal API.
- You can now build a really minimal perl called microperl. Building microperl does not require even running Configure; `make -f Makefile.micro` should be enough. Beware: microperl makes many assumptions, some of which may be too bold; the resulting executable may crash or otherwise misbehave in wondrous ways. For careful hackers only.
- Added rsignal(), whichsig(), do_join(), op_clear, op_null, ptr_table_clear(), ptr_table_free(), sv_setref_uv(), and several UTF-8 interfaces to the publicised API. For the full list of the available APIs see *perlapi*.
- Made possible to propagate customised exceptions via croak()ing.
- Now xsubs can have attributes just like subs. (Well, at least the built-in attributes.)
- dTHR and djSP have been obsoleted; the former removed (because it's a no-op) and the latter replaced with dSP.
- PERL_OBJECT has been completely removed.
- The MAGIC constants (e.g. `'P'`) have been macrofied (e.g. `PERL_MAGIC_TIED`) for better source code readability and maintainability.
- The regex compiler now maintains a structure that identifies nodes in the compiled bytecode with the corresponding syntactic features of the original regex expression. The information is attached to the new `offsets` member of the `struct regexp`. See *perldebguts* for more complete information.

- The C code has been made much more `gcc -Wall` clean. Some warning messages still remain in some platforms, so if you are compiling with gcc you may see some warnings about dubious practices. The warnings are being worked on.
- *perly.c*, *sv.c*, and *sv.h* have now been extensively commented.
- Documentation on how to use the Perl source repository has been added to *Porting/repository.pod*.
- There are now several profiling make targets.

86.13 Security Vulnerability Closed [561]

(This change was already made in 5.7.0 but bears repeating here.) (5.7.0 came out before 5.6.1: the development branch 5.7 released earlier than the maintenance branch 5.6)

A potential security vulnerability in the optional suidperl component of Perl was identified in August 2000. suidperl is neither built nor installed by default. As of November 2001 the only known vulnerable platform is Linux, most likely all Linux distributions. CERT and various vendors and distributors have been alerted about the vulnerability. See http://www.cpan.org/src/5.0/sperl-2000-08-05/sperl-2000-08-05.txt for more information.

The problem was caused by Perl trying to report a suspected security exploit attempt using an external program, /bin/mail. On Linux platforms the /bin/mail program had an undocumented feature which when combined with suidperl gave access to a root shell, resulting in a serious compromise instead of reporting the exploit attempt. If you don't have /bin/mail, or if you have 'safe setuid scripts', or if suidperl is not installed, you are safe.

The exploit attempt reporting feature has been completely removed from Perl 5.8.0 (and the maintenance release 5.6.1, and it was removed also from all the Perl 5.7 releases), so that particular vulnerability isn't there anymore. However, further security vulnerabilities are, unfortunately, always possible. The suidperl functionality is most probably going to be removed in Perl 5.10. In any case, suidperl should only be used by security experts who know exactly what they are doing and why they are using suidperl instead of some other solution such as sudo (see http://www.courtesan.com/sudo/).

86.14 New Tests

Several new tests have been added, especially for the *lib* and *ext* subsections. There are now about 69 000 individual tests (spread over about 700 test scripts), in the regression suite (5.6.1 has about 11 700 tests, in 258 test scripts) The exact numbers depend on the platform and Perl configuration used. Many of the new tests are of course introduced by the new modules, but still in general Perl is now more thoroughly tested.

Because of the large number of tests, running the regression suite will take considerably longer time than it used to: expect the suite to take up to 4-5 times longer to run than in perl 5.6. On a really fast machine you can hope to finish the suite in about 6-8 minutes (wallclock time).

The tests are now reported in a different order than in earlier Perls. (This happens because the test scripts from under t/lib have been moved to be closer to the library/extension they are testing.)

86.15 Known Problems

86.15.1 The Compiler Suite Is Still Very Experimental

The compiler suite is slowly getting better but it continues to be highly experimental. Use in production environments is discouraged.

86.15.2 Localising Tied Arrays and Hashes Is Broken

```
    local %tied_array;
```

doesn't work as one would expect: the old value is restored incorrectly. This will be changed in a future release, but we don't know yet what the new semantics will exactly be. In any case, the change will break existing code that relies on the current (ill-defined) semantics, so just avoid doing this in general.

86.15.3 Building Extensions Can Fail Because Of Largefiles

Some extensions like mod_perl are known to have issues with 'largefiles', a change brought by Perl 5.6.0 in which file offsets default to 64 bits wide, where supported. Modules may fail to compile at all, or they may compile and work incorrectly. Currently, there is no good solution for the problem, but Configure now provides appropriate non-largefile ccflags, ldflags, libswanted, and libs in the %Config hash (e.g., $Config{ccflags_nolargefiles}) so the extensions that are having problems can try configuring themselves without the largefileness. This is admittedly not a clean solution, and the solution may not even work at all. One potential failure is whether one can (or, if one can, whether it's a good idea to) link together at all binaries with different ideas about file offsets; all this is platform-dependent.

86.15.4 Modifying $ _ Inside for(..)

```
   for (1..5) { $_++ }
```

works without complaint. It shouldn't. (You should be able to modify only lvalue elements inside the loops.) You can see the correct behaviour by replacing the 1..5 with 1, 2, 3, 4, 5.

86.15.5 mod_perl 1.26 Doesn't Build With Threaded Perl

Use mod_perl 1.27 or higher.

86.15.6 lib/ftmp-security tests warn 'system possibly insecure'

Don't panic. Read the 'make test' section of INSTALL instead.

86.15.7 libwww-perl (LWP) fails base/date #51

Use libwww-perl 5.65 or later.

86.15.8 PDL failing some tests

Use PDL 2.3.4 or later.

86.15.9 Perl_get_sv

You may get errors like 'Undefined symbol "Perl_get_sv"' or "can't resolve symbol 'Perl_get_sv'", or the symbol may be "Perl_sv_2pv". This probably means that you are trying to use an older shared Perl library (or extensions linked with such) with Perl 5.8.0 executable. Perl used to have such a subroutine, but that is no more the case. Check your shared library path, and any shared Perl libraries in those directories.

Sometimes this problem may also indicate a partial Perl 5.8.0 installation, see §86.16.15 for an example and how to deal with it.

86.15.10 Self-tying Problems

Self-tying of arrays and hashes is broken in rather deep and hard-to-fix ways. As a stop-gap measure to avoid people from getting frustrated at the mysterious results (core dumps, most often), it is forbidden for now (you will get a fatal error even from an attempt).

A change to self-tying of globs has caused them to be recursively referenced (see: Two-Phased Garbage Collection in *perlobj*). You will now need an explicit untie to destroy a self-tied glob. This behaviour may be fixed at a later date.

Self-tying of scalars and IO thingies works.

86.15.11 ext/threads/t/libc

If this test fails, it indicates that your libc (C library) is not threadsafe. This particular test stress tests the localtime() call to find out whether it is threadsafe. See *perlthrtut* for more information.

86.15.12 Failure of Thread (5.005-style) tests

Note that support for 5.005-style threading is deprecated, experimental and practically unsupported. In 5.10, it is expected to be removed. You should migrate your code to ithreads.

The following tests are known to fail due to fundamental problems in the 5.005 threading implementation. These are not new failures–Perl 5.005_0x has the same bugs, but didn't have these tests.

```
../ext/B/t/xref.t                  255 65280    14   12  85.71%  3-14
../ext/List/Util/t/first.t         255 65280     7    4  57.14%  2 5-7
../lib/English.t                     2   512    54    2   3.70%  2-3
../lib/FileCache.t                               5    1  20.00%  5
../lib/Filter/Simple/t/data.t                    6    3  50.00%  1-3
../lib/Filter/Simple/t/filter_only.              9    3  33.33%  1-2 5
../lib/Math/BigInt/t/bare_mbf.t               1627    4   0.25%  8 11 1626-1627
../lib/Math/BigInt/t/bigfltpm.t               1629    4   0.25%  10 13 1628-
                                                                 1629
../lib/Math/BigInt/t/sub_mbf.t                1633    4   0.24%  8 11 1632-1633
../lib/Math/BigInt/t/with_sub.t               1628    4   0.25%  9 12 1627-1628
../lib/Tie/File/t/31_autodefer.t   255 65280    65   32  49.23%  34-65
../lib/autouse.t                                10    1  10.00%  4
op/flip.t                                       15    1   6.67%  15
```

These failures are unlikely to get fixed as 5.005-style threads are considered fundamentally broken. (Basically what happens is that competing threads can corrupt shared global state, one good example being regular expression engine's state.)

86.15.13 Timing problems

The following tests may fail intermittently because of timing problems, for example if the system is heavily loaded.

```
    t/op/alarm.t
    ext/Time/HiRes/HiRes.t
    lib/Benchmark.t
    lib/Memoize/t/expmod_t.t
    lib/Memoize/t/speed.t
```

In case of failure please try running them manually, for example

```
    ./perl -Ilib ext/Time/HiRes/HiRes.t
```

86.15.14 Tied/Magical Array/Hash Elements Do Not Autovivify

For normal arrays `$foo = \$bar[1]` will assign `undef` to `$bar[1]` (assuming that it didn't exist before), but for tied/magical arrays and hashes such autovivification does not happen because there is currently no way to catch the reference creation. The same problem affects slicing over non-existent indices/keys of a tied/magical array/hash.

86.15.15 Unicode in package/class and subroutine names does not work

One can have Unicode in identifier names, but not in package/class or subroutine names. While some limited functionality towards this does exist as of Perl 5.8.0, that is more accidental than designed; use of Unicode for the said purposes is unsupported.

One reason of this unfinishedness is its (currently) inherent unportability: since both package names and subroutine names may need to be mapped to file and directory names, the Unicode capability of the filesystem becomes important– and there unfortunately aren't portable answers.

86.16 Platform Specific Problems

86.16.1 AIX

- If using the AIX native make command, instead of just "make" issue "make all". In some setups the former has been known to spuriously also try to run "make install". Alternatively, you may want to use GNU make.
- In AIX 4.2, Perl extensions that use C++ functions that use statics may have problems in that the statics are not getting initialized. In newer AIX releases, this has been solved by linking Perl with the libC_r library, but unfortunately in AIX 4.2 the said library has an obscure bug where the various functions related to time (such as time() and gettimeofday()) return broken values, and therefore in AIX 4.2 Perl is not linked against libC_r.
- vac 5.0.0.0 May Produce Buggy Code For Perl

  The AIX C compiler vac version 5.0.0.0 may produce buggy code, resulting in a few random tests failing when run as part of "make test", but when the failing tests are run by hand, they succeed. We suggest upgrading to at least vac version 5.0.1.0, that has been known to compile Perl correctly. "lslpp -L|grep vac.C" will tell you the vac version. See README.aix.
- If building threaded Perl, you may get compilation warning from pp_sys.c:

  ```
  "pp_sys.c", line 4651.39: 1506-280 (W) Function argument assignment between types "unsigned char
  ```

  This is harmless; it is caused by the getnetbyaddr() and getnetbyaddr_r() having slightly different types for their first argument.

86.16.2 Alpha systems with old gccs fail several tests

If you see op/pack, op/pat, op/regexp, or ext/Storable tests failing in a Linux/alpha or *BSD/Alpha, it's probably time to upgrade your gcc. gccs prior to 2.95.3 are definitely not good enough, and gcc 3.1 may be even better. (RedHat Linux/alpha with gcc 3.1 reported no problems, as did Linux 2.4.18 with gcc 2.95.4.) (In Tru64, it is preferable to use the bundled C compiler.)

86.16.3 AmigaOS

Perl 5.8.0 doesn't build in AmigaOS. It broke at some point during the ithreads work and we could not find Amiga experts to unbreak the problems. Perl 5.6.1 still works for AmigaOS (as does the the 5.7.2 development release).

86.16.4 BeOS

The following tests fail on 5.8.0 Perl in BeOS Personal 5.03:

```
t/op/lfs............................FAILED at test 17
t/op/magic..........................FAILED at test 24
ext/Fcntl/t/syslfs..................FAILED at test 17
ext/File/Glob/t/basic...............FAILED at test 3
ext/POSIX/t/sigaction...............FAILED at test 13
ext/POSIX/t/waitpid.................FAILED at test 1
```

See *perlbeos* (README.beos) for more details.

86.16.5 Cygwin "unable to remap"

For example when building the Tk extension for Cygwin, you may get an error message saying "unable to remap". This is known problem with Cygwin, and a workaround is detailed in here:
http://sources.redhat.com/ml/cygwin/2001-12/msg00894.html

86.16.6 Cygwin ndbm tests fail on FAT

One can build but not install (or test the build of) the NDBM_File on FAT filesystems. Installation (or build) on NTFS works fine. If one attempts the test on a FAT install (or build) the following failures are expected:

```
../ext/NDBM_File/ndbm.t       13  3328    71   59  83.10%  1-2 4 16-71
../ext/ODBM_File/odbm.t      255 65280    ??   ??       %  ??
../lib/AnyDBM_File.t           2   512    12    2  16.67%  1 4
../lib/Memoize/t/errors.t      0   139    11    5  45.45%  7-11
../lib/Memoize/t/tie_ndbm.t   13  3328     4    4 100.00%  1-4
run/fresh_perl.t                          97    1   1.03%  91
```

NDBM_File fails and ODBM_File just coredumps.

If you intend to run only on FAT (or if using AnyDBM_File on FAT), run Configure with the -Ui_ndbm and -Ui_dbm options to prevent NDBM_File and ODBM_File being built.

86.16.7 DJGPP Failures

```
t/op/stat...........................FAILED at test 29
lib/File/Find/t/find................FAILED at test 1
lib/File/Find/t/taint...............FAILED at test 1
lib/h2xs............................FAILED at test 15
lib/Pod/t/eol.......................FAILED at test 1
lib/Test/Harness/t/strap-analyze....FAILED at test 8
lib/Test/Harness/t/test-harness.....FAILED at test 23
lib/Test/Simple/t/exit..............FAILED at test 1
```

The above failures are known as of 5.8.0 with native builds with long filenames, but there are a few more if running under dosemu because of limitations (and maybe bugs) of dosemu:

```
t/comp/cpp..........................FAILED at test 3
t/op/inccode........................(crash)
```

and a few lib/ExtUtils tests, and several hundred Encode/t/Aliases.t failures that work fine with long filenames. So you really might prefer native builds and long filenames.

86.16.8 FreeBSD built with ithreads coredumps reading large directories

This is a known bug in FreeBSD 4.5's readdir_r(), it has been fixed in FreeBSD 4.6 (see *perlfreebsd* (README.freebsd)).

86.16.9 FreeBSD Failing locale Test 117 For ISO 8859-15 Locales

The ISO 8859-15 locales may fail the locale test 117 in FreeBSD. This is caused by the characters \xFF (y with diaeresis) and \xBE (Y with diaeresis) not behaving correctly when being matched case-insensitively. Apparently this problem has been fixed in the latest FreeBSD releases. (http://www.freebsd.org/cgi/query-pr.cgi?pr=34308)

86.16.10 IRIX fails ext/List/Util/t/shuffle.t or Digest::MD5

IRIX with MIPSpro 7.3.1.2m or 7.3.1.3m compiler may fail the List::Util test ext/List/Util/t/shuffle.t by dumping core. This seems to be a compiler error since if compiled with gcc no core dump ensues, and no failures have been seen on the said test on any other platform.

Similarly, building the Digest::MD5 extension has been known to fail with "*** Termination code 139 (bu21)".

The cure is to drop optimization level (Configure -Doptimize=-O2).

86.16.11 HP-UX lib/posix Subtest 9 Fails When LP64-Configured

If perl is configured with -Duse64bitall, the successful result of the subtest 10 of lib/posix may arrive before the successful result of the subtest 9, which confuses the test harness so much that it thinks the subtest 9 failed.

86.16.12 Linux with glibc 2.2.5 fails t/op/int subtest #6 with -Duse64bitint

This is a known bug in the glibc 2.2.5 with long long integers. (http://bugzilla.redhat.com/bugzilla/show_bug.cgi?id=65612)

86.16.13 Linux With Sfio Fails op/misc Test 48

No known fix.

86.16.14 Mac OS X

Please remember to set your environment variable LC_ALL to "C" (setenv LC_ALL C) before running "make test" to avoid a lot of warnings about the broken locales of Mac OS X.

The following tests are known to fail in Mac OS X 10.1.5 because of buggy (old) implementations of Berkeley DB included in Mac OS X:

```
Failed Test                 Stat Wstat Total Fail  Failed  List of Failed
-------------------------------------------------------------------------
../ext/DB_File/t/db-btree.t    0    11    ??   ??       %  ??
../ext/DB_File/t/db-recno.t              149    3   2.01%  61 63 65
```

If you are building on a UFS partition, you will also probably see t/op/stat.t subtest #9 fail. This is caused by Darwin's UFS not supporting inode change time.

Also the ext/POSIX/t/posix.t subtest #10 fails but it is skipped for now because the failure is Apple's fault, not Perl's (blocked signals are lost).

If you Configure with ithreads, ext/threads/t/libc.t will fail. Again, this is not Perl's fault– the libc of Mac OS X is not threadsafe (in this particular test, the localtime() call is found to be threadunsafe.)

86.16.15 Mac OS X dyld undefined symbols

If after installing Perl 5.8.0 you are getting warnings about missing symbols, for example

```
    dyld: perl Undefined symbols
    _perl_sv_2pv
    _perl_get_sv
```

you probably have an old pre-Perl-5.8.0 installation (or parts of one) in /Library/Perl (the undefined symbols used to exist in pre-5.8.0 Perls). It seems that for some reason "make install" doesn't always completely overwrite the files in /Library/Perl. You can move the old Perl shared library out of the way like this:

```
    cd /Library/Perl/darwin/CORE
    mv libperl.dylib libperlold.dylib
```

and then reissue "make install". Note that the above of course is extremely disruptive for anything using the /usr/local/bin/perl. If that doesn't help, you may have to try removing all the .bundle files from beneath /Library/Perl, and again "make install"-ing.

86.16.16 OS/2 Test Failures

The following tests are known to fail on OS/2 (for clarity only the failures are shown, not the full error messages):

```
../lib/ExtUtils/t/Mkbootstrap.t    1   256    18    1   5.56%  8
../lib/ExtUtils/t/Packlist.t       1   256    34    1   2.94%  17
../lib/ExtUtils/t/basic.t          1   256    17    1   5.88%  14
lib/os2_process.t                  2   512   227    2   0.88%  174 209
lib/os2_process_kid.t                        227    2   0.88%  174 209
lib/rx_cmprt.t                   255 65280    18    3  16.67%  16-18
```

86.16.17 op/sprintf tests 91, 129, and 130

The op/sprintf tests 91, 129, and 130 are known to fail on some platforms. Examples include any platform using sfio, and Compaq/Tandem's NonStop-UX.

Test 91 is known to fail on QNX6 (nto), because `sprintf '%e',0` incorrectly produces `0.000000e+0` instead of `0.000000e+00`.

For tests 129 and 130, the failing platforms do not comply with the ANSI C Standard: lines 19ff on page 134 of ANSI X3.159 1989, to be exact. (They produce something other than "1" and "-1" when formatting 0.6 and -0.6 using the printf format "%.0f"; most often, they produce "0" and "-0".)

86.16.18 SCO

The socketpair tests are known to be unhappy in SCO 3.2v5.0.4:

```
ext/Socket/socketpair.t...............FAILED tests 15-45
```

86.16.19 Solaris 2.5

In case you are still using Solaris 2.5 (aka SunOS 5.5), you may experience failures (the test core dumping) in lib/locale.t. The suggested cure is to upgrade your Solaris.

86.16.20 Solaris x86 Fails Tests With -Duse64bitint

The following tests are known to fail in Solaris x86 with Perl configured to use 64 bit integers:

```
ext/Data/Dumper/t/dumper............FAILED at test 268
ext/Devel/Peek/Peek.................FAILED at test 7
```

86.16.21 SUPER-UX (NEC SX)

The following tests are known to fail on SUPER-UX:

```
op/64bitint..........................FAILED tests 29-30, 32-33, 35-36
op/arith.............................FAILED tests 128-130
op/pack..............................FAILED tests 25-5625
op/pow...............................
op/taint.............................# msgsnd failed
../ext/IO/lib/IO/t/io_poll...........FAILED tests 3-4
../ext/IPC/SysV/ipcsysv..............FAILED tests 2, 5-6
../ext/IPC/SysV/t/msg................FAILED tests 2, 4-6
../ext/Socket/socketpair.............FAILED tests 12
../lib/IPC/SysV......................FAILED tests 2, 5-6
../lib/warnings......................FAILED tests 115-116, 118-119
```

The op/pack failure ("Cannot compress negative numbers at op/pack.t line 126") is serious but as of yet unsolved. It points at some problems with the signedness handling of the C compiler, as do the 64bitint, arith, and pow failures. Most of the rest point at problems with SysV IPC.

86.16.22 Term::ReadKey not working on Win32

Use Term::ReadKey 2.20 or later.

86.16.23 UNICOS/mk

- During Configure, the test

  ```
  Guessing which symbols your C compiler and preprocessor define...
  ```

  will probably fail with error messages like

  ```
  CC-20 cc: ERROR File = try.c, Line = 3
    The identifier "bad" is undefined.

    bad switch yylook 79bad switch yylook 79bad switch yylook 79bad switch yylook 79#ifdef A29K
    ^

  CC-65 cc: ERROR File = try.c, Line = 3
    A semicolon is expected at this point.
  ```

  This is caused by a bug in the awk utility of UNICOS/mk. You can ignore the error, but it does cause a slight problem: you cannot fully benefit from the h2ph utility (see *h2ph*) that can be used to convert C headers to Perl libraries, mainly used to be able to access from Perl the constants defined using C preprocessor, cpp. Because of the above error, parts of the converted headers will be invisible. Luckily, these days the need for h2ph is rare.

- If building Perl with interpreter threads (ithreads), the getgrent(), getgrnam(), and getgrgid() functions cannot return the list of the group members due to a bug in the multithreaded support of UNICOS/mk. What this means is that in list context the functions will return only three values, not four.

86.16.24 UTS

There are a few known test failures, see *perluts* (README.uts).

86.16.25 VOS (Stratus)

When Perl is built using the native build process on VOS Release 14.5.0 and GNU C++/GNU Tools 2.0.1, all attempted tests either pass or result in TODO (ignored) failures.

86.16.26 VMS

There should be no reported test failures with a default configuration, though there are a number of tests marked TODO that point to areas needing further debugging and/or porting work.

86.16.27 Win32

In multi-CPU boxes, there are some problems with the I/O buffering: some output may appear twice.

86.16.28 XML::Parser not working

Use XML::Parser 2.31 or later.

86.16.29 z/OS (OS/390)

z/OS has rather many test failures but the situation is actually much better than it was in 5.6.0; it's just that so many new modules and tests have been added.

```
Failed Test                   Stat Wstat Total Fail  Failed  List of Failed
---------------------------------------------------------------------------
../ext/Data/Dumper/t/dumper.t              357    8   2.24%  311 314 325 327
                                                             331 333 337 339
../ext/IO/lib/IO/t/io_unix.t                 5    4  80.00%  2-5
../ext/Storable/t/downgrade.t   12  3072   169   12   7.10%  14-15 46-47 78-79
                                                             110-111 150 161
../lib/ExtUtils/t/Constant.t   121 30976    48   48 100.00%  1-48
../lib/ExtUtils/t/Embed.t                    9    9 100.00%  1-9
op/pat.t                                   922    7   0.76%  665 776 785 832-
                                                             834 845
op/sprintf.t                               224    3   1.34%  98 100 136
op/tr.t                                     97    5   5.15%  63 71-74
uni/fold.t                                 780    6   0.77%  61 169 196 661
                                                             710-711
```

The failures in dumper.t and downgrade.t are problems in the tests, those in io_unix and sprintf are problems in the USS (UDP sockets and printf formats). The pat, tr, and fold failures are genuine Perl problems caused by EBCDIC (and in the pat and fold cases, combining that with Unicode). The Constant and Embed are probably problems in the tests (since they test Perl's ability to build extensions, and that seems to be working reasonably well.)

86.16.30 Unicode Support on EBCDIC Still Spotty

Though mostly working, Unicode support still has problem spots on EBCDIC platforms. One such known spot are the `\p{}` and `\P{}` regular expression constructs for code points less than 256: the `pP` are testing for Unicode code points, not knowing about EBCDIC.

86.16.31 Seen In Perl 5.7 But Gone Now

`Time::Piece` (previously known as `Time::Object`) was removed because it was felt that it didn't have enough value in it to be a core module. It is still a useful module, though, and is available from the CPAN.

Perl 5.8 unfortunately does not build anymore on AmigaOS; this broke accidentally at some point. Since there are not that many Amiga developers available, we could not get this fixed and tested in time for 5.8.0. Perl 5.6.1 still works for AmigaOS (as does the the 5.7.2 development release).

The `PerlIO::Scalar` and `PerlIO::Via` (capitalised) were renamed as `PerlIO::scalar` and `PerlIO::via` (all lowercase) just before 5.8.0. The main rationale was to have all core PerlIO layers to have all lowercase names. The "plugins" are named as usual, for example `PerlIO::via::QuotedPrint`.

The `threads::shared::queue` and `threads::shared::semaphore` were renamed as `Thread::Queue` and `Thread::Semaphore` just before 5.8.0. The main rationale was to have thread modules to obey normal naming, `Thread::` (the `threads` and `threads::shared` themselves are more pragma-like, they affect compile-time, so they stay lowercase).

86.17 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org/ . There may also be information at http://www.perl.com/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

Chapter 87

perl573delta

What's new for perl v5.7.3

87.1 DESCRIPTION

This document describes differences between the 5.7.2 release and the 5.7.3 release.

(To view the differences between the 5.6.0 release and the 5.7.0 release, see *perl570delta*. To view the differences between the 5.7.0 release and the 5.7.1 release, see *perl571delta*. To view the differences between the 5.7.1 release and the 5.7.2 release, see *perl572delta*.)

87.2 Changes

This is just a selected list of some of the more notable changes. The numbers refer to the Perl repository change numbers; see *Changes58* (or *Changes* in Perl 5.8.1). In addition to these changes, lots of work took place in integrating threads, PerlIO, and Unicode; general code cleanup; and last but not least porting to non-UNIX lands such as Win32, VMS, Cygwin, DJGPP, VOS, MacOS Classic, and EBCDIC.

1. add LC_MESSAGES to POSIX :locale_h export tag
2. add DEL to [:cntrl:]
3. make h2ph understand constants like 1234L and 5678LL
4. Win32: fix bugs in handling of the virtualized environment
5. fix a bug in the security taint checking of open()
6. make perl fork() safe even on platforms that don't have pthread_atfork()
7. make switching optimization and debugging levels during Perl builds easier via the OPTIMIZE environment variable
8. make split()'s unused captures to be undef, not ''
9. Search::Dict: allow transforming lines before comparing
10. allow installing extra modules or bundles when building Perl
11. add -Wall in cflags when compiling with gcc to weed out dubious C practices
12. pluggable optimizer
13. WinCE: integrate the port

14. Win32: 4-arg select was broken
15. introduce the perlivp utility for verifying the Perl installation (IVP = Installation Verification Procedure)
16. rename lib/unicode to lib/unicore to avoid case-insensitivity problems with lib/Unicode
17. remove Time::Piece
18. document that use utf8 is not the right way most of the time
19. allow builing perl with -DUSE_UTF8_SCRIPTS which makes UTF-8 the default script encoding (not the default since that would break all scripts having legacy eight-bit data in them)
20. division preserving 64-bit integers
21. document the coderef-in-@INC feature
22. modulo (%) preserving 64-bit integers
23. update to Unicode 3.1.1
24. add the \[$@%&*] prototype support
25. oct() and hex() in glorious 64 bit
26. Class::Struct: allow recursive classes
27. fix unpack U to be the reverse of pack U
28. VMS: waitpid enhancements
29. unpack("Z*Z*", pack("Z*Z*", ..)) was broken
30. Devel::Peek: display UTF-8 SVs also also as \x{...}
31. Data::Dumper: option to sort hashes
32. add perlpodspec
33. threadsafe DynaLoader, re, Opcode, File::Glob, and B
34. support BeOS better
35. read-only hashes (user-level interface is Hash::Util)
36. add Devel::PPPort
37. add the sort pragma
38. VMS: fix perl -P
39. add perlpacktut
40. SUPER-UX: add hints file
41. Win32: non-blocking waitpid(-1,WNOHANG)
42. introduce the -t option for gentler taint checking
43. add the if pragma
44. implement IV/UV/NV/long double un/packing with j/J/F/D
45. document the new taint behaviour of exec LIST and system LIST

87.3 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org. There may also be information at http://www.perl.com/, the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

Chapter 88

perl572delta

What's new for perl v5.7.2

88.1 DESCRIPTION

This document describes differences between the 5.7.1 release and the 5.7.2 release.

(To view the differences between the 5.6.0 release and the 5.7.0 release, see *perl570delta*. To view the differences between the 5.7.0 release and the 5.7.1 release, see *perl571delta*.)

88.2 Security Vulnerability Closed

(This change was already made in 5.7.0 but bears repeating here.)

A security vulnerability affecting all Perl versions prior to 5.6.1 was found in August 2000. The vulnerability does not affect default installations and as far as is known affects only the Linux platform.

You should upgrade your Perl to 5.6.1 as soon as possible. Patches for earlier releases exist but using the patches require full recompilation from the source code anyway, so 5.6.1 is your best choice.

See http://www.cpan.org/src/5.0/sperl-2000-08-05/sperl-2000-08-05.txt for more information.

88.3 Incompatible Changes

88.3.1 64-bit platforms and malloc

If your pointers are 64 bits wide, the Perl malloc is no more being used because it simply does not work with 8-byte pointers. Also, usually the system malloc on such platforms are much better optimized for such large memory models than the Perl malloc.

88.3.2 AIX Dynaloading

The AIX dynaloading now uses in AIX releases 4.3 and newer the native dlopen interface of AIX instead of the old emulated interface. This change will probably break backward compatibility with compiled modules. The change was made to make Perl more compliant with other applications like modperl which are using the AIX native interface.

88.3.3 Socket Extension Dynamic in VMS

The Socket extension is now dynamically loaded instead of being statically built in. This may or may not be a problem with ancient TCP/IP stacks of VMS: we do not know since we weren't able to test Perl in such configurations.

88.3.4 Different Definition of the Unicode Character Classes \p{In...}

As suggested by the Unicode consortium, the Unicode character classes now prefer *scripts* as opposed to *blocks* (as defined by Unicode); in Perl, when the `\p{In....}` and the `\p{In....}` regular expression constructs are used. This has changed the definition of some of those character classes.

The difference between scripts and blocks is that scripts are the glyphs used by a language or a group of languages, while the blocks are more artificial groupings of 256 characters based on the Unicode numbering.

In general this change results in more inclusive Unicode character classes, but changes to the other direction also do take place: for example while the script `Latin` includes all the Latin characters and their various diacritic-adorned versions, it does not include the various punctuation or digits (since they are not solely `Latin`).

Changes in the character class semantics may have happened if a script and a block happen to have the same name, for example `Hebrew`. In such cases the script wins and `\p{InHebrew}` now means the script definition of Hebrew. The block definition in still available, though, by appending `Block` to the name: `\p{InHebrewBlock}` means what `\p{InHebrew}` meant in perl 5.6.0. For the full list of affected character classes, see Blocks in *perlunicode*.

88.3.5 Deprecations

The current user-visible implementation of pseudo-hashes (the weird use of the first array element) is deprecated starting from Perl 5.8.0 and will be removed in Perl 5.10.0, and the feature will be implemented differently. Not only is the current interface rather ugly, but the current implementation slows down normal array and hash use quite noticeably. The `fields` pragma interface will remain available.

The syntaxes `@a->[...]` and `@h->{...}` have now been deprecated.

The suidperl is also considered to be too much a risk to continue maintaining and the suidperl code is likely to be removed in a future release.

The `package;` syntax (`package` without an argument has been deprecated. Its semantics were never that clear and its implementation even less so. If you have used that feature to disallow all but fully qualified variables, `use strict;` instead.

The chdir(undef) and chdir(”) behaviors to match chdir() has been deprecated. In future versions, chdir(undef) and chdir(”) will simply fail.

88.4 Core Enhancements

In general a lot of fixing has happened in the area of Perl's understanding of numbers, both integer and floating point. Since in many systems the standard number parsing functions like `strtoul()` and `atof()` seem to have bugs, Perl tries to work around their deficiencies. This results hopefully in more accurate numbers.

- The rules for allowing underscores (underbars) in numeric constants have been relaxed and simplified: now you can have an underscore **between digits**.
- GMAGIC (right-hand side magic) could in many cases such as string concatenation be invoked too many times.
- Lexicals I: lexicals outside an eval "" weren't resolved correctly inside a subroutine definition inside the eval "" if they were not already referenced in the top level of the eval""ed code.
- Lexicals II: lexicals leaked at file scope into subroutines that were declared before the lexicals.
- Lvalue subroutines can now return `undef` in list context.
- The `op_clear` and `op_null` are now exported.
- A new special regular expression variable has been introduced: `$^N`, which contains the most-recently closed group (submatch).
- *utime* now supports `utime undef, undef, @files` to change the file timestamps to the current time.

- The Perl parser has been stress tested using both random input and Markov chain input.
- `eval "v200"` now works.
- VMS now works under PerlIO.
- END blocks are now run even if you exit/die in a BEGIN block. The execution of END blocks is now controlled by PL_exit_flags & PERL_EXIT_DESTRUCT_END. This enables the new behaviour for perl embedders. This will default in 5.10. See *perlembed*.

88.5 Modules and Pragmata

88.5.1 New Modules and Distributions

- *Attribute::Handlers* - Simpler definition of attribute handlers
- *ExtUtils::Constant* - generate XS code to import C header constants
- *I18N::Langinfo* - query locale information
- *I18N::LangTags* - functions for dealing with RFC3066-style language tags
- *libnet* - a collection of perl5 modules related to network programming

  Perl installation leaves libnet unconfigured, use *libnetcfg* to configure.
- *List::Util* - selection of general-utility list subroutines
- *Locale::Maketext* - framework for localization
- *Memoize* - Make your functions faster by trading space for time
- *NEXT* - pseudo-class for method redispatch
- *Scalar::Util* - selection of general-utility scalar subroutines
- *Test::More* - yet another framework for writing test scripts
- *Test::Simple* - Basic utilities for writing tests
- *Time::HiRes* - high resolution ualarm, usleep, and gettimeofday
- *Time::Piece* - Object Oriented time objects

  (Previously known as *Time::Object*.)
- *Time::Seconds* - a simple API to convert seconds to other date values
- *UnicodeCD* - Unicode Character Database

88.5.2 Updated And Improved Modules and Pragmata

- *B::Deparse* module has been significantly enhanced. It now can deparse almost all of the standard test suite (so that the tests still succeed). There is a make target "test.deparse" for trying this out.
- *Class::Struct* now assigns the array/hash element if the accessor is called with an array/hash element as the **sole** argument.
- *Cwd* extension is now (even) faster.
- DB_File extension has been updated to version 1.77.
- *Fcntl*, *Socket*, and *Sys::Syslog* have been rewritten to use the new-style constant dispatch section (see *ExtUtils::Constant*).

- *File::Find* is now (again) reentrant. It also has been made more portable.
- *File::Glob* now supports `GLOB_LIMIT` constant to limit the size of the returned list of filenames.
- *IO::Socket::INET* now supports `LocalPort` of zero (usually meaning that the operating system will make one up.)
- The *vars* pragma now supports declaring fully qualified variables. (Something that `our()` does not and will not support.)

88.6 Utility Changes

- The *emacs/e2ctags.pl* is now much faster.
- *h2ph* now supports C trigraphs.
- *h2xs* uses the new *ExtUtils::Constant* module which will affect newly created extensions that define constants. Since the new code is more correct (if you have two constants where the first one is a prefix of the second one, the first constant **never** gets defined), less lossy (it uses integers for integer constant, as opposed to the old code that used floating point numbers even for integer constants), and slightly faster, you might want to consider regenerating your extension code (the new scheme makes regenerating easy). *h2xs* now also supports C trigraphs.
- *libnetcfg* has been added to configure the libnet.
- The *Pod::Html* (and thusly *pod2html*) now allows specifying a cache directory.

88.7 New Documentation

- *Locale::Maketext::TPJ13* is an article about software localization, originally published in The Perl Journal #13, republished here with kind permission.
- More README.$PLATFORM files have been converted into pod, which also means that they also be installed as perl$PLATFORM documentation files. The new files are *perlapollo*, *perlbeos*, *perldgux*, *perlhurd*, *perlmint*, *perlnetware*, *perlplan9*, *perlqnx*, and *perltru64*.
- The *Todo* and *Todo-5.6* files have been merged into *perltodo*.
- Use of the *gprof* tool to profile Perl has been documented in *perlhack*. There is a make target "perl.gprof" for generating a gprofiled Perl executable.

88.8 Installation and Configuration Improvements

88.8.1 New Or Improved Platforms

- AIX should now work better with gcc, threads, and 64-bitness. Also the long doubles support in AIX should be better now. See *perlaix*.
- AtheOS (http://www.atheos.cx/) is a new platform.
- DG/UX platform now supports the 5.005-style threads. See *perldgux*.
- DYNIX/ptx platform (a.k.a. dynixptx) is supported at or near osvers 4.5.2.
- Several Mac OS (Classic) portability patches have been applied. We hope to get a fully working port by 5.8.0. (The remaining problems relate to the changed IO model of Perl.) See *perlmacos*.
- Mac OS X (or Darwin) should now be able to build Perl even on HFS+ filesystems. (The case-insensitivity confused the Perl build process.)
- NetWare from Novell is now supported. See *perlnetware*.
- The Amdahl UTS UNIX mainframe platform is now supported.

88.8.2 Generic Improvements

- In AFS installations one can configure the root of the AFS to be somewhere else than the default */afs* by using the Configure parameter `-Dafsroot=/some/where/else`.
- The version of Berkeley DB used when the Perl (and, presumably, the DB_File extension) was built is now available as `@Config{qw(db_version_major db_version_minor db_version_patch)}` from Perl and as `DB_VERSION_MAJOR_CFG DB_VERSION_MINOR_CFG DB_VERSION_PATCH_CFG` from C.
- The Thread extension is now not built at all under ithreads (`Configure -Duseithreads`) because it wouldn't work anyway (the Thread extension requires being Configured with `-Duse5005threads`).
- The `B::Deparse` compiler backend has been so significantly improved that almost the whole Perl test suite passes after being deparsed. A make target has been added to help in further testing: `make test.deparse`.

88.9 Selected Bug Fixes

- The autouse pragma didn't work for Multi::Part::Function::Names.
- The behaviour of non-decimal but numeric string constants such as "0x23" was platform-dependent: in some platforms that was seen as 35, in some as 0, in some as a floating point number (don't ask). This was caused by Perl using the operating system libraries in a situation where the result of the string to number conversion is undefined: now Perl consistently handles such strings as zero in numeric contexts.
- *dprofpp* -R didn't work.
- PERL5OPT with embedded spaces didn't work.
- *Sys::Syslog* ignored the `LOG_AUTH` constant.

88.9.1 Platform Specific Changes and Fixes

- Some versions of glibc have a broken modfl(). This affects builds with `-Duselongdouble`. This version of Perl detects this brokenness and has a workaround for it. The glibc release 2.2.2 is known to have fixed the modfl() bug.

88.10 New or Changed Diagnostics

- In the regular expression diagnostics the `<< HERE` marker introduced in 5.7.0 has been changed to be `<- HERE` since too many people found the << to be too similar to here-document starters.
- If you try to pack in *perlfunc* a number less than 0 or larger than 255 using the `"C"` format you will get an optional warning. Similarly for the `"c"` format and a number less than -128 or more than 127.
- Certain regex modifiers such as `(?o)` make sense only if applied to the entire regex. You will an optional warning if you try to do otherwise.
- Using arrays or hashes as references (e.g. `%foo->{bar}` has been deprecated for a while. Now you will get an optional warning.

88.11 Source Code Enhancements

88.11.1 MAGIC constants

The MAGIC constants (e.g. `'P'`) have been macrofied (e.g. `PERL_MAGIC_TIED`) for better source code readability and maintainability.

88.11.2 Better commented code

perly.c, *sv.c*, and *sv.h* have now been extensively commented.

88.11.3 Regex pre-/post-compilation items matched up

The regex compiler now maintains a structure that identifies nodes in the compiled bytecode with the corresponding syntactic features of the original regex expression. The information is attached to the new `offsets` member of the `struct regexp`. See *perldebguts* for more complete information.

88.11.4 gcc -Wall

The C code has been made much more `gcc -Wall` clean. Some warning messages still remain, though, so if you are compiling with gcc you will see some warnings about dubious practices. The warnings are being worked on.

88.12 New Tests

Several new tests have been added, especially for the *lib* subsection.

The tests are now reported in a different order than in earlier Perls. (This happens because the test scripts from under t/lib have been moved to be closer to the library/extension they are testing.)

88.13 Known Problems

Note that unlike other sections in this document (which describe changes since 5.7.0) this section is cumulative containing known problems for all the 5.7 releases.

88.13.1 AIX

- In AIX 4.2 Perl extensions that use C++ functions that use statics may have problems in that the statics are not getting initialized. In newer AIX releases this has been solved by linking Perl with the libC_r library, but unfortunately in AIX 4.2 the said library has an obscure bug where the various functions related to time (such as time() and gettimeofday()) return broken values, and therefore in AIX 4.2 Perl is not linked against the libC_r.
- vac 5.0.0.0 May Produce Buggy Code For Perl

  The AIX C compiler vac version 5.0.0.0 may produce buggy code, resulting in few random tests failing, but when the failing tests are run by hand, they succeed. We suggest upgrading to at least vac version 5.0.1.0, that has been known to compile Perl correctly. "lslpp -L|grep vac.C" will tell you the vac version.

88.13.2 Amiga Perl Invoking Mystery

One cannot call Perl using the `volume:` syntax, that is, `perl -v` works, but for example `bin:perl -v` doesn't. The exact reason is known but the current suspect is the *ixemul* library.

88.13.3 lib/ftmp-security tests warn 'system possibly insecure'

Don't panic. Read INSTALL 'make test' section instead.

88.13.4 Cygwin intermittent failures of lib/Memoize/t/expire_file 11 and 12

The subtests 11 and 12 sometimes fail and sometimes work.

88.13.5 HP-UX lib/io_multihomed Fails When LP64-Configured

The lib/io_multihomed test may hang in HP-UX if Perl has been configured to be 64-bit. Because other 64-bit platforms do not hang in this test, HP-UX is suspect. All other tests pass in 64-bit HP-UX. The test attempts to create and connect to "multihomed" sockets (sockets which have multiple IP addresses).

88.13.6 HP-UX lib/posix Subtest 9 Fails When LP64-Configured

If perl is configured with -Duse64bitall, the successful result of the subtest 10 of lib/posix may arrive before the successful result of the subtest 9, which confuses the test harness so much that it thinks the subtest 9 failed.

88.13.7 Linux With Sfio Fails op/misc Test 48

No known fix.

88.13.8 OS/390

OS/390 has rather many test failures but the situation is actually better than it was in 5.6.0, it's just that so many new modules and tests have been added.

```
Failed Test                     Stat Wstat Total Fail  Failed  List of Failed

Failed 16/422 test scripts, 96.21% okay. 105/23251 subtests failed, 99.55% okay.
```

88.13.9 op/sprintf tests 129 and 130

The op/sprintf tests 129 and 130 are known to fail on some platforms. Examples include any platform using sfio, and Compaq/Tandem's NonStop-UX. The failing platforms do not comply with the ANSI C Standard, line 19ff on page 134 of ANSI X3.159 1989 to be exact. (They produce something other than "1" and "-1" when formatting 0.6 and -0.6 using the printf format "%.0f", most often they produce "0" and "-0".)

88.13.10 Failure of Thread tests

Note that support for 5.005-style threading remains experimental.

The following tests are known to fail due to fundamental problems in the 5.005 threading implementation. These are not new failures–Perl 5.005_0x has the same bugs, but didn't have these tests.

```
lib/autouse.t              4
t/lib/thr5005.t            19-20
```

88.13.11 UNICOS

- ext/POSIX/sigaction subtests 6 and 13 may fail.
- lib/ExtUtils may spuriously claim that subtest 28 failed, which is interesting since the test only has 27 tests.
- Numerous numerical test failures

```
    op/numconvert                209,210,217,218
    op/override                  7
    ext/Time/HiRes/HiRes         9
    lib/Math/BigInt/t/bigintpm   1145
    lib/Math/Trig                25
```

  These tests fail because of yet unresolved floating point inaccuracies.

88.13.12 UTS

There are a few known test failures, see *perluts*.

88.13.13 VMS

Rather many tests are failing in VMS but that actually more tests succeed in VMS than they used to, it's just that there are many, many more tests than there used to be.

Here are the known failures from some compiler/platform combinations.

DEC C V5.3-006 on OpenVMS VAX V6.2

```
  [-.ext.list.util.t]tainted..............FAILED on test 3
  [-.ext.posix]sigaction..................FAILED on test 7
  [-.ext.time.hires]hires.................FAILED on test 14
  [-.lib.file.find]taint..................FAILED on test 17
  [-.lib.math.bigint.t]bigintpm...........FAILED on test 1183
  [-.lib.test.simple.t]exit...............FAILED on test 1
  [.lib]vmsish............................FAILED on test 13
  [.op]sprintf............................FAILED on test 12
  Failed 8/399 tests, 91.23% okay.
```

DEC C V6.0-001 on OpenVMS Alpha V7.2-1 and Compaq C V6.2-008 on OpenVMS Alpha V7.1

```
  [-.ext.list.util.t]tainted..............FAILED on test 3
  [-.lib.file.find]taint..................FAILED on test 17
  [-.lib.test.simple.t]exit...............FAILED on test 1
  [.lib]vmsish............................FAILED on test 13
  Failed 4/399 tests, 92.48% okay.
```

Compaq C V6.4-005 on OpenVMS Alpha 7.2.1

```
  [-.ext.b]showlex........................FAILED on test 1
  [-.ext.list.util.t]tainted..............FAILED on test 3
  [-.lib.file.find]taint..................FAILED on test 17
  [-.lib.test.simple.t]exit...............FAILED on test 1
  [.lib]vmsish............................FAILED on test 13
  [.op]misc...............................FAILED on test 49
  Failed 6/401 tests, 92.77% okay.
```

88.13.14 Win32

In multi-CPU boxes there are some problems with the I/O buffering: some output may appear twice.

88.13.15 Localising a Tied Variable Leaks Memory

```
use Tie::Hash;
tie my %tie_hash => 'Tie::StdHash';

...

local($tie_hash{Foo}) = 1; # leaks
```

Code like the above is known to leak memory every time the local() is executed.

88.13.16 Self-tying of Arrays and Hashes Is Forbidden

Self-tying of arrays and hashes is broken in rather deep and hard-to-fix ways. As a stop-gap measure to avoid people from getting frustrated at the mysterious results (core dumps, most often) it is for now forbidden (you will get a fatal error even from an attempt).

88.13.17 Variable Attributes are not Currently Usable for Tieing

This limitation will hopefully be fixed in future. (Subroutine attributes work fine for tieing, see *Attribute::Handlers*).

88.13.18 Building Extensions Can Fail Because Of Largefiles

Some extensions like mod_perl are known to have issues with 'largefiles', a change brought by Perl 5.6.0 in which file offsets default to 64 bits wide, where supported. Modules may fail to compile at all or compile and work incorrectly. Currently there is no good solution for the problem, but Configure now provides appropriate non-largefile ccflags, ldflags, libswanted, and libs in the %Config hash (e.g., $Config{ccflags_nolargefiles}) so the extensions that are having problems can try configuring themselves without the largefileness. This is admittedly not a clean solution, and the solution may not even work at all. One potential failure is whether one can (or, if one can, whether it's a good idea) link together at all binaries with different ideas about file offsets, all this is platform-dependent.

88.13.19 The Compiler Suite Is Still Experimental

The compiler suite is slowly getting better but is nowhere near working order yet.

88.13.20 The Long Double Support is Still Experimental

The ability to configure Perl's numbers to use "long doubles", floating point numbers of hopefully better accuracy, is still experimental. The implementations of long doubles are not yet widespread and the existing implementations are not quite mature or standardised, therefore trying to support them is a rare and moving target. The gain of more precision may also be offset by slowdown in computations (more bits to move around, and the operations are more likely to be executed by less optimised libraries).

88.14 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org/ There may also be information at http://www.perl.com/perl/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

88.15 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

88.16 HISTORY

Written by Jarkko Hietaniemi <*jhi@iki.fi*>, with many contributions from The Perl Porters and Perl Users submitting feedback and patches.

Send omissions or corrections to <*perlbug@perl.org*>.

Chapter 89

perl571delta

What's new for perl v5.7.1

89.1 DESCRIPTION

This document describes differences between the 5.7.0 release and the 5.7.1 release.

(To view the differences between the 5.6.0 release and the 5.7.0 release, see *perl570delta*.)

89.2 Security Vulnerability Closed

(This change was already made in 5.7.0 but bears repeating here.)

A potential security vulnerability in the optional suidperl component of Perl was identified in August 2000. suidperl is neither built nor installed by default. As of April 2001 the only known vulnerable platform is Linux, most likely all Linux distributions. CERT and various vendors and distributors have been alerted about the vulnerability. See http://www.cpan.org/src/5.0/sperl-2000-08-05/sperl-2000-08-05.txt for more information.

The problem was caused by Perl trying to report a suspected security exploit attempt using an external program, /bin/mail. On Linux platforms the /bin/mail program had an undocumented feature which when combined with suidperl gave access to a root shell, resulting in a serious compromise instead of reporting the exploit attempt. If you don't have /bin/mail, or if you have 'safe setuid scripts', or if suidperl is not installed, you are safe.

The exploit attempt reporting feature has been completely removed from all the Perl 5.7 releases (and will be gone also from the maintenance release 5.6.1), so that particular vulnerability isn't there anymore. However, further security vulnerabilities are, unfortunately, always possible. The suidperl code is being reviewed and if deemed too risky to continue to be supported, it may be completely removed from future releases. In any case, suidperl should only be used by security experts who know exactly what they are doing and why they are using suidperl instead of some other solution such as sudo (see http://www.courtesan.com/sudo/).

89.3 Incompatible Changes

- Although "you shouldn't do that", it was possible to write code that depends on Perl's hashed key order (Data::Dumper does this). The new algorithm "One-at-a-Time" produces a different hashed key order. More details are in §89.6.
- The list of filenames from glob() (or <...>) is now by default sorted alphabetically to be csh-compliant. (bsd_glob() does still sort platform natively, ASCII or EBCDIC, unless GLOB_ALPHASORT is specified.)

89.4 Core Enhancements

89.4.1 AUTOLOAD Is Now Lvaluable

AUTOLOAD is now lvaluable, meaning that you can add the :lvalue attribute to AUTOLOAD subroutines and you can assign to the AUTOLOAD return value.

89.4.2 PerlIO is Now The Default

- IO is now by default done via PerlIO rather than system's "stdio". PerlIO allows "layers" to be "pushed" onto a file handle to alter the handle's behaviour. Layers can be specified at open time via 3-arg form of open:

  ```
  open($fh,'>:crlf :utf8', $path) || ...
  ```

  or on already opened handles via extended `binmode`:

  ```
  binmode($fh,':encoding(iso-8859-7)');
  ```

  The built-in layers are: unix (low level read/write), stdio (as in previous Perls), perlio (re-implementation of stdio buffering in a portable manner), crlf (does CRLF <=> "\n" translation as on Win32, but available on any platform). A mmap layer may be available if platform supports it (mostly UNIXes).

  Layers to be applied by default may be specified via the 'open' pragma.

  See §89.9 for the effects of PerlIO on your architecture name.

- File handles can be marked as accepting Perl's internal encoding of Unicode (UTF-8 or UTF-EBCDIC depending on platform) by a pseudo layer ":utf8" :

  ```
  open($fh,">:utf8","Uni.txt");
  ```

  Note for EBCDIC users: the pseudo layer ":utf8" is erroneously named for you since it's not UTF-8 what you will be getting but instead UTF-EBCDIC. See *perlunicode*, *utf8*, and http://www.unicode.org/unicode/reports/tr16/ for more information. In future releases this naming may change.

- File handles can translate character encodings from/to Perl's internal Unicode form on read/write via the ":encoding()" layer.

- File handles can be opened to "in memory" files held in Perl scalars via:

  ```
  open($fh,'>', \$variable) || ...
  ```

- Anonymous temporary files are available without need to 'use FileHandle' or other module via

  ```
  open($fh,"+>", undef) || ...
  ```

  That is a literal undef, not an undefined value.

- The list form of `open` is now implemented for pipes (at least on UNIX):

  ```
  open($fh,"-|", 'cat', '/etc/motd')
  ```

  creates a pipe, and runs the equivalent of exec('cat', '/etc/motd') in the child process.

- The following builtin functions are now overridable: chop(), chomp(), each(), keys(), pop(), push(), shift(), splice(), unshift().

- Formats now support zero-padded decimal fields.

- Perl now tries internally to use integer values in numeric conversions and basic arithmetics (+ - * /) if the arguments are integers, and tries also to keep the results stored internally as integers. This change leads into often slightly faster and always less lossy arithmetics. (Previously Perl always preferred floating point numbers in its math.)
- The printf() and sprintf() now support parameter reordering using the `%\d+\$` and `*\d+\$` syntaxes. For example

  ```
  print "%2\$s %1\$s\n", "foo", "bar";
  ```

  will print "bar foo\n"; This feature helps in writing internationalised software.
- Unicode in general should be now much more usable. Unicode can be used in hash keys, Unicode in regular expressions should work now, Unicode in tr/// should work now (though tr/// seems to be a particularly tricky to get right, so you have been warned)
- The Unicode Character Database coming with Perl has been upgraded to Unicode 3.1. For more information, see http://www.unicode.org/ , and http://www.unicode.org/unicode/reports/tr27/

  For developers interested in enhancing Perl's Unicode capabilities: almost all the UCD files are included with the Perl distribution in the lib/unicode subdirectory. The most notable omission, for space considerations, is the Unihan database.
- The Unicode character classes `\p{Blank}` and `\p{SpacePerl}` have been added. "Blank" is like C isblank(), that is, it contains only "horizontal whitespace" (the space character is, the newline isn't), and the "SpacePerl" is the Unicode equivalent of `\s` (`\p{Space}` isn't, since that includes the vertical tabulator character, whereas `\s` doesn't.)

89.4.3 Signals Are Now Safe

Perl used to be fragile in that signals arriving at inopportune moments could corrupt Perl's internal state.

89.5 Modules and Pragmata

89.5.1 New Modules

- B::Concise, by Stephen McCamant, is a new compiler backend for walking the Perl syntax tree, printing concise info about ops. The output is highly customisable.

  See *B::Concise* for more information.
- Class::ISA, by Sean Burke, for reporting the search path for a class's ISA tree, has been added.

  See *Class::ISA* for more information.
- Cwd has now a split personality: if possible, an extension is used, (this will hopefully be both faster and more secure and robust) but if not possible, the familiar Perl library implementation is used.
- Digest, a frontend module for calculating digests (checksums), from Gisle Aas, has been added.

  See *Digest* for more information.
- Digest::MD5 for calculating MD5 digests (checksums), by Gisle Aas, has been added.

  ```
  use Digest::MD5 'md5_hex';

  $digest = md5_hex("Thirsty Camel");

  print $digest, "\n"; # 01d19d9d2045e005c3f1b80e8b164de1
  ```

  NOTE: the MD5 backward compatibility module is deliberately not included since its use is discouraged.

  See *Digest::MD5* for more information.

- Encode, by Nick Ing-Simmons, provides a mechanism to translate between different character encodings. Support for Unicode, ISO-8859-*, ASCII, CP*, KOI8-R, and three variants of EBCDIC are compiled in to the module. Several other encodings (like Japanese, Chinese, and MacIntosh encodings) are included and will be loaded at runtime.

  Any encoding supported by Encode module is also available to the ":encoding()" layer if PerlIO is used.

  See *Encode* for more information.

- Filter::Simple is an easy-to-use frontend to Filter::Util::Call, from Damian Conway.

```
    # in MyFilter.pm:

    package MyFilter;

    use Filter::Simple sub {
        while (my ($from, $to) = splice @_, 0, 2) {
                s/$from/$to/g;
        }
    };

    1;

    # in user's code:

    use MyFilter qr/red/ => 'green';

    print "red\n";   # this code is filtered, will print "green\n"
    print "bored\n"; # this code is filtered, will print "bogreen\n"

    no MyFilter;

    print "red\n";   # this code is not filtered, will print "red\n"
```

  See *Filter::Simple* for more information.

- Filter::Util::Call, by Paul Marquess, provides you with the framework to write *Source Filters* in Perl. For most uses the frontend Filter::Simple is to be preferred. See *Filter::Util::Call* for more information.

- Locale::Constants, Locale::Country, Locale::Currency, and Locale::Language, from Neil Bowers, have been added. They provide the codes for various locale standards, such as "fr" for France, "usd" for US Dollar, and "jp" for Japanese.

```
    use Locale::Country;

    $country = code2country('jp');               # $country gets 'Japan'
    $code    = country2code('Norway');           # $code gets 'no'
```

  See *Locale::Constants*, *Locale::Country*, *Locale::Currency*, and *Locale::Language* for more information.

- MIME::Base64, by Gisle Aas, allows you to encode data in base64.

```
    use MIME::Base64;

    $encoded = encode_base64('Aladdin:open sesame');
    $decoded = decode_base64($encoded);

    print $encoded, "\n"; # "QWxhZGRpbjpvcGVuIHNlc2FtZQ=="
```

See *MIME::Base64* for more information.

- MIME::QuotedPrint, by Gisle Aas, allows you to encode data in quoted-printable encoding.

  ```
  use MIME::QuotedPrint;

  $encoded = encode_qp("Smiley in Unicode: \x{263a}");
  $decoded = decode_qp($encoded);

  print $encoded, "\n"; # "Smiley in Unicode: =263A"
  ```

  MIME::QuotedPrint has been enhanced to provide the basic methods necessary to use it with PerlIO::Via as in :

  ```
  use MIME::QuotedPrint;
  open($fh,">Via(MIME::QuotedPrint)",$path)
  ```

  See *MIME::QuotedPrint* for more information.

- PerlIO::Scalar, by Nick Ing-Simmons, provides the implementation of IO to "in memory" Perl scalars as discussed above. It also serves as an example of a loadable layer. Other future possibilities include PerlIO::Array and PerlIO::Code. See *PerlIO::Scalar* for more information.

- PerlIO::Via, by Nick Ing-Simmons, acts as a PerlIO layer and wraps PerlIO layer functionality provided by a class (typically implemented in perl code).

  ```
  use MIME::QuotedPrint;
  open($fh,">Via(MIME::QuotedPrint)",$path)
  ```

  This will automatically convert everything output to `$fh` to Quoted-Printable. See *PerlIO::Via* for more information.

- Pod::Text::Overstrike, by Joe Smith, has been added. It converts POD data to formatted overstrike text. See *Pod::Text::Overstrike* for more information.

- Switch from Damian Conway has been added. Just by saying

  ```
  use Switch;
  ```

  you have `switch` and `case` available in Perl.

  ```
  use Switch;

  switch ($val) {

              case 1          { print "number 1" }
              case "a"        { print "string a" }
              case [1..10,42] { print "number in list" }
              case (@array)   { print "number in list" }
              case /\w+/      { print "pattern" }
              case qr/\w+/    { print "pattern" }
              case (%hash)    { print "entry in hash" }
              case (\%hash)   { print "entry in hash" }
              case (\&sub)    { print "arg to subroutine" }
              else            { print "previous case not true" }
  }
  ```

  See *Switch* for more information.

- Text::Balanced from Damian Conway has been added, for extracting delimited text sequences from strings.

  ```
  use Text::Balanced 'extract_delimited';

  ($a, $b) = extract_delimited("'never say never', he never said", "'", '');
  ```

  $a will be "'never say never'", $b will be ', he never said'.

  In addition to extract_delimited() there are also extract_bracketed(), extract_quotelike(), extract_codeblock(), extract_variable(), extract_tagged(), extract_multiple(), gen_delimited_pat(), and gen_extract_tagged(). With these you can implement rather advanced parsing algorithms. See *Text::Balanced* for more information.

- Tie::RefHash::Nestable, by Edward Avis, allows storing hash references (unlike the standard Tie::RefHash) The module is contained within Tie::RefHash.

- XS::Typemap, by Tim Jenness, is a test extension that exercises XS typemaps. Nothing gets installed but for extension writers the code is worth studying.

89.5.2 Updated And Improved Modules and Pragmata

- B::Deparse should be now more robust. It still far from providing a full round trip for any random piece of Perl code, though, and is under active development: expect more robustness in 5.7.2.

- Class::Struct can now define the classes in compile time.

- Math::BigFloat has undergone much fixing, and in addition the fmod() function now supports modulus operations.

  (The fixed Math::BigFloat module is also available in CPAN for those who can't upgrade their Perl: http://www.cpan.org/authors/id/J/JP/JPEACOCK/)

- Devel::Peek now has an interface for the Perl memory statistics (this works only if you are using perl's malloc, and if you have compiled with debugging).

- IO::Socket has now atmark() method, which returns true if the socket is positioned at the out-of-band mark. The method is also exportable as a sockatmark() function.

- IO::Socket::INET has support for ReusePort option (if your platform supports it). The Reuse option now has an alias, ReuseAddr. For clarity you may want to prefer ReuseAddr.

- Net::Ping has been enhanced. There is now "external" protocol which uses Net::Ping::External module which runs external ping(1) and parses the output. An alpha version of Net::Ping::External is available in CPAN and in 5.7.2 the Net::Ping::External may be integrated to Perl.

- The `open` pragma allows layers other than ":raw" and ":crlf" when using PerlIO.

- POSIX::sigaction() is now much more flexible and robust. You can now install coderef handlers, 'DEFAULT', and 'IGNORE' handlers, installing new handlers was not atomic.

- The Test module has been significantly enhanced. Its use is greatly recommended for module writers.

- The utf8:: name space (as in the pragma) provides various Perl-callable functions to provide low level access to Perl's internal Unicode representation. At the moment only length() has been implemented.

The following modules have been upgraded from the versions at CPAN: CPAN, CGI, DB_File, File::Temp, Getopt::Long, Pod::Man, Pod::Text, Storable, Text-Tabs+Wrap.

89.6 Performance Enhancements

- Hashes now use Bob Jenkins "One-at-a-Time" hashing key algorithm (http://burtleburtle.net/bob/hash/doobs.html). This algorithm is reasonably fast while producing a much better spread of values than the old hashing algorithm (originally by Chris Torek, later tweaked by Ilya Zakharevich). Hash values output from the algorithm on a hash of all 3-char printable ASCII keys comes much closer to passing the DIEHARD random number generation tests. According to perlbench, this change has not affected the overall speed of Perl.
- unshift() should now be noticeably faster.

89.7 Utility Changes

- h2xs now produces template README.
- s2p has been completely rewritten in Perl. (It is in fact a full implementation of sed in Perl.)
- xsubpp now supports OUT keyword.

89.8 New Documentation

89.8.1 perlclib

Internal replacements for standard C library functions. (Interesting only for extension writers and Perl core hackers.)

89.8.2 perliol

Internals of PerlIO with layers.

89.8.3 README.aix

Documentation on compiling Perl on AIX has been added. AIX has several different C compilers and getting the right patch level is essential. On install README.aix will be installed as *perlaix*.

89.8.4 README.bs2000

Documentation on compiling Perl on the POSIX-BC platform (an EBCDIC mainframe environment) has been added.

This was formerly known as README.posix-bc but the name was considered to be too confusing (it has nothing to do with the POSIX module or the POSIX standard). On install README.bs2000 will be installed as *perlbs2000*.

89.8.5 README.macos

In perl 5.7.1 (and in the 5.6.1) the MacPerl sources have been synchronised with the standard Perl sources. To compile MacPerl some additional steps are required, and this file documents those steps. On install README.macos will be installed as *perlmacos*.

89.8.6 README.mpeix

The README.mpeix has been podified, which means that this information about compiling and using Perl on the MPE/iX miniframe platform will be installed as *perlmpeix*.

89.8.7 README.solaris

README.solaris has been created and Solaris wisdom from elsewhere in the Perl documentation has been collected there. On install README.solaris will be installed as *perlsolaris*.

89.8.8 README.vos

The README.vos has been podified, which means that this information about compiling and using Perl on the Stratus VOS miniframe platform will be installed as *perlvos*.

89.8.9 Porting/repository.pod

Documentation on how to use the Perl source repository has been added.

89.9 Installation and Configuration Improvements

- Because PerlIO is now the default on most platforms, "-perlio" doesn't get appended to the $Config{archname} (also known as $ˆO) anymore. Instead, if you explicitly choose not to use perlio (Configure command line option -Uuseperlio), you will get "-stdio" appended.
- Another change related to the architecture name is that "-64all" (-Duse64bitall, or "maximally 64-bit") is appended only if your pointers are 64 bits wide. (To be exact, the use64bitall is ignored.)
- APPLLIB_EXP, a less-know configuration-time definition, has been documented. It can be used to prepend site-specific directories to Perl's default search path (@INC), see INSTALL for information.
- Building Berkeley DB3 for compatibility modes for DB, NDBM, and ODBM has been documented in INSTALL.
- If you are on IRIX or Tru64 platforms, new profiling/debugging options have been added, see *perlhack* for more information about pixie and Third Degree.

89.9.1 New Or Improved Platforms

For the list of platforms known to support Perl, see Supported Platforms in *perlport*.

- AIX dynamic loading should be now better supported.
- After a long pause, AmigaOS has been verified to be happy with Perl.
- EBCDIC platforms (z/OS, also known as OS/390, POSIX-BC, and VM/ESA) have been regained. Many test suite tests still fail and the co-existence of Unicode and EBCDIC isn't quite settled, but the situation is much better than with Perl 5.6. See *perlos390*, *perlbs2000* (for POSIX-BC), and *perlvmesa* for more information.
- Building perl with -Duseithreads or -Duse5005threads now works under HP-UX 10.20 (previously it only worked under 10.30 or later). You will need a thread library package installed. See README.hpux.
- Mac OS Classic (MacPerl has of course been available since perl 5.004 but now the source code bases of standard Perl and MacPerl have been synchronised)
- NCR MP-RAS is now supported.
- NonStop-UX is now supported.
- Amdahl UTS is now supported.
- z/OS (formerly known as OS/390, formerly known as MVS OE) has now support for dynamic loading. This is not selected by default, however, you must specify -Dusedl in the arguments of Configure.

89.9.2 Generic Improvements

- Configure no longer includes the DBM libraries (dbm, gdbm, db, ndbm) when building the Perl binary. The only exception to this is SunOS 4.x, which needs them.
- Some new Configure symbols, useful for extension writers:

  d_cmsghdr
  For struct cmsghdr.

  d_fcntl_can_lock
  Whether fcntl() can be used for file locking.

  d_fsync

  d_getitimer

  d_getpagsz
  For getpagesize(), though you should prefer POSIX::sysconf(_SC_PAGE_SIZE))

  d_msghdr_s
  For struct msghdr.

  need_va_copy
  Whether one needs to use Perl_va_copy() to copy varargs.

  d_readv

  d_recvmsg

  d_sendmsg

  sig_size
  The number of elements in an array needed to hold all the available signals.

  d_sockatmark

  d_strtoq

  d_u32align
  Whether one needs to access character data aligned by U32 sized pointers.

  d_ualarm

  d_usleep

- Removed Configure symbols: the PDP-11 memory model settings: huge, large, medium, models.
- SOCKS support is now much more robust.
- If your file system supports symbolic links you can build Perl outside of the source directory by

```
mkdir perl/build/directory
cd perl/build/directory
sh /path/to/perl/source/Configure -Dmksymlinks ...
```

  This will create in perl/build/directory a tree of symbolic links pointing to files in /path/to/perl/source. The original files are left unaffected. After Configure has finished you can just say

```
make all test
```

  and Perl will be built and tested, all in perl/build/directory.

89.10 Selected Bug Fixes

Numerous memory leaks and uninitialized memory accesses have been hunted down. Most importantly anonymous subs used to leak quite a bit.

- chop(@list) in list context returned the characters chopped in reverse order. This has been reversed to be in the right order.
- The order of DESTROYs has been made more predictable.
- mkdir() now ignores trailing slashes in the directory name, as mandated by POSIX.
- Attributes (like :shared) didn't work with our().
- The PERL5OPT environment variable (for passing command line arguments to Perl) didn't work for more than a single group of options.
- The tainting behaviour of sprintf() has been rationalized. It does not taint the result of floating point formats anymore, making the behaviour consistent with that of string interpolation.
- All but the first argument of the IO syswrite() method are now optional.
- Tie::ARRAY SPLICE method was broken.
- vec() now tries to work with characters <= 255 when possible, but it leaves higher character values in place. In that case, if vec() was used to modify the string, it is no longer considered to be utf8-encoded.

89.10.1 Platform Specific Changes and Fixes

- Linux previously had problems related to sockaddrlen when using accept(), revcfrom() (in Perl: recv()), getpeername(), and getsockname().
- Previously DYNIX/ptx had problems in its Configure probe for non-blocking I/O.
- Windows
  - Borland C++ v5.5 is now a supported compiler that can build Perl. However, the generated binaries continue to be incompatible with those generated by the other supported compilers (GCC and Visual C++).
  - Win32::GetCwd() correctly returns C:\ instead of C: when at the drive root. Other bugs in chdir() and Cwd::cwd() have also been fixed.
  - Duping socket handles with open(F, ">&MYSOCK") now works under Windows 9x.
  - HTML files will be installed in c:\perl\html instead of c:\perl\lib\pod\html
  - The makefiles now provide a single switch to bulk-enable all the features enabled in ActiveState ActivePerl (a popular binary distribution).

89.11 New or Changed Diagnostics

Two new debugging options have been added: if you have compiled your Perl with debugging, you can use the -DT and -DR options to trace tokenising and to add reference counts to displaying variables, respectively.

- If an attempt to use a (non-blessed) reference as an array index is made, a warning is given.
- `push @a;` and `unshift @a;` (with no values to push or unshift) now give a warning. This may be a problem for generated and evaled code.

89.12 Changed Internals

- Some new APIs: ptr_table_clear(), ptr_table_free(), sv_setref_uv(). For the full list of the available APIs see *perlapi*.
- dTHR and djSP have been obsoleted; the former removed (because it's a no-op) and the latter replaced with dSP.
- Perl now uses system malloc instead of Perl malloc on all 64-bit platforms, and even in some not-always-64-bit platforms like AIX, IRIX, and Solaris. This change breaks backward compatibility but Perl's malloc has problems with large address spaces and also the speed of vendors' malloc is generally better in large address space machines (Perl's malloc is mostly tuned for space).

89.13 New Tests

Many new tests have been added. The most notable is probably the lib/1_compile: it is very notable because running it takes quite a long time – it test compiles all the Perl modules in the distribution. Please be patient.

89.14 Known Problems

Note that unlike other sections in this document (which describe changes since 5.7.0) this section is cumulative containing known problems for all the 5.7 releases.

89.14.1 AIX vac 5.0.0.0 May Produce Buggy Code For Perl

The AIX C compiler vac version 5.0.0.0 may produce buggy code, resulting in few random tests failing, but when the failing tests are run by hand, they succeed. We suggest upgrading to at least vac version 5.0.1.0, that has been known to compile Perl correctly. "lslpp -L|grep vac.C" will tell you the vac version.

89.14.2 lib/ftmp-security tests warn 'system possibly insecure'

Don't panic. Read INSTALL 'make test' section instead.

89.14.3 lib/io_multihomed Fails In LP64-Configured HP-UX

The lib/io_multihomed test may hang in HP-UX if Perl has been configured to be 64-bit. Because other 64-bit platforms do not hang in this test, HP-UX is suspect. All other tests pass in 64-bit HP-UX. The test attempts to create and connect to "multihomed" sockets (sockets which have multiple IP addresses).

89.14.4 Test lib/posix Subtest 9 Fails In LP64-Configured HP-UX

If perl is configured with -Duse64bitall, the successful result of the subtest 10 of lib/posix may arrive before the successful result of the subtest 9, which confuses the test harness so much that it thinks the subtest 9 failed.

89.14.5 lib/b test 19

The test fails on various platforms (PA64 and IA64 are known), but the exact cause is still being investigated.

89.14.6 Linux With Sfio Fails op/misc Test 48

No known fix.

89.14.7 sigaction test 13 in VMS

The test is known to fail; whether it's because of VMS of because of faulty test is not known.

89.14.8 sprintf tests 129 and 130

The op/sprintf tests 129 and 130 are known to fail on some platforms. Examples include any platform using sfio, and Compaq/Tandem's NonStop-UX. The failing platforms do not comply with the ANSI C Standard, line 19ff on page 134 of ANSI X3.159 1989 to be exact. (They produce something else than "1" and "-1" when formatting 0.6 and -0.6 using the printf format "%.0f", most often they produce "0" and "-0".)

89.14.9 Failure of Thread tests

The subtests 19 and 20 of lib/thr5005.t test are known to fail due to fundamental problems in the 5.005 threading implementation. These are not new failures–Perl 5.005_0x has the same bugs, but didn't have these tests. (Note that support for 5.005-style threading remains experimental.)

89.14.10 Localising a Tied Variable Leaks Memory

```
    use Tie::Hash;
    tie my %tie_hash => 'Tie::StdHash';

    ...

    local($tie_hash{Foo}) = 1; # leaks
```

Code like the above is known to leak memory every time the local() is executed.

89.14.11 Self-tying of Arrays and Hashes Is Forbidden

Self-tying of arrays and hashes is broken in rather deep and hard-to-fix ways. As a stop-gap measure to avoid people from getting frustrated at the mysterious results (core dumps, most often) it is for now forbidden (you will get a fatal error even from an attempt).

89.14.12 Building Extensions Can Fail Because Of Largefiles

Some extensions like mod_perl are known to have issues with 'largefiles', a change brought by Perl 5.6.0 in which file offsets default to 64 bits wide, where supported. Modules may fail to compile at all or compile and work incorrectly. Currently there is no good solution for the problem, but Configure now provides appropriate non-largefile ccflags, ldflags, libswanted, and libs in the %Config hash (e.g., $Config{ccflags_nolargefiles}) so the extensions that are having problems can try configuring themselves without the largefileness. This is admittedly not a clean solution, and the solution may not even work at all. One potential failure is whether one can (or, if one can, whether it's a good idea) link together at all binaries with different ideas about file offsets, all this is platform-dependent.

89.14.13 The Compiler Suite Is Still Experimental

The compiler suite is slowly getting better but is nowhere near working order yet.

89.15 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org/ There may also be information at http://www.perl.com/perl/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

89.16 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

89.17 HISTORY

Written by Jarkko Hietaniemi <*jhi@iki.fi*>, with many contributions from The Perl Porters and Perl Users submitting feedback and patches.

Send omissions or corrections to <*perlbug@perl.org*>.

Chapter 90

perl570delta

What's new for perl v5.7.0

90.1 DESCRIPTION

This document describes differences between the 5.6.0 release and the 5.7.0 release.

90.2 Security Vulnerability Closed

A potential security vulnerability in the optional suidperl component of Perl has been identified. suidperl is neither built nor installed by default. As of September the 2nd, 2000, the only known vulnerable platform is Linux, most likely all Linux distributions. CERT and various vendors have been alerted about the vulnerability.

The problem was caused by Perl trying to report a suspected security exploit attempt using an external program, /bin/mail. On Linux platforms the /bin/mail program had an undocumented feature which when combined with suidperl gave access to a root shell, resulting in a serious compromise instead of reporting the exploit attempt. If you don't have /bin/mail, or if you have 'safe setuid scripts', or if suidperl is not installed, you are safe.

The exploit attempt reporting feature has been completely removed from the Perl 5.7.0 release, so that particular vulnerability isn't there anymore. However, further security vulnerabilities are, unfortunately, always possible. The suidperl code is being reviewed and if deemed too risky to continue to be supported, it may be completely removed from future releases. In any case, suidperl should only be used by security experts who know exactly what they are doing and why they are using suidperl instead of some other solution such as sudo (see http://www.courtesan.com/sudo/).

90.3 Incompatible Changes

- Arrays now always interpolate into double-quoted strings: constructs like "foo@bar" now always assume `@bar` is an array, whether or not the compiler has seen use of `@bar`.
- The semantics of bless(REF, REF) were unclear and until someone proves it to make some sense, it is forbidden.
- A reference to a reference now stringify as "REF(0x81485ec)" instead of "SCALAR(0x81485ec)" in order to be more consistent with the return value of ref().
- The very dusty examples in the eg/ directory have been removed. Suggestions for new shiny examples welcome but the main issue is that the examples need to be documented, tested and (most importantly) maintained.
- The obsolete chat2 library that should never have been allowed to escape the laboratory has been decommissioned.
- The unimplemented POSIX regex features [[.cc.]] and [[=c=]] are still recognised but now cause fatal errors. The previous behaviour of ignoring them by default and warning if requested was unacceptable since it, in a way, falsely promised that the features could be used.

- The (bogus) escape sequences \8 and \9 now give an optional warning ("Unrecognized escape passed through"). There is no need to \-escape any `\w` character.
- lstat(FILEHANDLE) now gives a warning because the operation makes no sense. In future releases this may become a fatal error.
- The long deprecated uppercase aliases for the string comparison operators (EQ, NE, LT, LE, GE, GT) have now been removed.
- The regular expression captured submatches ($1, $2, ...) are now more consistently unset if the match fails, instead of leaving false data lying around in them.
- The tr///C and tr///U features have been removed and will not return; the interface was a mistake. Sorry about that. For similar functionality, see pack('U0', ...) and pack('C0', ...).

90.4 Core Enhancements

- `perl -d:Module=arg,arg,arg` now works (previously one couldn't pass in multiple arguments.)
- my __PACKAGE__ $obj now works.
- `no Module;` now works even if there is no "sub unimport" in the Module.
- The numerical comparison operators return `undef` if either operand is a NaN. Previously the behaviour was unspecified.
- `pack('U0a*', ...)` can now be used to force a string to UTF-8.
- prototype(\&) is now available.
- There is now an UNTIE method.

90.5 Modules and Pragmata

90.5.1 New Modules

- File::Temp allows one to create temporary files and directories in an easy, portable, and secure way.
- Storable gives persistence to Perl data structures by allowing the storage and retrieval of Perl data to and from files in a fast and compact binary format.

90.5.2 Updated And Improved Modules and Pragmata

- The following independently supported modules have been updated to newer versions from CPAN: CGI, CPAN, DB_File, File::Spec, Getopt::Long, the podlators bundle, Pod::LaTeX, Pod::Parser, Term::ANSIColor, Test.
- Bug fixes and minor enhancements have been applied to B::Deparse, Data::Dumper, IO::Poll, IO::Socket::INET, Math::BigFloat, Math::Complex, Math::Trig, Net::protoent, the re pragma, SelfLoader, Sys::SysLog, Test::Harness, Text::Wrap, UNIVERSAL, and the warnings pragma.
- The attributes::reftype() now works on tied arguments.
- AutoLoader can now be disabled with `no AutoLoader;`,
- The English module can now be used without the infamous performance hit by saying

```
        use English '-no_performance_hit';
```

(Assuming, of course, that one doesn't need the troublesome variables `` $` ``, `$&`, or `$'`.) Also, introduced `@LAST_MATCH_START` and `@LAST_MATCH_END` English aliases for `@-` and `@+`.

- File::Find now has pre- and post-processing callbacks. It also correctly changes directories when chasing symbolic links. Callbacks (naughtily) exiting with "next;" instead of "return;" now work.
- File::Glob::glob() renamed to File::Glob::bsd_glob() to avoid prototype mismatch with CORE::glob().
- IPC::Open3 now allows the use of numeric file descriptors.
- use lib now works identically to @INC. Removing directories with 'no lib' now works.
- `%INC` now localised in a Safe compartment so that use/require work.
- The Shell module now has an OO interface.

90.6 Utility Changes

- The Emacs perl mode (emacs/cperl-mode.el) has been updated to version 4.31.
- Perlbug is now much more robust. It also sends the bug report to perl.org, not perl.com.
- The perlcc utility has been rewritten and its user interface (that is, command line) is much more like that of the UNIX C compiler, cc.
- The xsubpp utility for extension writers now understands POD documentation embedded in the *.xs files.

90.7 New Documentation

- perl56delta details the changes between the 5.005 release and the 5.6.0 release.
- perldebtut is a Perl debugging tutorial.
- perlebcdic contains considerations for running Perl on EBCDIC platforms. Note that unfortunately EBCDIC platforms that used to supported back in Perl 5.005 are still unsupported by Perl 5.7.0; the plan, however, is to bring them back to the fold.
- perlnewmod tells about writing and submitting a new module.
- perlposix-bc explains using Perl on the POSIX-BC platform (an EBCDIC mainframe platform).
- perlretut is a regular expression tutorial.
- perlrequick is a regular expressions quick-start guide. Yes, much quicker than perlretut.
- perlutil explains the command line utilities packaged with the Perl distribution.

90.8 Performance Enhancements

- map() that changes the size of the list should now work faster.
- sort() has been changed to use mergesort internally as opposed to the earlier quicksort. For very small lists this may result in slightly slower sorting times, but in general the speedup should be at least 20%. Additional bonuses are that the worst case behaviour of sort() is now better (in computer science terms it now runs in time O(N log N), as opposed to quicksort's Theta(N**2) worst-case run time behaviour), and that sort() is now stable (meaning that elements with identical keys will stay ordered as they were before the sort).

90.9 Installation and Configuration Improvements

90.9.1 Generic Improvements

- INSTALL now explains how you can configure Perl to use 64-bit integers even on non-64-bit platforms.
- Policy.sh policy change: if you are reusing a Policy.sh file (see INSTALL) and you use Configure -Dprefix=/foo/bar and in the old Policy $prefix eq $siteprefix and $prefix eq $vendorprefix, all of them will now be changed to the new prefix, /foo/bar. (Previously only $prefix changed.) If you do not like this new behaviour, specify prefix, siteprefix, and vendorprefix explicitly.
- A new optional location for Perl libraries, otherlibdirs, is available. It can be used for example for vendor add-ons without disturbing Perl's own library directories.
- In many platforms the vendor-supplied 'cc' is too stripped-down to build Perl (basically, 'cc' doesn't do ANSI C). If this seems to be the case and 'cc' does not seem to be the GNU C compiler 'gcc', an automatic attempt is made to find and use 'gcc' instead.
- gcc needs to closely track the operating system release to avoid build problems. If Configure finds that gcc was built for a different operating system release than is running, it now gives a clearly visible warning that there may be trouble ahead.
- If binary compatibility with the 5.005 release is not wanted, Configure no longer suggests including the 5.005 modules in @INC.
- Configure `-S` can now run non-interactively.
- configure.gnu now works with options with whitespace in them.
- installperl now outputs everything to STDERR.
- $Config{byteorder} is now computed dynamically (this is more robust with "fat binaries" where an executable image contains binaries for more than one binary platform.)

90.10 Selected Bug Fixes

- Several debugger fixes: exit code now reflects the script exit code, condition `"0"` now treated correctly, the `d` command now checks line number, the `$.` no longer gets corrupted, all debugger output now goes correctly to the socket if RemotePort is set.
- `*foo{FORMAT}` now works.
- Lexical warnings now propagating correctly between scopes.
- Line renumbering with eval and `#line` now works.
- Fixed numerous memory leaks, especially in eval "".
- Modulus of unsigned numbers now works (4063328477 % 65535 used to return 27406, instead of 27047).
- Some "not a number" warnings introduced in 5.6.0 eliminated to be more compatible with 5.005. Infinity is now recognised as a number.
- our() variables will not cause "will not stay shared" warnings.
- pack "Z" now correctly terminates the string with "\0".
- Fix password routines which in some shadow password platforms (e.g. HP-UX) caused getpwent() to return every other entry.
- printf() no longer resets the numeric locale to "C".

- `q(a\\b)` now parses correctly as `'a\\b'`.
- Printing quads (64-bit integers) with printf/sprintf now works without the q L ll prefixes (assuming you are on a quad-capable platform).
- Regular expressions on references and overloaded scalars now work.
- scalar() now forces scalar context even when used in void context.
- sort() arguments are now compiled in the right wantarray context (they were accidentally using the context of the sort() itself).
- Changed the POSIX character class `[[:space:]]` to include the (very rare) vertical tab character. Added a new POSIX-ish character class `[[:blank:]]` which stands for horizontal whitespace (currently, the space and the tab).
- $AUTOLOAD, sort(), lock(), and spawning subprocesses in multiple threads simultaneously are now thread-safe.
- Allow read-only string on left hand side of non-modifying tr///.
- Several Unicode fixes (but still not perfect).
  - BOMs (byte order marks) in the beginning of Perl files (scripts, modules) should now be transparently skipped. UTF-16 (UCS-2) encoded Perl files should now be read correctly.
  - The character tables have been updated to Unicode 3.0.1.
  - chr() for values greater than 127 now create utf8 when under use utf8.
  - Comparing with utf8 data does not magically upgrade non-utf8 data into utf8.
  - `IsAlnum`, `IsAlpha`, and `IsWord` now match titlecase.
  - Concatenation with the `.` operator or via variable interpolation, `eq`, `substr`, `reverse`, `quotemeta`, the `x` operator, substitution with `s///`, single-quoted UTF-8, should now work–in theory.
  - The `tr///` operator now works *slightly* better but is still rather broken. Note that the `tr///CU` functionality has been removed (but see pack('U0', ...)).
  - vec() now refuses to deal with characters >255.
  - Zero entries were missing from the Unicode classes like `IsDigit`.
- UNIVERSAL::isa no longer caches methods incorrectly. (This broke the Tk extension with 5.6.0.)

90.10.1 Platform Specific Changes and Fixes

- BSDI 4.*

  Perl now works on post-4.0 BSD/OSes.
- All BSDs

  Setting `$0` now works (as much as possible; see perlvar for details).
- Cygwin

  Numerous updates; currently synchronised with Cygwin 1.1.4.
- EPOC

  EPOC update after Perl 5.6.0. See README.epoc.
- FreeBSD 3.*

  Perl now works on post-3.0 FreeBSDs.
- HP-UX

  README.hpux updated; `Configure -Duse64bitall` now almost works.

- IRIX

  Numerous compilation flag and hint enhancements; accidental mixing of 32-bit and 64-bit libraries (a doomed attempt) made much harder.

- Linux

  Long doubles should now work (see INSTALL).

- Mac OS Classic

  Compilation of the standard Perl distribution in Mac OS Classic should now work if you have the Metrowerks development environment and the missing Mac-specific toolkit bits. Contact the macperl mailing list for details.

- MPE/iX

  MPE/iX update after Perl 5.6.0. See README.mpeix.

- NetBSD/sparc

  Perl now works on NetBSD/sparc.

- OS/2

  Now works with usethreads (see INSTALL).

- Solaris

  64-bitness using the Sun Workshop compiler now works.

- Tru64 (aka Digital UNIX, aka DEC OSF/1)

  The operating system version letter now recorded in $Config{osvers}. Allow compiling with gcc (previously explicitly forbidden). Compiling with gcc still not recommended because buggy code results, even with gcc 2.95.2.

- Unicos

  Fixed various alignment problems that lead into core dumps either during build or later; no longer dies on math errors at runtime; now using full quad integers (64 bits), previously was using only 46 bit integers for speed.

- VMS

  chdir() now works better despite a CRT bug; now works with MULTIPLICITY (see INSTALL); now works with Perl's malloc.

- Windows

  – accept() no longer leaks memory.
  – Better chdir() return value for a non-existent directory.
  – New %ENV entries now propagate to subprocesses.
  – $ENV{LIB} now used to search for libs under Visual C.
  – A failed (pseudo)fork now returns undef and sets errno to EAGAIN.
  – Allow REG_EXPAND_SZ keys in the registry.
  – Can now send() from all threads, not just the first one.
  – Fake signal handling reenabled, bugs and all.
  – Less stack reserved per thread so that more threads can run concurrently. (Still 16M per thread.)
  – `File::Spec->tmpdir()` now prefers C:/temp over /tmp (works better when perl is running as service).
  – Better UNC path handling under ithreads.
  – wait() and waitpid() now work much better.
  – winsock handle leak fixed.

90.11 New or Changed Diagnostics

All regular expression compilation error messages are now hopefully easier to understand both because the error message now comes before the failed regex and because the point of failure is now clearly marked.

The various "opened only for", "on closed", "never opened" warnings drop the `main::` prefix for filehandles in the `main` package, for example `STDIN` instead of <main::STDIN>.

The "Unrecognized escape" warning has been extended to include `\8`, `\9`, and `\_`. There is no need to escape any of the `\w` characters.

90.12 Changed Internals

- perlapi.pod (a companion to perlguts) now attempts to document the internal API.
- You can now build a really minimal perl called microperl. Building microperl does not require even running Configure; `make -f Makefile.micro` should be enough. Beware: microperl makes many assumptions, some of which may be too bold; the resulting executable may crash or otherwise misbehave in wondrous ways. For careful hackers only.
- Added rsignal(), whichsig(), do_join() to the publicised API.
- Made possible to propagate customised exceptions via croak()ing.
- Added is_utf8_char(), is_utf8_string(), bytes_to_utf8(), and utf8_to_bytes().
- Now xsubs can have attributes just like subs.

90.13 Known Problems

90.13.1 Unicode Support Still Far From Perfect

We're working on it. Stay tuned.

90.13.2 EBCDIC Still A Lost Platform

The plan is to bring them back.

90.13.3 Building Extensions Can Fail Because Of Largefiles

Certain extensions like mod_perl and BSD::Resource are known to have issues with 'largefiles', a change brought by Perl 5.6.0 in which file offsets default to 64 bits wide, where supported. Modules may fail to compile at all or compile and work incorrectly. Currently there is no good solution for the problem, but Configure now provides appropriate non-largefile ccflags, ldflags, libswanted, and libs in the %Config hash (e.g., $Config{ccflags_nolargefiles}) so the extensions that are having problems can try configuring themselves without the largefileness. This is admittedly not a clean solution, and the solution may not even work at all. One potential failure is whether one can (or, if one can, whether it's a good idea) link together at all binaries with different ideas about file offsets, all this is platform-dependent.

90.13.4 ftmp-security tests warn 'system possibly insecure'

Don't panic. Read INSTALL 'make test' section instead.

90.13.5 Test lib/posix Subtest 9 Fails In LP64-Configured HP-UX

If perl is configured with -Duse64bitall, the successful result of the subtest 10 of lib/posix may arrive before the successful result of the subtest 9, which confuses the test harness so much that it thinks the subtest 9 failed.

90.13.6 Long Doubles Still Don't Work In Solaris

The experimental long double support is still very much so in Solaris. (Other platforms like Linux and Tru64 are beginning to solidify in this area.)

90.13.7 Linux With Sfio Fails op/misc Test 48

No known fix.

90.13.8 Storable tests fail in some platforms

If any Storable tests fail the use of Storable is not advisable.

- Many Storable tests fail on AIX configured with 64 bit integers.

  So far unidentified problems break Storable in AIX if Perl is configured to use 64 bit integers. AIX in 32-bit mode works and other 64-bit platforms work with Storable.
- DOS DJGPP may hang when testing Storable.
- st-06compat fails in UNICOS and UNICOS/mk.

  This means that you cannot read old (pre-Storable-0.7) Storable images made in other platforms.
- st-store.t and st-retrieve may fail with Compaq C 6.2 on OpenVMS Alpha 7.2.

90.13.9 Threads Are Still Experimental

Multithreading is still an experimental feature. Some platforms emit the following message for lib/thr5005

```
    #
    # This is a KNOWN FAILURE, and one of the reasons why threading
    # is still an experimental feature.  It is here to stop people
    # from deploying threads in production. ;-)
    #
```

and another known thread-related warning is

```
   pragma/overload......Unbalanced saves: 3 more saves than restores
   panic: magic_mutexfree during global destruction.
   ok
   lib/selfloader.......Unbalanced saves: 3 more saves than restores
   panic: magic_mutexfree during global destruction.
   ok
   lib/st-dclone........Unbalanced saves: 3 more saves than restores
   panic: magic_mutexfree during global destruction.
   ok
```

90.13.10 The Compiler Suite Is Still Experimental

The compiler suite is slowly getting better but is nowhere near working order yet. The backend part that has seen perhaps the most progress is the bytecode compiler.

90.14 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup and the perl bug database at http://bugs.perl.org/ There may also be information at http://www.perl.com/perl/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

90.15 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

90.16 HISTORY

Written by Jarkko Hietaniemi <*jhi@iki.fi*>, with many contributions from The Perl Porters and Perl Users submitting feedback and patches.

Send omissions or corrections to <*perlbug@perl.org*>.

Chapter 91

perl561delta

What's new for perl v5.6.x

91.1 DESCRIPTION

This document describes differences between the 5.005 release and the 5.6.1 release.

91.2 Summary of changes between 5.6.0 and 5.6.1

This section contains a summary of the changes between the 5.6.0 release and the 5.6.1 release. More details about the changes mentioned here may be found in the *Changes* files that accompany the Perl source distribution. See *perlhack* for pointers to online resources where you can inspect the individual patches described by these changes.

91.2.1 Security Issues

suidperl will not run /bin/mail anymore, because some platforms have a /bin/mail that is vulnerable to buffer overflow attacks.

Note that suidperl is neither built nor installed by default in any recent version of perl. Use of suidperl is highly discouraged. If you think you need it, try alternatives such as sudo first. See http://www.courtesan.com/sudo/ .

91.2.2 Core bug fixes

This is not an exhaustive list. It is intended to cover only the significant user-visible changes.

`UNIVERSAL::isa()`

A bug in the caching mechanism used by `UNIVERSAL::isa()` that affected base.pm has been fixed. The bug has existed since the 5.005 releases, but wasn't tickled by base.pm in those releases.

Memory leaks

Various cases of memory leaks and attempts to access uninitialized memory have been cured. See §91.14 below for further issues.

Numeric conversions

Numeric conversions did not recognize changes in the string value properly in certain circumstances.

In other situations, large unsigned numbers (those above 2**31) could sometimes lose their unsignedness, causing bogus results in arithmetic operations.

Integer modulus on large unsigned integers sometimes returned incorrect values.

Perl 5.6.0 generated "not a number" warnings on certain conversions where previous versions didn't.

These problems have all been rectified.

Infinity is now recognized as a number.

qw(a\\b)

In Perl 5.6.0, qw(a\\b) produced a string with two backslashes instead of one, in a departure from the behavior in previous versions. The older behavior has been reinstated.

caller()

caller() could cause core dumps in certain situations. Carp was sometimes affected by this problem.

Bugs in regular expressions

Pattern matches on overloaded values are now handled correctly.

Perl 5.6.0 parsed m/\x{ab}/ incorrectly, leading to spurious warnings. This has been corrected.

The RE engine found in Perl 5.6.0 accidentally pessimised certain kinds of simple pattern matches. These are now handled better.

Regular expression debug output (whether through `use re 'debug'` or via `-Dr`) now looks better.

Multi-line matches like `"a\nxb\n" =~ /(?!\A)x/m` were flawed. The bug has been fixed.

Use of $& could trigger a core dump under some situations. This is now avoided.

Match variables $1 et al., weren't being unset when a pattern match was backtracking, and the anomaly showed up inside `/...(?{ ...  })...` etc. These variables are now tracked correctly.

pos() did not return the correct value within s///ge in earlier versions. This is now handled correctly.

"slurp" mode

readline() on files opened in "slurp" mode could return an extra "" at the end in certain situations. This has been corrected.

Autovivification of symbolic references to special variables

Autovivification of symbolic references of special variables described in *perlvar* (as in `${$num}`) was accidentally disabled. This works again now.

Lexical warnings

Lexical warnings now propagate correctly into `eval "..."`.

`use warnings qw(FATAL all)` did not work as intended. This has been corrected.

Lexical warnings could leak into other scopes in some situations. This is now fixed.

warnings::enabled() now reports the state of $^W correctly if the caller isn't using lexical warnings.

Spurious warnings and errors

Perl 5.6.0 could emit spurious warnings about redefinition of dl_error() when statically building extensions into perl. This has been corrected.

"our" variables could result in bogus "Variable will not stay shared" warnings. This is now fixed.

"our" variables of the same name declared in two sibling blocks resulted in bogus warnings about "redeclaration" of the variables. The problem has been corrected.

glob()

Compatibility of the builtin glob() with old csh-based glob has been improved with the addition of GLOB_ALPHASORT option. See `File::Glob`.

File::Glob::glob() has been renamed to File::Glob::bsd_glob() because the name clashes with the builtin glob(). The older name is still available for compatibility, but is deprecated.

Spurious syntax errors generated in certain situations, when glob() caused File::Glob to be loaded for the first time, have been fixed.

Tainting

Some cases of inconsistent taint propagation (such as within hash values) have been fixed.

The tainting behavior of sprintf() has been rationalized. It does not taint the result of floating point formats anymore, making the behavior consistent with that of string interpolation.

sort()

Arguments to sort() weren't being provided the right wantarray() context. The comparison block is now run in scalar context, and the arguments to be sorted are always provided list context.

sort() is also fully reentrant, in the sense that the sort function can itself call sort(). This did not work reliably in previous releases.

#line directives

#line directives now work correctly when they appear at the very beginning of `eval "..."`.

Subroutine prototypes

The (\&) prototype now works properly.

map()

map() could get pathologically slow when the result list it generates is larger than the source list. The performance has been improved for common scenarios.

Debugger

Debugger exit code now reflects the script exit code.

Condition `"0"` in breakpoints is now treated correctly.

The `d` command now checks the line number.

`$.` is no longer corrupted by the debugger.

All debugger output now correctly goes to the socket if RemotePort is set.

PERL5OPT

PERL5OPT can be set to more than one switch group. Previously, it used to be limited to one group of options only.

chop()

chop(@list) in list context returned the characters chopped in reverse order. This has been reversed to be in the right order.

Unicode support

Unicode support has seen a large number of incremental improvements, but continues to be highly experimental. It is not expected to be fully supported in the 5.6.x maintenance releases.

substr(), join(), repeat(), reverse(), quotemeta() and string concatenation were all handling Unicode strings incorrectly in Perl 5.6.0. This has been corrected.

Support for `tr///CU` and `tr///UC` etc., have been removed since we realized the interface is broken. For similar functionality, see `pack` in *perlfunc*.

The Unicode Character Database has been updated to version 3.0.1 with additions made available to the public as of August 30, 2000.

The Unicode character classes \p{Blank} and \p{SpacePerl} have been added. "Blank" is like C isblank(), that is, it contains only "horizontal whitespace" (the space character is, the newline isn't), and the "SpacePerl" is the Unicode equivalent of `\s` (\p{Space} isn't, since that includes the vertical tabulator character, whereas `\s` doesn't.)

If you are experimenting with Unicode support in perl, the development versions of Perl may have more to offer. In particular, I/O layers are now available in the development track, but not in the maintenance track, primarily to do backward compatibility issues. Unicode support is also evolving rapidly on a daily basis in the development track–the maintenance track only reflects the most conservative of these changes.

64-bit support

Support for 64-bit platforms has been improved, but continues to be experimental. The level of support varies greatly among platforms.

Compiler

The B Compiler and its various backends have had many incremental improvements, but they continue to remain highly experimental. Use in production environments is discouraged.

The perlcc tool has been rewritten so that the user interface is much more like that of a C compiler.

The perlbc tools has been removed. Use `perlcc -B` instead.

Lvalue subroutines

There have been various bugfixes to support lvalue subroutines better. However, the feature still remains experimental.

IO::Socket

IO::Socket::INET failed to open the specified port if the service name was not known. It now correctly uses the supplied port number as is.

File::Find

File::Find now chdir()s correctly when chasing symbolic links.

xsubpp

xsubpp now tolerates embedded POD sections.

`no Module;`

`no Module;` does not produce an error even if Module does not have an unimport() method. This parallels the behavior of `use` vis-a-vis `import`.

Tests

A large number of tests have been added.

91.2.3 Core features

untie() will now call an UNTIE() hook if it exists. See *perltie* for details.

The `-DT` command line switch outputs copious tokenizing information. See *perlrun*.

Arrays are now always interpolated in double-quotish strings. Previously, `"foo@bar.com"` used to be a fatal error at compile time, if an array `@bar` was not used or declared. This transitional behavior was intended to help migrate perl4 code, and is deemed to be no longer useful. See §91.3.55.

keys(), each(), pop(), push(), shift(), splice() and unshift() can all be overridden now.

`my __PACKAGE__ $obj` now does the expected thing.

91.2.4 Configuration issues

On some systems (IRIX and Solaris among them) the system malloc is demonstrably better. While the defaults haven't been changed in order to retain binary compatibility with earlier releases, you may be better off building perl with `Configure -Uusemymalloc ...` as discussed in the *INSTALL* file.

`Configure` has been enhanced in various ways:

- Minimizes use of temporary files.
- By default, does not link perl with libraries not used by it, such as the various dbm libraries. SunOS 4.x hints preserve behavior on that platform.
- Support for pdp11-style memory models has been removed due to obsolescence.

- Building outside the source tree is supported on systems that have symbolic links. This is done by running

  ```
  sh /path/to/source/Configure -Dmksymlinks ...
  make all test install
  ```

  in a directory other than the perl source directory. See *INSTALL*.
- `Configure -S` can be run non-interactively.

91.2.5 Documentation

README.aix, README.solaris and README.macos have been added. README.posix-bc has been renamed to README.bs2000. These are installed as *perlaix*, *perlsolaris*, *perlmacos*, and *perlbs2000* respectively.

The following pod documents are brand new:

```
perlclib    Internal replacements for standard C library functions
perldebtut  Perl debugging tutorial
perlebcdic  Considerations for running Perl on EBCDIC platforms
perlnewmod  Perl modules: preparing a new module for distribution
perlrequick Perl regular expressions quick start
perlretut   Perl regular expressions tutorial
perlutil    utilities packaged with the Perl distribution
```

The *INSTALL* file has been expanded to cover various issues, such as 64-bit support.

A longer list of contributors has been added to the source distribution. See the file `AUTHORS`.

Numerous other changes have been made to the included documentation and FAQs.

91.2.6 Bundled modules

The following modules have been added.

B::Concise

Walks Perl syntax tree, printing concise info about ops. See *B::Concise*.

File::Temp

Returns name and handle of a temporary file safely. See *File::Temp*.

Pod::LaTeX

Converts Pod data to formatted LaTeX. See *Pod::LaTeX*.

Pod::Text::Overstrike

Converts POD data to formatted overstrike text. See *Pod::Text::Overstrike*.

The following modules have been upgraded.

CGI

CGI v2.752 is now included.

CPAN

CPAN v1.59_54 is now included.

Class::Struct

Various bugfixes have been added.

DB_File

DB_File v1.75 supports newer Berkeley DB versions, among other improvements.

Devel::Peek

Devel::Peek has been enhanced to support dumping of memory statistics, when perl is built with the included malloc().

File::Find

File::Find now supports pre and post-processing of the files in order to sort() them, etc.

Getopt::Long

Getopt::Long v2.25 is included.

IO::Poll

Various bug fixes have been included.

IPC::Open3

IPC::Open3 allows use of numeric file descriptors.

Math::BigFloat

The fmod() function supports modulus operations. Various bug fixes have also been included.

Math::Complex

Math::Complex handles inf, NaN etc., better.

Net::Ping

ping() could fail on odd number of data bytes, and when the echo service isn't running. This has been corrected.

Opcode

A memory leak has been fixed.

Pod::Parser

Version 1.13 of the Pod::Parser suite is included.

Pod::Text

Pod::Text and related modules have been upgraded to the versions in podlators suite v2.08.

SDBM_File

On dosish platforms, some keys went missing because of lack of support for files with "holes". A workaround for the problem has been added.

Sys::Syslog

Various bug fixes have been included.

Tie::RefHash

Now supports Tie::RefHash::Nestable to automagically tie hashref values.

Tie::SubstrHash

Various bug fixes have been included.

91.2.7 Platform-specific improvements

The following new ports are now available.

NCR MP-RAS

NonStop-UX

Perl now builds under Amdahl UTS.

Perl has also been verified to build under Amiga OS.

Support for EPOC has been much improved. See README.epoc.

Building perl with -Duseithreads or -Duse5005threads now works under HP-UX 10.20 (previously it only worked under 10.30 or later). You will need a thread library package installed. See README.hpux.

Long doubles should now work under Linux.

Mac OS Classic is now supported in the mainstream source package. See README.macos.

Support for MPE/iX has been updated. See README.mpeix.

Support for OS/2 has been improved. See `os2/Changes` and README.os2.

Dynamic loading on z/OS (formerly OS/390) has been improved. See README.os390.

Support for VMS has seen many incremental improvements, including better support for operators like backticks and system(), and better %ENV handling. See `README.vms` and *perlvms*.

Support for Stratus VOS has been improved. See `vos/Changes` and README.vos.

Support for Windows has been improved.

- fork() emulation has been improved in various ways, but still continues to be experimental. See *perlfork* for known bugs and caveats.
- %SIG has been enabled under USE_ITHREADS, but its use is completely unsupported under all configurations.
- Borland C++ v5.5 is now a supported compiler that can build Perl. However, the generated binaries continue to be incompatible with those generated by the other supported compilers (GCC and Visual C++).
- Non-blocking waits for child processes (or pseudo-processes) are supported via `waitpid($pid, &POSIX::WNOHANG)`.
- A memory leak in accept() has been fixed.
- wait(), waitpid() and backticks now return the correct exit status under Windows 9x.
- Trailing new %ENV entries weren't propagated to child processes. This is now fixed.
- Current directory entries in %ENV are now correctly propagated to child processes.
- Duping socket handles with open(F, ">&MYSOCK") now works under Windows 9x.
- The makefiles now provide a single switch to bulk-enable all the features enabled in ActiveState ActivePerl (a popular binary distribution).
- Win32::GetCwd() correctly returns C:\ instead of C: when at the drive root. Other bugs in chdir() and Cwd::cwd() have also been fixed.
- fork() correctly returns undef and sets EAGAIN when it runs out of pseudo-process handles.
- ExtUtils::MakeMaker now uses $ENV{LIB} to search for libraries.
- UNC path handling is better when perl is built to support fork().
- A handle leak in socket handling has been fixed.
- send() works from within a pseudo-process.

Unless specifically qualified otherwise, the remainder of this document covers changes between the 5.005 and 5.6.0 releases.

91.3 Core Enhancements

91.3.1 Interpreter cloning, threads, and concurrency

Perl 5.6.0 introduces the beginnings of support for running multiple interpreters concurrently in different threads. In conjunction with the perl_clone() API call, which can be used to selectively duplicate the state of any given interpreter, it is possible to compile a piece of code once in an interpreter, clone that interpreter one or more times, and run all the resulting interpreters in distinct threads.

On the Windows platform, this feature is used to emulate fork() at the interpreter level. See *perlfork* for details about that.

This feature is still in evolution. It is eventually meant to be used to selectively clone a subroutine and data reachable from that subroutine in a separate interpreter and run the cloned subroutine in a separate thread. Since there is no shared data between the interpreters, little or no locking will be needed (unless parts of the symbol table are explicitly shared). This is obviously intended to be an easy-to-use replacement for the existing threads support.

Support for cloning interpreters and interpreter concurrency can be enabled using the -Dusethreads Configure option (see win32/Makefile for how to enable it on Windows.) The resulting perl executable will be functionally identical to one that was built with -Dmultiplicity, but the perl_clone() API call will only be available in the former.

-Dusethreads enables the cpp macro USE_ITHREADS by default, which in turn enables Perl source code changes that provide a clear separation between the op tree and the data it operates with. The former is immutable, and can therefore be shared between an interpreter and all of its clones, while the latter is considered local to each interpreter, and is therefore copied for each clone.

Note that building Perl with the -Dusemultiplicity Configure option is adequate if you wish to run multiple **independent** interpreters concurrently in different threads. -Dusethreads only provides the additional functionality of the perl_clone() API call and other support for running **cloned** interpreters concurrently.

```
    NOTE: This is an experimental feature.  Implementation details are
    subject to change.
```

91.3.2 Lexically scoped warning categories

You can now control the granularity of warnings emitted by perl at a finer level using the `use warnings` pragma. *warnings* and *perllexwarn* have copious documentation on this feature.

91.3.3 Unicode and UTF-8 support

Perl now uses UTF-8 as its internal representation for character strings. The `utf8` and `bytes` pragmas are used to control this support in the current lexical scope. See *perlunicode*, *utf8* and *bytes* for more information.

This feature is expected to evolve quickly to support some form of I/O disciplines that can be used to specify the kind of input and output data (bytes or characters). Until that happens, additional modules from CPAN will be needed to complete the toolkit for dealing with Unicode.

```
    NOTE: This should be considered an experimental feature.  Implementation
    details are subject to change.
```

91.3.4 Support for interpolating named characters

The new `\N` escape interpolates named characters within strings. For example, `"Hi!  \N{WHITE SMILING FACE}"` evaluates to a string with a Unicode smiley face at the end.

91.3.5 "our" declarations

An "our" declaration introduces a value that can be best understood as a lexically scoped symbolic alias to a global variable in the package that was current where the variable was declared. This is mostly useful as an alternative to the `vars` pragma, but also provides the opportunity to introduce typing and other attributes for such variables. See our in *perlfunc*.

91.3.6 Support for strings represented as a vector of ordinals

Literals of the form `v1.2.3.4` are now parsed as a string composed of characters with the specified ordinals. This is an alternative, more readable way to construct (possibly Unicode) strings instead of interpolating characters, as in `"\x{1}\x{2}\x{3}\x{4}"`. The leading `v` may be omitted if there are more than two ordinals, so `1.2.3` is parsed the same as `v1.2.3`.

Strings written in this form are also useful to represent version "numbers". It is easy to compare such version "numbers" (which are really just plain strings) using any of the usual string comparison operators `eq`, `ne`, `lt`, `gt`, etc., or perform bitwise string operations on them using |, &, etc.

In conjunction with the new `$^V` magic variable (which contains the perl version as a string), such literals can be used as a readable way to check if you're running a particular version of Perl:

```
# this will parse in older versions of Perl also
if ($^V and $^V gt v5.6.0) {
    # new features supported
}
```

`require` and `use` also have some special magic to support such literals. They will be interpreted as a version rather than as a module name:

```
require v5.6.0;             # croak if $^V lt v5.6.0
use v5.6.0;                 # same, but croaks at compile-time
```

Alternatively, the `v` may be omitted if there is more than one dot:

```
require 5.6.0;
use 5.6.0;
```

Also, `sprintf` and `printf` support the Perl-specific format flag `%v` to print ordinals of characters in arbitrary strings:

```
printf "v%vd", $^V;         # prints current version, such as "v5.5.650"
printf "%*vX", ":", $addr;  # formats IPv6 address
printf "%*vb", " ", $bits;  # displays bitstring
```

See Scalar value constructors in *perldata* for additional information.

91.3.7 Improved Perl version numbering system

Beginning with Perl version 5.6.0, the version number convention has been changed to a "dotted integer" scheme that is more commonly found in open source projects.

Maintenance versions of v5.6.0 will be released as v5.6.1, v5.6.2 etc. The next development series following v5.6.0 will be numbered v5.7.x, beginning with v5.7.0, and the next major production release following v5.6.0 will be v5.8.0.

The English module now sets $PERL_VERSION to $^V (a string value) rather than `$]` (a numeric value). (This is a potential incompatibility. Send us a report via perlbug if you are affected by this.)

The v1.2.3 syntax is also now legal in Perl. See Support for strings represented as a vector of ordinals for more on that.

To cope with the new versioning system's use of at least three significant digits for each version component, the method used for incrementing the subversion number has also changed slightly. We assume that versions older than v5.6.0 have been incrementing the subversion component in multiples of 10. Versions after v5.6.0 will increment them by 1. Thus, using the new notation, 5.005_03 is the "same" as v5.5.30, and the first maintenance version following v5.6.0 will be v5.6.1 (which should be read as being equivalent to a floating point value of 5.006_001 in the older format, stored in `$]`).

91.3.8 New syntax for declaring subroutine attributes

Formerly, if you wanted to mark a subroutine as being a method call or as requiring an automatic lock() when it is entered, you had to declare that with a `use attrs` pragma in the body of the subroutine. That can now be accomplished with declaration syntax, like this:

```
    sub mymethod : locked method ;
    ...
    sub mymethod : locked method {
        ...
    }

    sub othermethod :locked :method ;
    ...
    sub othermethod :locked :method {
        ...
    }
```

(Note how only the first `:` is mandatory, and whitespace surrounding the `:` is optional.)

AutoSplit.pm and *SelfLoader.pm* have been updated to keep the attributes with the stubs they provide. See *attributes*.

91.3.9 File and directory handles can be autovivified

Similar to how constructs such as `$x->[0]` autovivify a reference, handle constructors (open(), opendir(), pipe(), socketpair(), sysopen(), socket(), and accept()) now autovivify a file or directory handle if the handle passed to them is an uninitialized scalar variable. This allows the constructs such as `open(my $fh, ...)` and `open(local $fh,...)` to be used to create filehandles that will conveniently be closed automatically when the scope ends, provided there are no other references to them. This largely eliminates the need for typeglobs when opening filehandles that must be passed around, as in the following example:

```
    sub myopen {
        open my $fh, "@_"
             or die "Can't open '@_': $!";
        return $fh;
    }

    {
        my $f = myopen("</etc/motd");
        print <$f>;
        # $f implicitly closed here
    }
```

91.3.10 open() with more than two arguments

If open() is passed three arguments instead of two, the second argument is used as the mode and the third argument is taken to be the file name. This is primarily useful for protecting against unintended magic behavior of the traditional two-argument form. See open in *perlfunc*.

91.3.11 64-bit support

Any platform that has 64-bit integers either

```
        (1) natively as longs or ints
        (2) via special compiler flags
        (3) using long long or int64_t
```

is able to use "quads" (64-bit integers) as follows:

- constants (decimal, hexadecimal, octal, binary) in the code
- arguments to oct() and hex()
- arguments to print(), printf() and sprintf() (flag prefixes ll, L, q)
- printed as such
- pack() and unpack() "q" and "Q" formats
- in basic arithmetics: + - * / % (NOTE: operating close to the limits of the integer values may produce surprising results)
- in bit arithmetics: & | ^ ~ << >> (NOTE: these used to be forced to be 32 bits wide but now operate on the full native width.)
- vec()

Note that unless you have the case (a) you will have to configure and compile Perl using the -Duse64bitint Configure flag.

```
NOTE: The Configure flags -Duselonglong and -Duse64bits have been
deprecated.  Use -Duse64bitint instead.
```

There are actually two modes of 64-bitness: the first one is achieved using Configure -Duse64bitint and the second one using Configure -Duse64bitall. The difference is that the first one is minimal and the second one maximal. The first works in more places than the second.

The `use64bitint` does only as much as is required to get 64-bit integers into Perl (this may mean, for example, using "long longs") while your memory may still be limited to 2 gigabytes (because your pointers could still be 32-bit). Note that the name `64bitint` does not imply that your C compiler will be using 64-bit `int`s (it might, but it doesn't have to): the `use64bitint` means that you will be able to have 64 bits wide scalar values.

The `use64bitall` goes all the way by attempting to switch also integers (if it can), longs (and pointers) to being 64-bit. This may create an even more binary incompatible Perl than -Duse64bitint: the resulting executable may not run at all in a 32-bit box, or you may have to reboot/reconfigure/rebuild your operating system to be 64-bit aware.

Natively 64-bit systems like Alpha and Cray need neither -Duse64bitint nor -Duse64bitall.

Last but not least: note that due to Perl's habit of always using floating point numbers, the quads are still not true integers. When quads overflow their limits (0...18_446_744_073_709_551_615 unsigned, -9_223_372_036_854_775_808...9_223_372_036_854_775_807 signed), they are silently promoted to floating point numbers, after which they will start losing precision (in their lower digits).

```
NOTE: 64-bit support is still experimental on most platforms.
Existing support only covers the LP64 data model.  In particular, the
LLP64 data model is not yet supported.  64-bit libraries and system
APIs on many platforms have not stabilized--your mileage may vary.
```

91.3.12 Large file support

If you have filesystems that support "large files" (files larger than 2 gigabytes), you may now also be able to create and access them from Perl.

```
NOTE: The default action is to enable large file support, if
available on the platform.
```

If the large file support is on, and you have a Fcntl constant O_LARGEFILE, the O_LARGEFILE is automatically added to the flags of sysopen().

Beware that unless your filesystem also supports "sparse files" seeking to umpteen petabytes may be inadvisable.

Note that in addition to requiring a proper file system to do large files you may also need to adjust your per-process (or your per-system, or per-process-group, or per-user-group) maximum filesize limits before running Perl scripts that try to handle large files, especially if you intend to write such files.

Finally, in addition to your process/process group maximum filesize limits, you may have quota limits on your filesystems that stop you (your user id or your user group id) from using large files.

Adjusting your process/user/group/file system/operating system limits is outside the scope of Perl core language. For process limits, you may try increasing the limits using your shell's limits/limit/ulimit command before running Perl. The BSD::Resource extension (not included with the standard Perl distribution) may also be of use, it offers the getrlimit/setrlimit interface that can be used to adjust process resource usage limits, including the maximum filesize limit.

91.3.13 Long doubles

In some systems you may be able to use long doubles to enhance the range and precision of your double precision floating point numbers (that is, Perl's numbers). Use Configure -Duselongdouble to enable this support (if it is available).

91.3.14 "more bits"

You can "Configure -Dusemorebits" to turn on both the 64-bit support and the long double support.

91.3.15 Enhanced support for sort() subroutines

Perl subroutines with a prototype of `($$)`, and XSUBs in general, can now be used as sort subroutines. In either case, the two elements to be compared are passed as normal parameters in @_. See sort in *perlfunc*.

For unprototyped sort subroutines, the historical behavior of passing the elements to be compared as the global variables $a and $b remains unchanged.

91.3.16 `sort $coderef @foo` allowed

sort() did not accept a subroutine reference as the comparison function in earlier versions. This is now permitted.

91.3.17 File globbing implemented internally

Perl now uses the File::Glob implementation of the glob() operator automatically. This avoids using an external csh process and the problems associated with it.

```
    NOTE: This is currently an experimental feature.  Interfaces and
    implementation are subject to change.
```

91.3.18 Support for CHECK blocks

In addition to `BEGIN`, `INIT`, `END`, `DESTROY` and `AUTOLOAD`, subroutines named `CHECK` are now special. These are queued up during compilation and behave similar to END blocks, except they are called at the end of compilation rather than at the end of execution. They cannot be called directly.

91.3.19 POSIX character class syntax [: :] supported

For example to match alphabetic characters use /[[:alpha:]]/. See *perlre* for details.

91.3.20 Better pseudo-random number generator

In 5.005_0x and earlier, perl's rand() function used the C library rand(3) function. As of 5.005_52, Configure tests for drand48(), random(), and rand() (in that order) and picks the first one it finds.

These changes should result in better random numbers from rand().

91.3.21 Improved `qw//` operator

The `qw//` operator is now evaluated at compile time into a true list instead of being replaced with a run time call to `split()`. This removes the confusing misbehaviour of `qw//` in scalar context, which had inherited that behaviour from split().

Thus:

```
    $foo = ($bar) = qw(a b c); print "$foo|$bar\n";
```

now correctly prints "3|a", instead of "2|a".

91.3.22 Better worst-case behavior of hashes

Small changes in the hashing algorithm have been implemented in order to improve the distribution of lower order bits in the hashed value. This is expected to yield better performance on keys that are repeated sequences.

91.3.23 pack() format 'Z' supported

The new format type 'Z' is useful for packing and unpacking null-terminated strings. See pack in *perlfunc*.

91.3.24 pack() format modifier '!' supported

The new format type modifier '!' is useful for packing and unpacking native shorts, ints, and longs. See pack in *perlfunc*.

91.3.25 pack() and unpack() support counted strings

The template character '/' can be used to specify a counted string type to be packed or unpacked. See pack in *perlfunc*.

91.3.26 Comments in pack() templates

The '#' character in a template introduces a comment up to end of the line. This facilitates documentation of pack() templates.

91.3.27 Weak references

In previous versions of Perl, you couldn't cache objects so as to allow them to be deleted if the last reference from outside the cache is deleted. The reference in the cache would hold a reference count on the object and the objects would never be destroyed.

Another familiar problem is with circular references. When an object references itself, its reference count would never go down to zero, and it would not get destroyed until the program is about to exit.

Weak references solve this by allowing you to "weaken" any reference, that is, make it not count towards the reference count. When the last non-weak reference to an object is deleted, the object is destroyed and all the weak references to the object are automatically undef-ed.

To use this feature, you need the Devel::WeakRef package from CPAN, which contains additional documentation.

```
    NOTE: This is an experimental feature.  Details are subject to change.
```

91.3.28 Binary numbers supported

Binary numbers are now supported as literals, in s?printf formats, and `oct()`:

```
    $answer = 0b101010;
    printf "The answer is: %b\n", oct("0b101010");
```

91.3.29 Lvalue subroutines

Subroutines can now return modifiable lvalues. See Lvalue subroutines in *perlsub*.

```
    NOTE: This is an experimental feature.  Details are subject to change.
```

91.3.30 Some arrows may be omitted in calls through references

Perl now allows the arrow to be omitted in many constructs involving subroutine calls through references. For example, `$foo[10]->('foo')` may now be written `$foo[10]('foo')`. This is rather similar to how the arrow may be omitted from `$foo[10]->{'foo'}`. Note however, that the arrow is still required for `foo(10)->('bar')`.

91.3.31 Boolean assignment operators are legal lvalues

Constructs such as `($a ||= 2) += 1` are now allowed.

91.3.32 exists() is supported on subroutine names

The exists() builtin now works on subroutine names. A subroutine is considered to exist if it has been declared (even if implicitly). See exists in *perlfunc* for examples.

91.3.33 exists() and delete() are supported on array elements

The exists() and delete() builtins now work on simple arrays as well. The behavior is similar to that on hash elements.

exists() can be used to check whether an array element has been initialized. This avoids autovivifying array elements that don't exist. If the array is tied, the EXISTS() method in the corresponding tied package will be invoked.

delete() may be used to remove an element from the array and return it. The array element at that position returns to its uninitialized state, so that testing for the same element with exists() will return false. If the element happens to be the one at the end, the size of the array also shrinks up to the highest element that tests true for exists(), or 0 if none such is found. If the array is tied, the DELETE() method in the corresponding tied package will be invoked.

See exists in *perlfunc* and delete in *perlfunc* for examples.

91.3.34 Pseudo-hashes work better

Dereferencing some types of reference values in a pseudo-hash, such as `$ph->{foo}[1]`, was accidentally disallowed. This has been corrected.

When applied to a pseudo-hash element, exists() now reports whether the specified value exists, not merely if the key is valid.

delete() now works on pseudo-hashes. When given a pseudo-hash element or slice it deletes the values corresponding to the keys (but not the keys themselves). See Pseudo-hashes: Using an array as a hash in *perlref*.

Pseudo-hash slices with constant keys are now optimized to array lookups at compile-time.

List assignments to pseudo-hash slices are now supported.

The `fields` pragma now provides ways to create pseudo-hashes, via fields::new() and fields::phash(). See *fields*.

```
    NOTE: The pseudo-hash data type continues to be experimental.
    Limiting oneself to the interface elements provided by the
    fields pragma will provide protection from any future changes.
```

91.3.35 Automatic flushing of output buffers

fork(), exec(), system(), qx//, and pipe open()s now flush buffers of all files opened for output when the operation was attempted. This mostly eliminates confusing buffering mishaps suffered by users unaware of how Perl internally handles I/O.

This is not supported on some platforms like Solaris where a suitably correct implementation of fflush(NULL) isn't available.

91.3.36 Better diagnostics on meaningless filehandle operations

Constructs such as `open(<FH>)` and `close(<FH>)` are compile time errors. Attempting to read from filehandles that were opened only for writing will now produce warnings (just as writing to read-only filehandles does).

91.3.37 Where possible, buffered data discarded from duped input filehandle

`open(NEW, "<&OLD")` now attempts to discard any data that was previously read and buffered in `OLD` before duping the handle. On platforms where doing this is allowed, the next read operation on `NEW` will return the same data as the corresponding operation on `OLD`. Formerly, it would have returned the data from the start of the following disk block instead.

91.3.38 eof() has the same old magic as <>

`eof()` would return true if no attempt to read from <> had yet been made. `eof()` has been changed to have a little magic of its own, it now opens the <> files.

91.3.39 binmode() can be used to set :crlf and :raw modes

binmode() now accepts a second argument that specifies a discipline for the handle in question. The two pseudo-disciplines ":raw" and ":crlf" are currently supported on DOS-derivative platforms. See binmode in *perlfunc* and *open*.

91.3.40 `-T` filetest recognizes UTF-8 encoded files as "text"

The algorithm used for the `-T` filetest has been enhanced to correctly identify UTF-8 content as "text".

91.3.41 system(), backticks and pipe open now reflect exec() failure

On Unix and similar platforms, system(), qx() and open(FOO, "cmd |") etc., are implemented via fork() and exec(). When the underlying exec() fails, earlier versions did not report the error properly, since the exec() happened to be in a different process.

The child process now communicates with the parent about the error in launching the external command, which allows these constructs to return with their usual error value and set $!.

91.3.42 Improved diagnostics

Line numbers are no longer suppressed (under most likely circumstances) during the global destruction phase.

Diagnostics emitted from code running in threads other than the main thread are now accompanied by the thread ID.

Embedded null characters in diagnostics now actually show up. They used to truncate the message in prior versions.

$foo::a and $foo::b are now exempt from "possible typo" warnings only if sort() is encountered in package `foo`.

Unrecognized alphabetic escapes encountered when parsing quote constructs now generate a warning, since they may take on new semantics in later versions of Perl.

Many diagnostics now report the internal operation in which the warning was provoked, like so:

```
    Use of uninitialized value in concatenation (.) at (eval 1) line 1.
    Use of uninitialized value in print at (eval 1) line 1.
```

Diagnostics that occur within eval may also report the file and line number where the eval is located, in addition to the eval sequence number and the line number within the evaluated text itself. For example:

```
    Not enough arguments for scalar at (eval 4)[newlib/perl5db.pl:1411] line 2, at EOF
```

91.3.43 Diagnostics follow STDERR

Diagnostic output now goes to whichever file the `STDERR` handle is pointing at, instead of always going to the underlying C runtime library's `stderr`.

91.3.44 More consistent close-on-exec behavior

On systems that support a close-on-exec flag on filehandles, the flag is now set for any handles created by pipe(), socketpair(), socket(), and accept(), if that is warranted by the value of $^F that may be in effect. Earlier versions neglected to set the flag for handles created with these operators. See pipe in *perlfunc*, socketpair in *perlfunc*, socket in *perlfunc*, accept in *perlfunc*, and $^F in *perlvar*.

91.3.45 syswrite() ease-of-use

The length argument of `syswrite()` has become optional.

91.3.46 Better syntax checks on parenthesized unary operators

Expressions such as:

```
    print defined(&foo,&bar,&baz);
    print uc("foo","bar","baz");
    undef($foo,&bar);
```

used to be accidentally allowed in earlier versions, and produced unpredictable behaviour. Some produced ancillary warnings when used in this way; others silently did the wrong thing.

The parenthesized forms of most unary operators that expect a single argument now ensure that they are not called with more than one argument, making the cases shown above syntax errors. The usual behaviour of:

```
    print defined &foo, &bar, &baz;
    print uc "foo", "bar", "baz";
    undef $foo, &bar;
```

remains unchanged. See *perlop*.

91.3.47 Bit operators support full native integer width

The bit operators (& | ^ ~ << >>) now operate on the full native integral width (the exact size of which is available in $Config{ivsize}). For example, if your platform is either natively 64-bit or if Perl has been configured to use 64-bit integers, these operations apply to 8 bytes (as opposed to 4 bytes on 32-bit platforms). For portability, be sure to mask off the excess bits in the result of unary ~, e.g., `~$x & 0xffffffff`.

91.3.48 Improved security features

More potentially unsafe operations taint their results for improved security.

The `passwd` and `shell` fields returned by the getpwent(), getpwnam(), and getpwuid() are now tainted, because the user can affect their own encrypted password and login shell.

The variable modified by shmread(), and messages returned by msgrcv() (and its object-oriented interface IPC::SysV::Msg::rcv) are also tainted, because other untrusted processes can modify messages and shared memory segments for their own nefarious purposes.

91.3.49 More functional bareword prototype (*)

Bareword prototypes have been rationalized to enable them to be used to override builtins that accept barewords and interpret them in a special way, such as `require` or `do`.

Arguments prototyped as * will now be visible within the subroutine as either a simple scalar or as a reference to a typeglob. See Prototypes in *perlsub*.

91.3.50 `require` and do may be overridden

`require` and `do 'file'` operations may be overridden locally by importing subroutines of the same name into the current package (or globally by importing them into the CORE::GLOBAL:: namespace). Overriding `require` will also affect `use`, provided the override is visible at compile-time. See Overriding Built-in Functions in *perlsub*.

91.3.51 $ ˆX variables may now have names longer than one character

Formerly, $ˆX was synonymous with ${"\cX"}, but $ˆXY was a syntax error. Now variable names that begin with a control character may be arbitrarily long. However, for compatibility reasons, these variables *must* be written with explicit braces, as `${ˆXY}` for example. `${ˆXYZ}` is synonymous with ${"\cXYZ"}. Variable names with more than one control character, such as `${ˆXYˆZ}`, are illegal.

The old syntax has not changed. As before, 'ˆX' may be either a literal control-X character or the two-character sequence 'caret' plus 'X'. When braces are omitted, the variable name stops after the control character. Thus `"$ˆXYZ"` continues to be synonymous with `$ˆX . "YZ"` as before.

As before, lexical variables may not have names beginning with control characters. As before, variables whose names begin with a control character are always forced to be in package 'main'. All such variables are reserved for future extensions, except those that begin with `ˆ_`, which may be used by user programs and are guaranteed not to acquire special meaning in any future version of Perl.

91.3.52 New variable $ ˆC reflects `-c` switch

`$ˆC` has a boolean value that reflects whether perl is being run in compile-only mode (i.e. via the `-c` switch). Since BEGIN blocks are executed under such conditions, this variable enables perl code to determine whether actions that make sense only during normal running are warranted. See *perlvar*.

91.3.53 New variable $ ˆV contains Perl version as a string

`$ˆV` contains the Perl version number as a string composed of characters whose ordinals match the version numbers, i.e. v5.6.0. This may be used in string comparisons.

See `Support for strings represented as a vector of ordinals` for an example.

91.3.54 Optional Y2K warnings

If Perl is built with the cpp macro `PERL_Y2KWARN` defined, it emits optional warnings when concatenating the number 19 with another number.

This behavior must be specifically enabled when running Configure. See *INSTALL* and *README.Y2K*.

91.3.55 Arrays now always interpolate into double-quoted strings

In double-quoted strings, arrays now interpolate, no matter what. The behavior in earlier versions of perl 5 was that arrays would interpolate into strings if the array had been mentioned before the string was compiled, and otherwise Perl would raise a fatal compile-time error. In versions 5.000 through 5.003, the error was

```
        Literal @example now requires backslash
```

In versions 5.004_01 through 5.6.0, the error was

```
        In string, @example now must be written as \@example
```

The idea here was to get people into the habit of writing `"fred\@example.com"` when they wanted a literal `@` sign, just as they have always written `"Give me back my \$5"` when they wanted a literal `$` sign.

Starting with 5.6.1, when Perl now sees an `@` sign in a double-quoted string, it *always* attempts to interpolate an array, regardless of whether or not the array has been used or declared already. The fatal error has been downgraded to an optional warning:

```
        Possible unintended interpolation of @example in string
```

This warns you that `"fred@example.com"` is going to turn into `fred.com` if you don't backslash the `@`. See http://www.plover.com/˜mjd/perl/at-error.html for more details about the history here.

91.4 Modules and Pragmata

91.4.1 Modules

attributes

While used internally by Perl as a pragma, this module also provides a way to fetch subroutine and variable attributes. See *attributes*.

B

The Perl Compiler suite has been extensively reworked for this release. More of the standard Perl testsuite passes when run under the Compiler, but there is still a significant way to go to achieve production quality compiled executables.

```
    NOTE: The Compiler suite remains highly experimental.  The
    generated code may not be correct, even when it manages to execute
    without errors.
```

Benchmark

Overall, Benchmark results exhibit lower average error and better timing accuracy.

You can now run tests for *n* seconds instead of guessing the right number of tests to run: e.g., timethese(-5, ...) will run each code for at least 5 CPU seconds. Zero as the "number of repetitions" means "for at least 3 CPU seconds". The output format has also changed. For example:

```
   use Benchmark;$x=3;timethese(-5,{a=>sub{$x*$x},b=>sub{$x**2}})
```

will now output something like this:

```
   Benchmark: running a, b, each for at least 5 CPU seconds...
            a:  5 wallclock secs ( 5.77 usr +  0.00 sys =  5.77 CPU) @ 200551.91/s (n=1156516)
            b:  4 wallclock secs ( 5.00 usr +  0.02 sys =  5.02 CPU) @ 159605.18/s (n=800686)
```

New features: "each for at least N CPU seconds...", "wallclock secs", and the "@ operations/CPU second (n=operations)".

timethese() now returns a reference to a hash of Benchmark objects containing the test results, keyed on the names of the tests.

timethis() now returns the iterations field in the Benchmark result object instead of 0.

timethese(), timethis(), and the new cmpthese() (see below) can also take a format specifier of 'none' to suppress output.

A new function countit() is just like timeit() except that it takes a TIME instead of a COUNT.

A new function cmpthese() prints a chart comparing the results of each test returned from a timethese() call. For each possible pair of tests, the percentage speed difference (iters/sec or seconds/iter) is shown.

For other details, see *Benchmark*.

ByteLoader

The ByteLoader is a dedicated extension to generate and run Perl bytecode. See *ByteLoader*.

constant

References can now be used.

The new version also allows a leading underscore in constant names, but disallows a double leading underscore (as in "__LINE__"). Some other names are disallowed or warned against, including BEGIN, END, etc. Some names which were forced into main:: used to fail silently in some cases; now they're fatal (outside of main::) and an optional warning (inside of main::). The ability to detect whether a constant had been set with a given name has been added.

See *constant*.

charnames

This pragma implements the `\N` string escape. See *charnames*.

Data::Dumper

A `Maxdepth` setting can be specified to avoid venturing too deeply into deep data structures. See *Data::Dumper*.

The XSUB implementation of Dump() is now automatically called if the `Useqq` setting is not in use.

Dumping `qr//` objects works correctly.

DB

`DB` is an experimental module that exposes a clean abstraction to Perl's debugging API.

DB_File

DB_File can now be built with Berkeley DB versions 1, 2 or 3. See `ext/DB_File/Changes`.

Devel::DProf

Devel::DProf, a Perl source code profiler has been added. See *Devel::DProf* and *dprofpp*.

Devel::Peek

The Devel::Peek module provides access to the internal representation of Perl variables and data. It is a data debugging tool for the XS programmer.

Dumpvalue

The Dumpvalue module provides screen dumps of Perl data.

DynaLoader

DynaLoader now supports a dl_unload_file() function on platforms that support unloading shared objects using dlclose().

Perl can also optionally arrange to unload all extension shared objects loaded by Perl. To enable this, build Perl with the Configure option `-Accflags=-DDL_UNLOAD_ALL_AT_EXIT`. (This maybe useful if you are using Apache with mod_perl.)

English

$PERL_VERSION now stands for `$^V` (a string value) rather than for `$]` (a numeric value).

Env

Env now supports accessing environment variables like PATH as array variables.

Fcntl

More Fcntl constants added: F_SETLK64, F_SETLKW64, O_LARGEFILE for large file (more than 4GB) access (NOTE: the O_LARGEFILE is automatically added to sysopen() flags if large file support has been configured, as is the default), Free/Net/OpenBSD locking behaviour flags F_FLOCK, F_POSIX, Linux F_SHLCK, and O_ACCMODE: the combined mask of O_RDONLY, O_WRONLY, and O_RDWR. The seek()/sysseek() constants SEEK_SET, SEEK_CUR, and SEEK_END are available via the `:seek` tag. The chmod()/stat() S_IF* constants and S_IS* functions are available via the `:mode` tag.

File::Compare

A compare_text() function has been added, which allows custom comparison functions. See *File::Compare*.

File::Find

File::Find now works correctly when the wanted() function is either autoloaded or is a symbolic reference.

A bug that caused File::Find to lose track of the working directory when pruning top-level directories has been fixed.

File::Find now also supports several other options to control its behavior. It can follow symbolic links if the `follow` option is specified. Enabling the `no_chdir` option will make File::Find skip changing the current directory when walking directories. The `untaint` flag can be useful when running with taint checks enabled.

See *File::Find*.

File::Glob

This extension implements BSD-style file globbing. By default, it will also be used for the internal implementation of the glob() operator. See *File::Glob*.

File::Spec

New methods have been added to the File::Spec module: devnull() returns the name of the null device (/dev/null on Unix) and tmpdir() the name of the temp directory (normally /tmp on Unix). There are now also methods to convert between absolute and relative filenames: abs2rel() and rel2abs(). For compatibility with operating systems that specify volume names in file paths, the splitpath(), splitdir(), and catdir() methods have been added.

File::Spec::Functions

The new File::Spec::Functions modules provides a function interface to the File::Spec module. Allows shorthand

```
    $fullname = catfile($dir1, $dir2, $file);
```

instead of

```
    $fullname = File::Spec->catfile($dir1, $dir2, $file);
```

Getopt::Long

Getopt::Long licensing has changed to allow the Perl Artistic License as well as the GPL. It used to be GPL only, which got in the way of non-GPL applications that wanted to use Getopt::Long.

Getopt::Long encourages the use of Pod::Usage to produce help messages. For example:

```
    use Getopt::Long;
    use Pod::Usage;
    my $man = 0;
    my $help = 0;
    GetOptions('help|?' => \$help, man => \$man) or pod2usage(2);
    pod2usage(1) if $help;
    pod2usage(-exitstatus => 0, -verbose => 2) if $man;
```

```
__END__

=head1 NAME

sample - Using Getopt::Long and Pod::Usage

=head1 SYNOPSIS

sample [options] [file ...]

 Options:
   -help            brief help message
   -man             full documentation

=head1 OPTIONS

=over 8

=item B<-help>

Print a brief help message and exits.

=item B<-man>

Prints the manual page and exits.

=back

=head1 DESCRIPTION

B<This program> will read the given input file(s) and do something
useful with the contents thereof.

=cut
```

See *Pod::Usage* for details.

A bug that prevented the non-option call-back <> from being specified as the first argument has been fixed.

To specify the characters < and > as option starters, use ><. Note, however, that changing option starters is strongly deprecated.

IO

write() and syswrite() will now accept a single-argument form of the call, for consistency with Perl's syswrite().

You can now create a TCP-based IO::Socket::INET without forcing a connect attempt. This allows you to configure its options (like making it non-blocking) and then call connect() manually.

A bug that prevented the IO::Socket::protocol() accessor from ever returning the correct value has been corrected.

IO::Socket::connect now uses non-blocking IO instead of alarm() to do connect timeouts.

IO::Socket::accept now uses select() instead of alarm() for doing timeouts.

IO::Socket::INET->new now sets $! correctly on failure. $@ is still set for backwards compatibility.

JPL

Java Perl Lingo is now distributed with Perl. See jpl/README for more information.

lib

`use lib` now weeds out any trailing duplicate entries. `no lib` removes all named entries.

Math::BigInt

The bitwise operations <<, >>, &, |, and ~ are now supported on bigints.

Math::Complex

The accessor methods Re, Im, arg, abs, rho, and theta can now also act as mutators (accessor $z->Re(), mutator $z->Re(3)).

The class method `display_format` and the corresponding object method `display_format`, in addition to accepting just one argument, now can also accept a parameter hash. Recognized keys of a parameter hash are `"style"`, which corresponds to the old one parameter case, and two new parameters: `"format"`, which is a printf()-style format string (defaults usually to `"%.15g"`, you can revert to the default by setting the format string to `undef`) used for both parts of a complex number, and `"polar_pretty_print"` (defaults to true), which controls whether an attempt is made to try to recognize small multiples and rationals of pi (2pi, pi/2) at the argument (angle) of a polar complex number.

The potentially disruptive change is that in list context both methods now *return the parameter hash*, instead of only the value of the `"style"` parameter.

Math::Trig

A little bit of radial trigonometry (cylindrical and spherical), radial coordinate conversions, and the great circle distance were added.

Pod::Parser, Pod::InputObjects

Pod::Parser is a base class for parsing and selecting sections of pod documentation from an input stream. This module takes care of identifying pod paragraphs and commands in the input and hands off the parsed paragraphs and commands to user-defined methods which are free to interpret or translate them as they see fit.

Pod::InputObjects defines some input objects needed by Pod::Parser, and for advanced users of Pod::Parser that need more about a command besides its name and text.

As of release 5.6.0 of Perl, Pod::Parser is now the officially sanctioned "base parser code" recommended for use by all pod2xxx translators. Pod::Text (pod2text) and Pod::Man (pod2man) have already been converted to use Pod::Parser and efforts to convert Pod::HTML (pod2html) are already underway. For any questions or comments about pod parsing and translating issues and utilities, please use the pod-people@perl.org mailing list.

For further information, please see *Pod::Parser* and *Pod::InputObjects*.

Pod::Checker, podchecker

This utility checks pod files for correct syntax, according to *perlpod*. Obvious errors are flagged as such, while warnings are printed for mistakes that can be handled gracefully. The checklist is not complete yet. See *Pod::Checker*.

Pod::ParseUtils, Pod::Find

These modules provide a set of gizmos that are useful mainly for pod translators. Pod::Find traverses directory structures and returns found pod files, along with their canonical names (like `File::Spec::Unix`). Pod::ParseUtils contains **Pod::List** (useful for storing pod list information), **Pod::Hyperlink** (for parsing the contents of `L<>` sequences) and **Pod::Cache** (for caching information about pod files, e.g., link nodes).

Pod::Select, podselect

Pod::Select is a subclass of Pod::Parser which provides a function named "podselect()" to filter out user-specified sections of raw pod documentation from an input stream. podselect is a script that provides access to Pod::Select from other scripts to be used as a filter. See *Pod::Select*.

Pod::Usage, pod2usage

Pod::Usage provides the function "pod2usage()" to print usage messages for a Perl script based on its embedded pod documentation. The pod2usage() function is generally useful to all script authors since it lets them write and maintain a single source (the pods) for documentation, thus removing the need to create and maintain redundant usage message text consisting of information already in the pods.

There is also a pod2usage script which can be used from other kinds of scripts to print usage messages from pods (even for non-Perl scripts with pods embedded in comments).

For details and examples, please see *Pod::Usage*.

Pod::Text and Pod::Man

Pod::Text has been rewritten to use Pod::Parser. While pod2text() is still available for backwards compatibility, the module now has a new preferred interface. See *Pod::Text* for the details. The new Pod::Text module is easily subclassed for tweaks to the output, and two such subclasses (Pod::Text::Termcap for man-page-style bold and underlining using termcap information, and Pod::Text::Color for markup with ANSI color sequences) are now standard.

pod2man has been turned into a module, Pod::Man, which also uses Pod::Parser. In the process, several outstanding bugs related to quotes in section headers, quoting of code escapes, and nested lists have been fixed. pod2man is now a wrapper script around this module.

SDBM_File

An EXISTS method has been added to this module (and sdbm_exists() has been added to the underlying sdbm library), so one can now call exists on an SDBM_File tied hash and get the correct result, rather than a runtime error.

A bug that may have caused data loss when more than one disk block happens to be read from the database in a single FETCH() has been fixed.

Sys::Syslog

Sys::Syslog now uses XSUBs to access facilities from syslog.h so it no longer requires syslog.ph to exist.

Sys::Hostname

Sys::Hostname now uses XSUBs to call the C library's gethostname() or uname() if they exist.

Term::ANSIColor

Term::ANSIColor is a very simple module to provide easy and readable access to the ANSI color and highlighting escape sequences, supported by most ANSI terminal emulators. It is now included standard.

Time::Local

The timelocal() and timegm() functions used to silently return bogus results when the date fell outside the machine's integer range. They now consistently croak() if the date falls in an unsupported range.

Win32

The error return value in list context has been changed for all functions that return a list of values. Previously these functions returned a list with a single element `undef` if an error occurred. Now these functions return the empty list in these situations. This applies to the following functions:

```
    Win32::FsType
    Win32::GetOSVersion
```

The remaining functions are unchanged and continue to return `undef` on error even in list context.

The Win32::SetLastError(ERROR) function has been added as a complement to the Win32::GetLastError() function.

The new Win32::GetFullPathName(FILENAME) returns the full absolute pathname for FILENAME in scalar context. In list context it returns a two-element list containing the fully qualified directory name and the filename. See *Win32*.

XSLoader

The XSLoader extension is a simpler alternative to DynaLoader. See *XSLoader*.

DBM Filters

A new feature called "DBM Filters" has been added to all the DBM modules–DB_File, GDBM_File, NDBM_File, ODBM_File, and SDBM_File. DBM Filters add four new methods to each DBM module:

```
filter_store_key
filter_store_value
filter_fetch_key
filter_fetch_value
```

These can be used to filter key-value pairs before the pairs are written to the database or just after they are read from the database. See *perldbmfilter* for further information.

91.4.2 Pragmata

`use attrs` is now obsolete, and is only provided for backward-compatibility. It's been replaced by the `sub : attributes` syntax. See Subroutine Attributes in *perlsub* and *attributes*.

Lexical warnings pragma, `use warnings;`, to control optional warnings. See *perllexwarn*.

`use filetest` to control the behaviour of filetests (`-r` `-w` ...). Currently only one subpragma implemented, "use filetest 'access';", that uses access(2) or equivalent to check permissions instead of using stat(2) as usual. This matters in filesystems where there are ACLs (access control lists): the stat(2) might lie, but access(2) knows better.

The `open` pragma can be used to specify default disciplines for handle constructors (e.g. open()) and for qx//. The two pseudo-disciplines `:raw` and `:crlf` are currently supported on DOS-derivative platforms (i.e. where binmode is not a no-op). See also §91.3.39.

91.5 Utility Changes

91.5.1 dprofpp

`dprofpp` is used to display profile data generated using `Devel::DProf`. See *dprofpp*.

91.5.2 find2perl

The `find2perl` utility now uses the enhanced features of the File::Find module. The -depth and -follow options are supported. Pod documentation is also included in the script.

91.5.3 h2xs

The `h2xs` tool can now work in conjunction with `C::Scan` (available from CPAN) to automatically parse real-life header files. The `-M`, `-a`, `-k`, and `-o` options are new.

91.5.4 perlcc

`perlcc` now supports the C and Bytecode backends. By default, it generates output from the simple C backend rather than the optimized C backend.

Support for non-Unix platforms has been improved.

91.5.5 perldoc

`perldoc` has been reworked to avoid possible security holes. It will not by default let itself be run as the superuser, but you may still use the **-U** switch to try to make it drop privileges first.

91.5.6 The Perl Debugger

Many bug fixes and enhancements were added to *perl5db.pl*, the Perl debugger. The help documentation was rearranged. New commands include `< ?`, `> ?`, and `{ ?` to list out current actions, `man` *`docpage`* to run your doc viewer on some perl docset, and support for quoted options. The help information was rearranged, and should be viewable once again if you're using **less** as your pager. A serious security hole was plugged–you should immediately remove all older versions of the Perl debugger as installed in previous releases, all the way back to perl3, from your system to avoid being bitten by this.

91.6 Improved Documentation

Many of the platform-specific README files are now part of the perl installation. See *perl* for the complete list.

perlapi.pod

The official list of public Perl API functions.

perlboot.pod

A tutorial for beginners on object-oriented Perl.

perlcompile.pod

An introduction to using the Perl Compiler suite.

perldbmfilter.pod

A howto document on using the DBM filter facility.

perldebug.pod

All material unrelated to running the Perl debugger, plus all low-level guts-like details that risked crushing the casual user of the debugger, have been relocated from the old manpage to the next entry below.

perldebguts.pod

This new manpage contains excessively low-level material not related to the Perl debugger, but slightly related to debugging Perl itself. It also contains some arcane internal details of how the debugging process works that may only be of interest to developers of Perl debuggers.

perlfork.pod

Notes on the fork() emulation currently available for the Windows platform.

perlfilter.pod

An introduction to writing Perl source filters.

perlhack.pod

Some guidelines for hacking the Perl source code.

perlintern.pod

A list of internal functions in the Perl source code. (List is currently empty.)

perllexwarn.pod

Introduction and reference information about lexically scoped warning categories.

perlnumber.pod

Detailed information about numbers as they are represented in Perl.

perlopentut.pod

A tutorial on using open() effectively.

perlreftut.pod

A tutorial that introduces the essentials of references.

perltootc.pod

A tutorial on managing class data for object modules.

perltodo.pod

Discussion of the most often wanted features that may someday be supported in Perl.

perlunicode.pod

An introduction to Unicode support features in Perl.

91.7 Performance enhancements

91.7.1 Simple sort() using { $ a <=> $ b } and the like are optimized

Many common sort() operations using a simple inlined block are now optimized for faster performance.

91.7.2 Optimized assignments to lexical variables

Certain operations in the RHS of assignment statements have been optimized to directly set the lexical variable on the LHS, eliminating redundant copying overheads.

91.7.3 Faster subroutine calls

Minor changes in how subroutine calls are handled internally provide marginal improvements in performance.

91.7.4 delete(), each(), values() and hash iteration are faster

The hash values returned by delete(), each(), values() and hashes in a list context are the actual values in the hash, instead of copies. This results in significantly better performance, because it eliminates needless copying in most situations.

91.8 Installation and Configuration Improvements

91.8.1 -Dusethreads means something different

The -Dusethreads flag now enables the experimental interpreter-based thread support by default. To get the flavor of experimental threads that was in 5.005 instead, you need to run Configure with "-Dusethreads -Duse5005threads".

As of v5.6.0, interpreter-threads support is still lacking a way to create new threads from Perl (i.e., `use Thread;` will not work with interpreter threads). `use Thread;` continues to be available when you specify the -Duse5005threads option to Configure, bugs and all.

```
    NOTE: Support for threads continues to be an experimental feature.
    Interfaces and implementation are subject to sudden and drastic changes.
```

91.8.2 New Configure flags

The following new flags may be enabled on the Configure command line by running Configure with `-Dflag`.

```
usemultiplicity
usethreads useithreads      (new interpreter threads: no Perl API yet)
usethreads use5005threads   (threads as they were in 5.005)

use64bitint                 (equal to now deprecated 'use64bits')
use64bitall

uselongdouble
usemorebits
uselargefiles
usesocks                    (only SOCKS v5 supported)
```

91.8.3 Threadedness and 64-bitness now more daring

The Configure options enabling the use of threads and the use of 64-bitness are now more daring in the sense that they no more have an explicit list of operating systems of known threads/64-bit capabilities. In other words: if your operating system has the necessary APIs and datatypes, you should be able just to go ahead and use them, for threads by Configure -Dusethreads, and for 64 bits either explicitly by Configure -Duse64bitint or implicitly if your system has 64-bit wide datatypes. See also §91.3.11.

91.8.4 Long Doubles

Some platforms have "long doubles", floating point numbers of even larger range than ordinary "doubles". To enable using long doubles for Perl's scalars, use -Duselongdouble.

91.8.5 -Dusemorebits

You can enable both -Duse64bitint and -Duselongdouble with -Dusemorebits. See also §91.3.11.

91.8.6 -Duselargefiles

Some platforms support system APIs that are capable of handling large files (typically, files larger than two gigabytes). Perl will try to use these APIs if you ask for -Duselargefiles.

See §91.3.12 for more information.

91.8.7 installusrbinperl

You can use "Configure -Uinstallusrbinperl" which causes installperl to skip installing perl also as /usr/bin/perl. This is useful if you prefer not to modify /usr/bin for some reason or another but harmful because many scripts assume to find Perl in /usr/bin/perl.

91.8.8 SOCKS support

You can use "Configure -Dusesocks" which causes Perl to probe for the SOCKS proxy protocol library (v5, not v4). For more information on SOCKS, see:

```
http://www.socks.nec.com/
```

91.8.9 `-A` flag

You can "post-edit" the Configure variables using the Configure `-A` switch. The editing happens immediately after the platform specific hints files have been processed but before the actual configuration process starts. Run `Configure -h` to find out the full `-A` syntax.

91.8.10 Enhanced Installation Directories

The installation structure has been enriched to improve the support for maintaining multiple versions of perl, to provide locations for vendor-supplied modules, scripts, and manpages, and to ease maintenance of locally-added modules, scripts, and manpages. See the section on Installation Directories in the INSTALL file for complete details. For most users building and installing from source, the defaults should be fine.

If you previously used `Configure -Dsitelib` or `-Dsitearch` to set special values for library directories, you might wish to consider using the new `-Dsiteprefix` setting instead. Also, if you wish to re-use a config.sh file from an earlier version of perl, you should be sure to check that Configure makes sensible choices for the new directories. See INSTALL for complete details.

91.8.11 gcc automatically tried if 'cc' does not seem to be working

In many platforms the vendor-supplied 'cc' is too stripped-down to build Perl (basically, the 'cc' doesn't do ANSI C). If this seems to be the case and the 'cc' does not seem to be the GNU C compiler 'gcc', an automatic attempt is made to find and use 'gcc' instead.

91.9 Platform specific changes

91.9.1 Supported platforms

- The Mach CThreads (NEXTSTEP, OPENSTEP) are now supported by the Thread extension.
- GNU/Hurd is now supported.
- Rhapsody/Darwin is now supported.
- EPOC is now supported (on Psion 5).
- The cygwin port (formerly cygwin32) has been greatly improved.

91.9.2 DOS

- Perl now works with djgpp 2.02 (and 2.03 alpha).
- Environment variable names are not converted to uppercase any more.
- Incorrect exit codes from backticks have been fixed.
- This port continues to use its own builtin globbing (not File::Glob).

91.9.3 OS390 (OpenEdition MVS)

Support for this EBCDIC platform has not been renewed in this release. There are difficulties in reconciling Perl's standardization on UTF-8 as its internal representation for characters with the EBCDIC character set, because the two are incompatible.

It is unclear whether future versions will renew support for this platform, but the possibility exists.

91.9.4 VMS

Numerous revisions and extensions to configuration, build, testing, and installation process to accommodate core changes and VMS-specific options.

Expand %ENV-handling code to allow runtime mapping to logical names, CLI symbols, and CRTL environ array.

Extension of subprocess invocation code to accept filespecs as command "verbs".

Add to Perl command line processing the ability to use default file types and to recognize Unix-style `2>&1`.

Expansion of File::Spec::VMS routines, and integration into ExtUtils::MM_VMS.

Extension of ExtUtils::MM_VMS to handle complex extensions more flexibly.

Barewords at start of Unix-syntax paths may be treated as text rather than only as logical names.

Optional secure translation of several logical names used internally by Perl.

Miscellaneous bugfixing and porting of new core code to VMS.

Thanks are gladly extended to the many people who have contributed VMS patches, testing, and ideas.

91.9.5 Win32

Perl can now emulate fork() internally, using multiple interpreters running in different concurrent threads. This support must be enabled at build time. See *perlfork* for detailed information.

When given a pathname that consists only of a drivename, such as `A:`, opendir() and stat() now use the current working directory for the drive rather than the drive root.

The builtin XSUB functions in the Win32:: namespace are documented. See *Win32*.

$^X now contains the full path name of the running executable.

A Win32::GetLongPathName() function is provided to complement Win32::GetFullPathName() and Win32::GetShortPathName(). See *Win32*.

POSIX::uname() is supported.

system(1,...) now returns true process IDs rather than process handles. kill() accepts any real process id, rather than strictly return values from system(1,...).

For better compatibility with Unix, `kill(0, $pid)` can now be used to test whether a process exists.

The `Shell` module is supported.

Better support for building Perl under command.com in Windows 95 has been added.

Scripts are read in binary mode by default to allow ByteLoader (and the filter mechanism in general) to work properly. For compatibility, the DATA filehandle will be set to text mode if a carriage return is detected at the end of the line containing the __END__ or __DATA__ token; if not, the DATA filehandle will be left open in binary mode. Earlier versions always opened the DATA filehandle in text mode.

The glob() operator is implemented via the `File::Glob` extension, which supports glob syntax of the C shell. This increases the flexibility of the glob() operator, but there may be compatibility issues for programs that relied on the older globbing syntax. If you want to preserve compatibility with the older syntax, you might want to run perl with `-MFile::DosGlob`. For details and compatibility information, see *File::Glob*.

91.10 Significant bug fixes

91.10.1 <HANDLE> on empty files

With `$/` set to `undef`, "slurping" an empty file returns a string of zero length (instead of `undef`, as it used to) the first time the HANDLE is read after `$/` is set to `undef`. Further reads yield `undef`.

This means that the following will append "foo" to an empty file (it used to do nothing):

```
perl -0777 -pi -e 's/^/foo/' empty_file
```

The behaviour of:

```
perl -pi -e 's/^/foo/' empty_file
```

is unchanged (it continues to leave the file empty).

91.10.2 `eval '...'` improvements

Line numbers (as reflected by caller() and most diagnostics) within `eval '...'` were often incorrect where here documents were involved. This has been corrected.

Lexical lookups for variables appearing in `eval '...'` within functions that were themselves called within an `eval '...'` were searching the wrong place for lexicals. The lexical search now correctly ends at the subroutine's block boundary.

The use of `return` within `eval {...}` caused $@ not to be reset correctly when no exception occurred within the eval. This has been fixed.

Parsing of here documents used to be flawed when they appeared as the replacement expression in `eval 's/.../.../e'`. This has been fixed.

91.10.3 All compilation errors are true errors

Some "errors" encountered at compile time were by necessity generated as warnings followed by eventual termination of the program. This enabled more such errors to be reported in a single run, rather than causing a hard stop at the first error that was encountered.

The mechanism for reporting such errors has been reimplemented to queue compile-time errors and report them at the end of the compilation as true errors rather than as warnings. This fixes cases where error messages leaked through in the form of warnings when code was compiled at run time using `eval STRING`, and also allows such errors to be reliably trapped using `eval "..."`.

91.10.4 Implicitly closed filehandles are safer

Sometimes implicitly closed filehandles (as when they are localized, and Perl automatically closes them on exiting the scope) could inadvertently set $? or $!. This has been corrected.

91.10.5 Behavior of list slices is more consistent

When taking a slice of a literal list (as opposed to a slice of an array or hash), Perl used to return an empty list if the result happened to be composed of all undef values.

The new behavior is to produce an empty list if (and only if) the original list was empty. Consider the following example:

```
    @a = (1,undef,undef,2)[2,1,2];
```

The old behavior would have resulted in @a having no elements. The new behavior ensures it has three undefined elements.

Note in particular that the behavior of slices of the following cases remains unchanged:

```
    @a = ()[1,2];
    @a = (getpwent)[7,0];
    @a = (anything_returning_empty_list())[2,1,2];
    @a = @b[2,1,2];
    @a = @c{'a','b','c'};
```

See *perldata*.

91.10.6 `(\$)` prototype and `$foo{a}`

A scalar reference prototype now correctly allows a hash or array element in that slot.

91.10.7 `goto &sub` and AUTOLOAD

The `goto &sub` construct works correctly when `&sub` happens to be autoloaded.

91.10.8 `-bareword` allowed under `use integer`

The autoquoting of barewords preceded by `-` did not work in prior versions when the `integer` pragma was enabled. This has been fixed.

91.10.9 Failures in DESTROY()

When code in a destructor threw an exception, it went unnoticed in earlier versions of Perl, unless someone happened to be looking in $@ just after the point the destructor happened to run. Such failures are now visible as warnings when warnings are enabled.

91.10.10 Locale bugs fixed

printf() and sprintf() previously reset the numeric locale back to the default "C" locale. This has been fixed.

Numbers formatted according to the local numeric locale (such as using a decimal comma instead of a decimal dot) caused "isn't numeric" warnings, even while the operations accessing those numbers produced correct results. These warnings have been discontinued.

91.10.11 Memory leaks

The `eval 'return sub {...}'` construct could sometimes leak memory. This has been fixed.

Operations that aren't filehandle constructors used to leak memory when used on invalid filehandles. This has been fixed.

Constructs that modified `@_` could fail to deallocate values in `@_` and thus leak memory. This has been corrected.

91.10.12 Spurious subroutine stubs after failed subroutine calls

Perl could sometimes create empty subroutine stubs when a subroutine was not found in the package. Such cases stopped later method lookups from progressing into base packages. This has been corrected.

91.10.13 Taint failures under `-U`

When running in unsafe mode, taint violations could sometimes cause silent failures. This has been fixed.

91.10.14 END blocks and the `-c` switch

Prior versions used to run BEGIN **and** END blocks when Perl was run in compile-only mode. Since this is typically not the expected behavior, END blocks are not executed anymore when the `-c` switch is used, or if compilation fails.

See §91.3.18 for how to run things when the compile phase ends.

91.10.15 Potential to leak DATA filehandles

Using the `__DATA__` token creates an implicit filehandle to the file that contains the token. It is the program's responsibility to close it when it is done reading from it.

This caveat is now better explained in the documentation. See *perldata*.

91.11 New or Changed Diagnostics

"%s" variable %s masks earlier declaration in same %s

(W misc) A "my" or "our" variable has been redeclared in the current scope or statement, effectively eliminating all access to the previous instance. This is almost always a typographical error. Note that the earlier variable will still exist until the end of the scope or until all closure referents to it are destroyed.

"my sub" not yet implemented

(F) Lexically scoped subroutines are not yet implemented. Don't try that yet.

"our" variable %s redeclared

(W misc) You seem to have already declared the same global once before in the current lexical scope.

'!' allowed only after types %s

(F) The '!' is allowed in pack() and unpack() only after certain types. See pack in *perlfunc*.

/ cannot take a count

(F) You had an unpack template indicating a counted-length string, but you have also specified an explicit size for the string. See pack in *perlfunc*.

/ must be followed by a, A or Z

(F) You had an unpack template indicating a counted-length string, which must be followed by one of the letters a, A or Z to indicate what sort of string is to be unpacked. See pack in *perlfunc*.

/ must be followed by a*, A* or Z*

(F) You had a pack template indicating a counted-length string, Currently the only things that can have their length counted are a*, A* or Z*. See pack in *perlfunc*.

/ must follow a numeric type

(F) You had an unpack template that contained a '#', but this did not follow some numeric unpack specification. See pack in *perlfunc*.

/%s/: Unrecognized escape \\%c passed through

(W regexp) You used a backslash-character combination which is not recognized by Perl. This combination appears in an interpolated variable or a `'`-delimited regular expression. The character was understood literally.

/%s/: Unrecognized escape \\%c in character class passed through

(W regexp) You used a backslash-character combination which is not recognized by Perl inside character classes. The character was understood literally.

/%s/ should probably be written as "%s"

(W syntax) You have used a pattern where Perl expected to find a string, as in the first argument to `join`. Perl will treat the true or false result of matching the pattern against $_ as the string, which is probably not what you had in mind.

%s() called too early to check prototype

(W prototype) You've called a function that has a prototype before the parser saw a definition or declaration for it, and Perl could not check that the call conforms to the prototype. You need to either add an early prototype declaration for the subroutine in question, or move the subroutine definition ahead of the call to get proper prototype checking. Alternatively, if you are certain that you're calling the function correctly, you may put an ampersand before the name to avoid the warning. See *perlsub*.

%s argument is not a HASH or ARRAY element

(F) The argument to exists() must be a hash or array element, such as:

```
    $foo{$bar}
    $ref->{"susie"}[12]
```

%s argument is not a HASH or ARRAY element or slice

(F) The argument to delete() must be either a hash or array element, such as:

```
$foo{$bar}
$ref->{"susie"}[12]
```

or a hash or array slice, such as:

```
@foo[$bar, $baz, $xyzzy]
@{$ref->[12]}{"susie", "queue"}
```

%s argument is not a subroutine name

(F) The argument to exists() for `exists &sub` must be a subroutine name, and not a subroutine call. `exists &sub()` will generate this error.

%s package attribute may clash with future reserved word: %s

(W reserved) A lowercase attribute name was used that had a package-specific handler. That name might have a meaning to Perl itself some day, even though it doesn't yet. Perhaps you should use a mixed-case attribute name, instead. See *attributes*.

(in cleanup) %s

(W misc) This prefix usually indicates that a DESTROY() method raised the indicated exception. Since destructors are usually called by the system at arbitrary points during execution, and often a vast number of times, the warning is issued only once for any number of failures that would otherwise result in the same message being repeated.

Failure of user callbacks dispatched using the `G_KEEPERR` flag could also result in this warning. See G_KEEPERR in *perlcall*.

<> should be quotes

(F) You wrote `require <file>` when you should have written `require 'file'`.

Attempt to join self

(F) You tried to join a thread from within itself, which is an impossible task. You may be joining the wrong thread, or you may need to move the join() to some other thread.

Bad evalled substitution pattern

(F) You've used the /e switch to evaluate the replacement for a substitution, but perl found a syntax error in the code to evaluate, most likely an unexpected right brace '}'.

Bad realloc() ignored

(S) An internal routine called realloc() on something that had never been malloc()ed in the first place. Mandatory, but can be disabled by setting environment variable `PERL_BADFREE` to 1.

Bareword found in conditional

(W bareword) The compiler found a bareword where it expected a conditional, which often indicates that an || or && was parsed as part of the last argument of the previous construct, for example:

```
open FOO || die;
```

It may also indicate a misspelled constant that has been interpreted as a bareword:

```
use constant TYPO => 1;
if (TYOP) { print "foo" }
```

The `strict` pragma is useful in avoiding such errors.

Binary number > 0b11111111111111111111111111111111 non-portable

(W portable) The binary number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

Bit vector size > 32 non-portable

(W portable) Using bit vector sizes larger than 32 is non-portable.

Buffer overflow in prime_env_iter: %s

(W internal) A warning peculiar to VMS. While Perl was preparing to iterate over %ENV, it encountered a logical name or symbol definition which was too long, so it was truncated to the string shown.

Can't check filesystem of script "%s"

(P) For some reason you can't check the filesystem of the script for nosuid.

Can't declare class for non-scalar %s in "%s"

(S) Currently, only scalar variables can declared with a specific class qualifier in a "my" or "our" declaration. The semantics may be extended for other types of variables in future.

Can't declare %s in "%s"

(F) Only scalar, array, and hash variables may be declared as "my" or "our" variables. They must have ordinary identifiers as names.

Can't ignore signal CHLD, forcing to default

(W signal) Perl has detected that it is being run with the SIGCHLD signal (sometimes known as SIGCLD) disabled. Since disabling this signal will interfere with proper determination of exit status of child processes, Perl has reset the signal to its default value. This situation typically indicates that the parent program under which Perl may be running (e.g., cron) is being very careless.

Can't modify non-lvalue subroutine call

(F) Subroutines meant to be used in lvalue context should be declared as such, see Lvalue subroutines in *perlsub*.

Can't read CRTL environ

(S) A warning peculiar to VMS. Perl tried to read an element of %ENV from the CRTL's internal environment array and discovered the array was missing. You need to figure out where your CRTL misplaced its environ or define *PERL_ENV_TABLES* (see *perlvms*) so that environ is not searched.

Can't remove %s: %s, skipping file

(S) You requested an inplace edit without creating a backup file. Perl was unable to remove the original file to replace it with the modified file. The file was left unmodified.

Can't return %s from lvalue subroutine

(F) Perl detected an attempt to return illegal lvalues (such as temporary or readonly values) from a subroutine used as an lvalue. This is not allowed.

Can't weaken a nonreference

(F) You attempted to weaken something that was not a reference. Only references can be weakened.

Character class [:%s: unknown]

(F) The class in the character class [: :] syntax is unknown. See *perlre*.

Character class syntax [%s belongs inside] **character classes**

(W unsafe) The character class constructs [: :], [= =], and [. .] go *inside* character classes, the [] are part of the construct, for example: /[012[:alpha:]345]/. Note that [= =] and [. .] are not currently implemented; they are simply placeholders for future extensions.

Constant is not %s reference

(F) A constant value (perhaps declared using the `use constant` pragma) is being dereferenced, but it amounts to the wrong type of reference. The message indicates the type of reference that was expected. This usually indicates a syntax error in dereferencing the constant value. See Constant Functions in *perlsub* and *constant*.

constant(%s): %s

(F) The parser found inconsistencies either while attempting to define an overloaded constant, or when trying to find the character name specified in the `\N{...}` escape. Perhaps you forgot to load the corresponding `overload` or `charnames` pragma? See *charnames* and *overload*.

CORE::%s is not a keyword

(F) The CORE:: namespace is reserved for Perl keywords.

defined(@array) is deprecated

(D) defined() is not usually useful on arrays because it checks for an undefined *scalar* value. If you want to see if the array is empty, just use `if (@array) { # not empty }` for example.

defined(%hash) is deprecated

(D) defined() is not usually useful on hashes because it checks for an undefined *scalar* value. If you want to see if the hash is empty, just use `if (%hash) { # not empty }` for example.

Did not produce a valid header

See Server error.

(Did you mean "local" instead of "our"?)

(W misc) Remember that "our" does not localize the declared global variable. You have declared it again in the same lexical scope, which seems superfluous.

Document contains no data

See Server error.

entering effective %s failed

(F) While under the `use filetest` pragma, switching the real and effective uids or gids failed.

false [range "%s" in regexp]

(W regexp) A character class range must start and end at a literal character, not another character class like `\d` or `[:alpha:]`. The "-" in your false range is interpreted as a literal "-". Consider quoting the "-", "\-". See *perlre*.

Filehandle %s opened only for output

(W io) You tried to read from a filehandle opened only for writing. If you intended it to be a read/write filehandle, you needed to open it with "+<" or "+>" or "+>>" instead of with "<" or nothing. If you intended only to read from the file, use "<". See open in *perlfunc*.

flock() on closed filehandle %s

(W closed) The filehandle you're attempting to flock() got itself closed some time before now. Check your logic flow. flock() operates on filehandles. Are you attempting to call flock() on a dirhandle by the same name?

Global symbol "%s" requires explicit package name

(F) You've said "use strict vars", which indicates that all variables must either be lexically scoped (using "my"), declared beforehand using "our", or explicitly qualified to say which package the global variable is in (using "::").

Hexadecimal number > 0xffffffff non-portable

(W portable) The hexadecimal number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

Ill-formed CRTL environ value "%s"

(W internal) A warning peculiar to VMS. Perl tried to read the CRTL's internal environ array, and encountered an element without the = delimiter used to separate keys from values. The element is ignored.

Ill-formed message in prime_env_iter: |%s|

(W internal) A warning peculiar to VMS. Perl tried to read a logical name or CLI symbol definition when preparing to iterate over %ENV, and didn't see the expected delimiter between key and value, so the line was ignored.

Illegal binary digit %s

(F) You used a digit other than 0 or 1 in a binary number.

Illegal binary digit %s ignored

(W digit) You may have tried to use a digit other than 0 or 1 in a binary number. Interpretation of the binary number stopped before the offending digit.

Illegal number of bits in vec

(F) The number of bits in vec() (the third argument) must be a power of two from 1 to 32 (or 64, if your platform supports that).

Integer overflow in %s number

(W overflow) The hexadecimal, octal or binary number you have specified either as a literal or as an argument to hex() or oct() is too big for your architecture, and has been converted to a floating point number. On a 32-bit architecture the largest hexadecimal, octal or binary number representable without overflow is 0xFFFFFFFF, 037777777777, or 0b11111111111111111111111111111111 respectively. Note that Perl transparently promotes all numbers to a floating point representation internally–subject to loss of precision errors in subsequent operations.

Invalid %s attribute: %s

The indicated attribute for a subroutine or variable was not recognized by Perl or by a user-supplied handler. See *attributes*.

Invalid %s attributes: %s

The indicated attributes for a subroutine or variable were not recognized by Perl or by a user-supplied handler. See *attributes*.

invalid [range "%s" in regexp]

The offending range is now explicitly displayed.

Invalid separator character %s in attribute list

(F) Something other than a colon or whitespace was seen between the elements of an attribute list. If the previous attribute had a parenthesised parameter list, perhaps that list was terminated too soon. See *attributes*.

Invalid separator character %s in subroutine attribute list

(F) Something other than a colon or whitespace was seen between the elements of a subroutine attribute list. If the previous attribute had a parenthesised parameter list, perhaps that list was terminated too soon.

leaving effective %s failed

(F) While under the `use filetest` pragma, switching the real and effective uids or gids failed.

Lvalue subs returning %s not implemented yet

(F) Due to limitations in the current implementation, array and hash values cannot be returned in subroutines used in lvalue context. See Lvalue subroutines in *perlsub*.

Method %s not permitted

See Server error.

Missing %sbrace%s on \N{}

(F) Wrong syntax of character name literal `\N{charname}` within double-quotish context.

Missing command in piped open

(W pipe) You used the `open(FH, "| command")` or `open(FH, "command |")` construction, but the command was missing or blank.

Missing name in "my sub"

(F) The reserved syntax for lexically scoped subroutines requires that they have a name with which they can be found.

No %s specified for -%c

(F) The indicated command line switch needs a mandatory argument, but you haven't specified one.

No package name allowed for variable %s in "our"

(F) Fully qualified variable names are not allowed in "our" declarations, because that doesn't make much sense under existing semantics. Such syntax is reserved for future extensions.

No space allowed after -%c

(F) The argument to the indicated command line switch must follow immediately after the switch, without intervening spaces.

no UTC offset information; assuming local time is UTC

(S) A warning peculiar to VMS. Perl was unable to find the local timezone offset, so it's assuming that local system time is equivalent to UTC. If it's not, define the logical name *SYS$ TIMEZONE_DIFFERENTIAL* to translate to the number of seconds which need to be added to UTC to get local time.

Octal number > 037777777777 non-portable

(W portable) The octal number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

See also *perlport* for writing portable code.

panic: del_backref

(P) Failed an internal consistency check while trying to reset a weak reference.

panic: kid popen errno read

(F) forked child returned an incomprehensible message about its errno.

panic: magic_killbackrefs

(P) Failed an internal consistency check while trying to reset all weak references to an object.

Parentheses missing around "%s" list

(W parenthesis) You said something like

```
    my $foo, $bar = @_;
```

when you meant

```
    my ($foo, $bar) = @_;
```

Remember that "my", "our", and "local" bind tighter than comma.

Possible unintended interpolation of %s in string

(W ambiguous) It used to be that Perl would try to guess whether you wanted an array interpolated or a literal @. It no longer does this; arrays are now *always* interpolated into strings. This means that if you try something like:

```
        print "fred@example.com";
```

and the array `@example` doesn't exist, Perl is going to print `fred.com`, which is probably not what you wanted. To get a literal `@` sign in a string, put a backslash before it, just as you would to get a literal `$` sign.

Possible Y2K bug: %s

(W y2k) You are concatenating the number 19 with another number, which could be a potential Year 2000 problem.

pragma "attrs" is deprecated, use "sub NAME : ATTRS" instead

(W deprecated) You have written something like this:

```
    sub doit
    {
        use attrs qw(locked);
    }
```

You should use the new declaration syntax instead.

```
    sub doit : locked
    {
        ...
```

The `use attrs` pragma is now obsolete, and is only provided for backward-compatibility. See Subroutine Attributes in *perlsub*.

Premature end of script headers

See Server error.

Repeat count in pack overflows

(F) You can't specify a repeat count so large that it overflows your signed integers. See pack in *perlfunc*.

Repeat count in unpack overflows

(F) You can't specify a repeat count so large that it overflows your signed integers. See unpack in *perlfunc*.

realloc() of freed memory ignored

(S) An internal routine called realloc() on something that had already been freed.

Reference is already weak

(W misc) You have attempted to weaken a reference that is already weak. Doing so has no effect.

setpgrp can't take arguments

(F) Your system has the setpgrp() from BSD 4.2, which takes no arguments, unlike POSIX setpgid(), which takes a process ID and process group ID.

Strange *+?{} on zero-length expression

(W regexp) You applied a regular expression quantifier in a place where it makes no sense, such as on a zero-width assertion. Try putting the quantifier inside the assertion instead. For example, the way to match "abc" provided that it is followed by three repetitions of "xyz" is `/abc(?=(?:xyz){3})/`, not `/abc(?=xyz){3}/`.

switching effective %s is not implemented

(F) While under the `use filetest` pragma, we cannot switch the real and effective uids or gids.

This Perl can't reset CRTL environ elements (%s)

This Perl can't set CRTL environ elements (%s=%s)

(W internal) Warnings peculiar to VMS. You tried to change or delete an element of the CRTL's internal environ array, but your copy of Perl wasn't built with a CRTL that contained the setenv() function. You'll need to rebuild Perl with a CRTL that does, or redefine *PERL_ENV_TABLES* (see *perlvms*) so that the environ array isn't the target of the change to %ENV which produced the warning.

Too late to run %s block

(W void) A CHECK or INIT block is being defined during run time proper, when the opportunity to run them has already passed. Perhaps you are loading a file with `require` or `do` when you should be using `use` instead. Or perhaps you should put the `require` or `do` inside a BEGIN block.

Unknown open() mode '%s'

(F) The second argument of 3-argument open() is not among the list of valid modes: <, >, >>, +<, +>, +>>, -|, |-.

Unknown process %x sent message to prime_env_iter: %s

(P) An error peculiar to VMS. Perl was reading values for %ENV before iterating over it, and someone else stuck a message in the stream of data Perl expected. Someone's very confused, or perhaps trying to subvert Perl's population of %ENV for nefarious purposes.

Unrecognized escape \\%c passed through

(W misc) You used a backslash-character combination which is not recognized by Perl. The character was understood literally.

Unterminated attribute parameter in attribute list

(F) The lexer saw an opening (left) parenthesis character while parsing an attribute list, but the matching closing (right) parenthesis character was not found. You may need to add (or remove) a backslash character to get your parentheses to balance. See *attributes*.

Unterminated attribute list

(F) The lexer found something other than a simple identifier at the start of an attribute, and it wasn't a semicolon or the start of a block. Perhaps you terminated the parameter list of the previous attribute too soon. See *attributes*.

Unterminated attribute parameter in subroutine attribute list

(F) The lexer saw an opening (left) parenthesis character while parsing a subroutine attribute list, but the matching closing (right) parenthesis character was not found. You may need to add (or remove) a backslash character to get your parentheses to balance.

Unterminated subroutine attribute list

(F) The lexer found something other than a simple identifier at the start of a subroutine attribute, and it wasn't a semicolon or the start of a block. Perhaps you terminated the parameter list of the previous attribute too soon.

Value of CLI symbol "%s" too long

(W misc) A warning peculiar to VMS. Perl tried to read the value of an %ENV element from a CLI symbol table, and found a resultant string longer than 1024 characters. The return value has been truncated to 1024 characters.

Version number must be a constant number

(P) The attempt to translate a `use Module n.n LIST` statement into its equivalent `BEGIN` block found an internal inconsistency with the version number.

91.12 New tests

lib/attrs

Compatibility tests for `sub : attrs` vs the older `use attrs`.

lib/env

Tests for new environment scalar capability (e.g., `use Env qw($BAR);`).

lib/env-array

Tests for new environment array capability (e.g., `use Env qw(@PATH);`).

lib/io_const

IO constants (SEEK_*, _IO*).

lib/io_dir

Directory-related IO methods (new, read, close, rewind, tied delete).

lib/io_multihomed

INET sockets with multi-homed hosts.

lib/io_poll

IO poll().

lib/io_unix

UNIX sockets.

op/attrs

Regression tests for `my ($x,@y,%z) : attrs` and <sub : attrs>.

op/filetest

File test operators.

op/lex_assign

Verify operations that access pad objects (lexicals and temporaries).

op/exists_sub

Verify `exists &sub` operations.

91.13 Incompatible Changes

91.13.1 Perl Source Incompatibilities

Beware that any new warnings that have been added or old ones that have been enhanced are **not** considered incompatible changes.

Since all new warnings must be explicitly requested via the `-w` switch or the `warnings` pragma, it is ultimately the programmer's responsibility to ensure that warnings are enabled judiciously.

CHECK is a new keyword

All subroutine definitions named CHECK are now special. See `/"Support for CHECK blocks"` for more information.

Treatment of list slices of undef has changed

There is a potential incompatibility in the behavior of list slices that are comprised entirely of undefined values. See §91.10.5.

Format of $ English::PERL_VERSION is different

The English module now sets $PERL_VERSION to $ˆV (a string value) rather than `$]` (a numeric value). This is a potential incompatibility. Send us a report via perlbug if you are affected by this.

See §91.3.7 for the reasons for this change.

Literals of the form `1.2.3` parse differently

Previously, numeric literals with more than one dot in them were interpreted as a floating point number concatenated with one or more numbers. Such "numbers" are now parsed as strings composed of the specified ordinals.

For example, `print 97.98.99` used to output `97.9899` in earlier versions, but now prints `abc`.

See §91.3.6.

Possibly changed pseudo-random number generator

Perl programs that depend on reproducing a specific set of pseudo-random numbers may now produce different output due to improvements made to the rand() builtin. You can use `sh Configure -Drandfunc=rand` to obtain the old behavior.

See §91.3.20.

Hashing function for hash keys has changed

Even though Perl hashes are not order preserving, the apparently random order encountered when iterating on the contents of a hash is actually determined by the hashing algorithm used. Improvements in the algorithm may yield a random order that is **different** from that of previous versions, especially when iterating on hashes.

See §91.3.22 for additional information.

`undef` fails on read only values

Using the `undef` operator on a readonly value (such as $1) has the same effect as assigning `undef` to the readonly value–it throws an exception.

Close-on-exec bit may be set on pipe and socket handles

Pipe and socket handles are also now subject to the close-on-exec behavior determined by the special variable $ˆF.

See §91.3.44.

Writing `"$$1"` to mean `"${$}1"` is unsupported

Perl 5.004 deprecated the interpretation of `$$1` and similar within interpolated strings to mean `$$ . "1"`, but still allowed it.

In Perl 5.6.0 and later, `"$$1"` always means `"${$1}"`.

delete(), each(), values() and `\(%h)`

operate on aliases to values, not copies

delete(), each(), values() and hashes (e.g. `\(%h)`) in a list context return the actual values in the hash, instead of copies (as they used to in earlier versions). Typical idioms for using these constructs copy the returned values, but this can make a significant difference when creating references to the returned values. Keys in the hash are still returned as copies when iterating on a hash.

See also §91.7.4.

vec(EXPR,OFFSET,BITS) enforces powers-of-two BITS

vec() generates a run-time error if the BITS argument is not a valid power-of-two integer.

Text of some diagnostic output has changed

Most references to internal Perl operations in diagnostics have been changed to be more descriptive. This may be an issue for programs that may incorrectly rely on the exact text of diagnostics for proper functioning.

`%@` has been removed

The undocumented special variable `%@` that used to accumulate "background" errors (such as those that happen in DESTROY()) has been removed, because it could potentially result in memory leaks.

Parenthesized not() behaves like a list operator

The `not` operator now falls under the "if it looks like a function, it behaves like a function" rule.

As a result, the parenthesized form can be used with `grep` and `map`. The following construct used to be a syntax error before, but it works as expected now:

```
    grep not($_), @things;
```

On the other hand, using `not` with a literal list slice may not work. The following previously allowed construct:

```
    print not (1,2,3)[0];
```

needs to be written with additional parentheses now:

```
    print not((1,2,3)[0]);
```

The behavior remains unaffected when `not` is not followed by parentheses.

Semantics of bareword prototype `(*)` have changed

The semantics of the bareword prototype * have changed. Perl 5.005 always coerced simple scalar arguments to a typeglob, which wasn't useful in situations where the subroutine must distinguish between a simple scalar and a typeglob. The new behavior is to not coerce bareword arguments to a typeglob. The value will always be visible as either a simple scalar or as a reference to a typeglob.

See §91.3.49.

Semantics of bit operators may have changed on 64-bit platforms

If your platform is either natively 64-bit or if Perl has been configured to used 64-bit integers, i.e., $Config{ivsize} is 8, there may be a potential incompatibility in the behavior of bitwise numeric operators (& | ^ ˜ << >>). These operators used to strictly operate on the lower 32 bits of integers in previous versions, but now operate over the entire native integral width. In particular, note that unary ˜ will produce different results on platforms that have different $Config{ivsize}. For portability, be sure to mask off the excess bits in the result of unary ˜, e.g., `~$x & 0xffffffff`.

See §91.3.47.

More builtins taint their results

As described in §91.3.48, there may be more sources of taint in a Perl program.

To avoid these new tainting behaviors, you can build Perl with the Configure option `-Accflags=-DINCOMPLETE_TAINTS`. Beware that the ensuing perl binary may be insecure.

91.13.2 C Source Incompatibilities

`PERL_POLLUTE`

Release 5.005 grandfathered old global symbol names by providing preprocessor macros for extension source compatibility. As of release 5.6.0, these preprocessor definitions are not available by default. You need to explicitly compile perl with `-DPERL_POLLUTE` to get these definitions. For extensions still using the old symbols, this option can be specified via MakeMaker:

```
    perl Makefile.PL POLLUTE=1
```

`PERL_IMPLICIT_CONTEXT`

This new build option provides a set of macros for all API functions such that an implicit interpreter/thread context argument is passed to every API function. As a result of this, something like `sv_setsv(foo,bar)` amounts to a macro invocation that actually translates to something like `Perl_sv_setsv(my_perl,foo,bar)`. While this is generally expected to not have any significant source compatibility issues, the difference between a macro and a real function call will need to be considered.

This means that there **is** a source compatibility issue as a result of this if your extensions attempt to use pointers to any of the Perl API functions.

Note that the above issue is not relevant to the default build of Perl, whose interfaces continue to match those of prior versions (but subject to the other options described here).

See The Perl API in *perlguts* for detailed information on the ramifications of building Perl with this option.

```
        NOTE: PERL_IMPLICIT_CONTEXT is automatically enabled whenever Perl is built
        with one of -Dusethreads, -Dusemultiplicity, or both.  It is not
        intended to be enabled by users at this time.
```

PERL_POLLUTE_MALLOC

Enabling Perl's malloc in release 5.005 and earlier caused the namespace of the system's malloc family of functions to be usurped by the Perl versions, since by default they used the same names. Besides causing problems on platforms that do not allow these functions to be cleanly replaced, this also meant that the system versions could not be called in programs that used Perl's malloc. Previous versions of Perl have allowed this behaviour to be suppressed with the HIDEMYMALLOC and EMBEDMYMALLOC preprocessor definitions.

As of release 5.6.0, Perl's malloc family of functions have default names distinct from the system versions. You need to explicitly compile perl with `-DPERL_POLLUTE_MALLOC` to get the older behaviour. HIDEMYMALLOC and EMBEDMYMALLOC have no effect, since the behaviour they enabled is now the default.

Note that these functions do **not** constitute Perl's memory allocation API. See Memory Allocation in *perlguts* for further information about that.

91.13.3 Compatible C Source API Changes

PATCHLEVEL is now PERL_VERSION

The cpp macros `PERL_REVISION`, `PERL_VERSION`, and `PERL_SUBVERSION` are now available by default from perl.h, and reflect the base revision, patchlevel, and subversion respectively. `PERL_REVISION` had no prior equivalent, while `PERL_VERSION` and `PERL_SUBVERSION` were previously available as `PATCHLEVEL` and `SUBVERSION`.

The new names cause less pollution of the **cpp** namespace and reflect what the numbers have come to stand for in common practice. For compatibility, the old names are still supported when *patchlevel.h* is explicitly included (as required before), so there is no source incompatibility from the change.

91.13.4 Binary Incompatibilities

In general, the default build of this release is expected to be binary compatible for extensions built with the 5.005 release or its maintenance versions. However, specific platforms may have broken binary compatibility due to changes in the defaults used in hints files. Therefore, please be sure to always check the platform-specific README files for any notes to the contrary.

The usethreads or usemultiplicity builds are **not** binary compatible with the corresponding builds in 5.005.

On platforms that require an explicit list of exports (AIX, OS/2 and Windows, among others), purely internal symbols such as parser functions and the run time opcodes are not exported by default. Perl 5.005 used to export all functions irrespective of whether they were considered part of the public API or not.

For the full list of public API functions, see *perlapi*.

91.14 Known Problems

91.14.1 Localizing a tied hash element may leak memory

As of the 5.6.1 release, there is a known leak when code such as this is executed:

```
    use Tie::Hash;
    tie my %tie_hash => 'Tie::StdHash';

    ...

    local($tie_hash{Foo}) = 1; # leaks
```

91.14.2 Known test failures

- 64-bit builds

  Subtest #15 of lib/b.t may fail under 64-bit builds on platforms such as HP-UX PA64 and Linux IA64. The issue is still being investigated.

  The lib/io_multihomed test may hang in HP-UX if Perl has been configured to be 64-bit. Because other 64-bit platforms do not hang in this test, HP-UX is suspect. All other tests pass in 64-bit HP-UX. The test attempts to create and connect to "multihomed" sockets (sockets which have multiple IP addresses).

  Note that 64-bit support is still experimental.

- Failure of Thread tests

  The subtests 19 and 20 of lib/thr5005.t test are known to fail due to fundamental problems in the 5.005 threading implementation. These are not new failures–Perl 5.005_0x has the same bugs, but didn't have these tests. (Note that support for 5.005-style threading remains experimental.)

- NEXTSTEP 3.3 POSIX test failure

  In NEXTSTEP 3.3p2 the implementation of the strftime(3) in the operating system libraries is buggy: the %j format numbers the days of a month starting from zero, which, while being logical to programmers, will cause the subtests 19 to 27 of the lib/posix test may fail.

- Tru64 (aka Digital UNIX, aka DEC OSF/1) lib/sdbm test failure with gcc

  If compiled with gcc 2.95 the lib/sdbm test will fail (dump core). The cure is to use the vendor cc, it comes with the operating system and produces good code.

91.14.3 EBCDIC platforms not fully supported

In earlier releases of Perl, EBCDIC environments like OS390 (also known as Open Edition MVS) and VM-ESA were supported. Due to changes required by the UTF-8 (Unicode) support, the EBCDIC platforms are not supported in Perl 5.6.0.

The 5.6.1 release improves support for EBCDIC platforms, but they are not fully supported yet.

91.14.4 UNICOS/mk CC failures during Configure run

In UNICOS/mk the following errors may appear during the Configure run:

```
        Guessing which symbols your C compiler and preprocessor define...
        CC-20 cc: ERROR File = try.c, Line = 3
        ...
          bad switch yylook 79bad switch yylook 79bad switch yylook 79bad switch yylook 79#ifdef A29K
        ...
        4 errors detected in the compilation of "try.c".
```

The culprit is the broken awk of UNICOS/mk. The effect is fortunately rather mild: Perl itself is not adversely affected by the error, only the h2ph utility coming with Perl, and that is rather rarely needed these days.

91.14.5 Arrow operator and arrays

When the left argument to the arrow operator -> is an array, or the `scalar` operator operating on an array, the result of the operation must be considered erroneous. For example:

```
    @x->[2]
    scalar(@x)->[2]
```

These expressions will get run-time errors in some future release of Perl.

91.14.6 Experimental features

As discussed above, many features are still experimental. Interfaces and implementation of these features are subject to change, and in extreme cases, even subject to removal in some future release of Perl. These features include the following:

Threads

Unicode

64-bit support

Lvalue subroutines

Weak references

The pseudo-hash data type

The Compiler suite

Internal implementation of file globbing

The DB module

The regular expression code constructs:

`(?{ code })` and `(??{ code })`

91.15 Obsolete Diagnostics

Character class syntax [: : is reserved] **for future extensions**

(W) Within regular expression character classes ([]) the syntax beginning with "[:" and ending with ":]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[:" and ":\]".

Ill-formed logical name |%s| in prime_env_iter

(W) A warning peculiar to VMS. A logical name was encountered when preparing to iterate over %ENV which violates the syntactic rules governing logical names. Because it cannot be translated normally, it is skipped, and will not appear in %ENV. This may be a benign occurrence, as some software packages might directly modify logical name tables and introduce nonstandard names, or it may indicate that a logical name table has been corrupted.

In string, @%s now must be written as \@%s

The description of this error used to say:

```
        (Someday it will simply assume that an unbackslashed @
         interpolates an array.)
```

That day has come, and this fatal error has been removed. It has been replaced by a non-fatal warning instead. See Arrays now always interpolate into double-quoted strings for details.

Probable precedence problem on %s

(W) The compiler found a bareword where it expected a conditional, which often indicates that an || or && was parsed as part of the last argument of the previous construct, for example:

```
    open FOO || die;
```

regexp too big

(F) The current implementation of regular expressions uses shorts as address offsets within a string. Unfortunately this means that if the regular expression compiles to longer than 32767, it'll blow up. Usually when you want a regular expression this big, there is a better way to do it with multiple statements. See *perlre*.

Use of "$ $ <digit>" to mean "$ {$ }<digit>" is deprecated

(D) Perl versions before 5.004 misinterpreted any type marker followed by "$" and a digit. For example, "$$0" was incorrectly taken to mean "${$}0" instead of "${$0}". This bug is (mostly) fixed in Perl 5.004.

However, the developers of Perl 5.004 could not fix this bug completely, because at least two widely-used modules depend on the old meaning of "$$0" in a string. So Perl 5.004 still interprets "$$<digit>" in the old (broken) way inside strings; but it generates this message as a warning. And in Perl 5.005, this special treatment will cease.

91.16 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup. There may also be information at http://www.perl.com/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

Chapter 92

perl56delta

What's new for perl v5.6.0

92.1 DESCRIPTION

This document describes differences between the 5.005 release and the 5.6.0 release.

92.2 Core Enhancements

92.2.1 Interpreter cloning, threads, and concurrency

Perl 5.6.0 introduces the beginnings of support for running multiple interpreters concurrently in different threads. In conjunction with the perl_clone() API call, which can be used to selectively duplicate the state of any given interpreter, it is possible to compile a piece of code once in an interpreter, clone that interpreter one or more times, and run all the resulting interpreters in distinct threads.

On the Windows platform, this feature is used to emulate fork() at the interpreter level. See *perlfork* for details about that.

This feature is still in evolution. It is eventually meant to be used to selectively clone a subroutine and data reachable from that subroutine in a separate interpreter and run the cloned subroutine in a separate thread. Since there is no shared data between the interpreters, little or no locking will be needed (unless parts of the symbol table are explicitly shared). This is obviously intended to be an easy-to-use replacement for the existing threads support.

Support for cloning interpreters and interpreter concurrency can be enabled using the -Dusethreads Configure option (see win32/Makefile for how to enable it on Windows.) The resulting perl executable will be functionally identical to one that was built with -Dmultiplicity, but the perl_clone() API call will only be available in the former.

-Dusethreads enables the cpp macro USE_ITHREADS by default, which in turn enables Perl source code changes that provide a clear separation between the op tree and the data it operates with. The former is immutable, and can therefore be shared between an interpreter and all of its clones, while the latter is considered local to each interpreter, and is therefore copied for each clone.

Note that building Perl with the -Dusemultiplicity Configure option is adequate if you wish to run multiple **independent** interpreters concurrently in different threads. -Dusethreads only provides the additional functionality of the perl_clone() API call and other support for running **cloned** interpreters concurrently.

```
    NOTE: This is an experimental feature.  Implementation details are
    subject to change.
```

92.2.2 Lexically scoped warning categories

You can now control the granularity of warnings emitted by perl at a finer level using the `use warnings` pragma. *warnings* and *perllexwarn* have copious documentation on this feature.

92.2.3 Unicode and UTF-8 support

Perl now uses UTF-8 as its internal representation for character strings. The `utf8` and `bytes` pragmas are used to control this support in the current lexical scope. See *perlunicode*, *utf8* and *bytes* for more information.

This feature is expected to evolve quickly to support some form of I/O disciplines that can be used to specify the kind of input and output data (bytes or characters). Until that happens, additional modules from CPAN will be needed to complete the toolkit for dealing with Unicode.

```
    NOTE: This should be considered an experimental feature.  Implementation
    details are subject to change.
```

92.2.4 Support for interpolating named characters

The new `\N` escape interpolates named characters within strings. For example, `"Hi!  \N{WHITE SMILING FACE}"` evaluates to a string with a unicode smiley face at the end.

92.2.5 "our" declarations

An "our" declaration introduces a value that can be best understood as a lexically scoped symbolic alias to a global variable in the package that was current where the variable was declared. This is mostly useful as an alternative to the `vars` pragma, but also provides the opportunity to introduce typing and other attributes for such variables. See our in *perlfunc*.

92.2.6 Support for strings represented as a vector of ordinals

Literals of the form `v1.2.3.4` are now parsed as a string composed of characters with the specified ordinals. This is an alternative, more readable way to construct (possibly unicode) strings instead of interpolating characters, as in `"\x{1}\x{2}\x{3}\x{4}"`. The leading `v` may be omitted if there are more than two ordinals, so `1.2.3` is parsed the same as `v1.2.3`.

Strings written in this form are also useful to represent version "numbers". It is easy to compare such version "numbers" (which are really just plain strings) using any of the usual string comparison operators `eq`, `ne`, `lt`, `gt`, etc., or perform bitwise string operations on them using |, &, etc.

In conjunction with the new `$^V` magic variable (which contains the perl version as a string), such literals can be used as a readable way to check if you're running a particular version of Perl:

```
    # this will parse in older versions of Perl also
    if ($^V and $^V gt v5.6.0) {
        # new features supported
    }
```

`require` and `use` also have some special magic to support such literals, but this particular usage should be avoided because it leads to misleading error messages under versions of Perl which don't support vector strings. Using a true version number will ensure correct behavior in all versions of Perl:

```
    require 5.006;    # run time check for v5.6
    use 5.006_001;    # compile time check for v5.6.1
```

Also, `sprintf` and `printf` support the Perl-specific format flag `%v` to print ordinals of characters in arbitrary strings:

```
    printf "v%vd", $^V;         # prints current version, such as "v5.5.650"
    printf "%*vX", ":", $addr;  # formats IPv6 address
    printf "%*vb", " ", $bits;  # displays bitstring
```

See Scalar value constructors in *perldata* for additional information.

92.2.7 Improved Perl version numbering system

Beginning with Perl version 5.6.0, the version number convention has been changed to a "dotted integer" scheme that is more commonly found in open source projects.

Maintenance versions of v5.6.0 will be released as v5.6.1, v5.6.2 etc. The next development series following v5.6.0 will be numbered v5.7.x, beginning with v5.7.0, and the next major production release following v5.6.0 will be v5.8.0.

The English module now sets $PERL_VERSION to $^V (a string value) rather than `$]` (a numeric value). (This is a potential incompatibility. Send us a report via perlbug if you are affected by this.)

The v1.2.3 syntax is also now legal in Perl. See Support for strings represented as a vector of ordinals for more on that.

To cope with the new versioning system's use of at least three significant digits for each version component, the method used for incrementing the subversion number has also changed slightly. We assume that versions older than v5.6.0 have been incrementing the subversion component in multiples of 10. Versions after v5.6.0 will increment them by 1. Thus, using the new notation, 5.005_03 is the "same" as v5.5.30, and the first maintenance version following v5.6.0 will be v5.6.1 (which should be read as being equivalent to a floating point value of 5.006_001 in the older format, stored in `$]`).

92.2.8 New syntax for declaring subroutine attributes

Formerly, if you wanted to mark a subroutine as being a method call or as requiring an automatic lock() when it is entered, you had to declare that with a `use attrs` pragma in the body of the subroutine. That can now be accomplished with declaration syntax, like this:

```
sub mymethod : locked method ;
...
sub mymethod : locked method {
    ...
}

sub othermethod :locked :method ;
...
sub othermethod :locked :method {
    ...
}
```

(Note how only the first `:` is mandatory, and whitespace surrounding the `:` is optional.)

AutoSplit.pm and *SelfLoader.pm* have been updated to keep the attributes with the stubs they provide. See *attributes*.

92.2.9 File and directory handles can be autovivified

Similar to how constructs such as `$x->[0]` autovivify a reference, handle constructors (open(), opendir(), pipe(), socketpair(), sysopen(), socket(), and accept()) now autovivify a file or directory handle if the handle passed to them is an uninitialized scalar variable. This allows the constructs such as `open(my $fh, ...)` and `open(local $fh,...)` to be used to create filehandles that will conveniently be closed automatically when the scope ends, provided there are no other references to them. This largely eliminates the need for typeglobs when opening filehandles that must be passed around, as in the following example:

```
sub myopen {
    open my $fh, "@_"
         or die "Can't open '@_': $!";
    return $fh;
}

{
    my $f = myopen("</etc/motd");
    print <$f>;
    # $f implicitly closed here
}
```

92.2.10 open() with more than two arguments

If open() is passed three arguments instead of two, the second argument is used as the mode and the third argument is taken to be the file name. This is primarily useful for protecting against unintended magic behavior of the traditional two-argument form. See open in *perlfunc*.

92.2.11 64-bit support

Any platform that has 64-bit integers either

```
        (1) natively as longs or ints
        (2) via special compiler flags
        (3) using long long or int64_t
```

is able to use "quads" (64-bit integers) as follows:

- constants (decimal, hexadecimal, octal, binary) in the code
- arguments to oct() and hex()
- arguments to print(), printf() and sprintf() (flag prefixes ll, L, q)
- printed as such
- pack() and unpack() "q" and "Q" formats
- in basic arithmetics: + - * / % (NOTE: operating close to the limits of the integer values may produce surprising results)
- in bit arithmetics: & | ˆ ˜ << >> (NOTE: these used to be forced to be 32 bits wide but now operate on the full native width.)
- vec()

Note that unless you have the case (a) you will have to configure and compile Perl using the -Duse64bitint Configure flag.

```
    NOTE: The Configure flags -Duselonglong and -Duse64bits have been
    deprecated.  Use -Duse64bitint instead.
```

There are actually two modes of 64-bitness: the first one is achieved using Configure -Duse64bitint and the second one using Configure -Duse64bitall. The difference is that the first one is minimal and the second one maximal. The first works in more places than the second.

The `use64bitint` does only as much as is required to get 64-bit integers into Perl (this may mean, for example, using "long longs") while your memory may still be limited to 2 gigabytes (because your pointers could still be 32-bit). Note that the name `64bitint` does not imply that your C compiler will be using 64-bit `int`s (it might, but it doesn't have to): the `use64bitint` means that you will be able to have 64 bits wide scalar values.

The `use64bitall` goes all the way by attempting to switch also integers (if it can), longs (and pointers) to being 64-bit. This may create an even more binary incompatible Perl than -Duse64bitint: the resulting executable may not run at all in a 32-bit box, or you may have to reboot/reconfigure/rebuild your operating system to be 64-bit aware.

Natively 64-bit systems like Alpha and Cray need neither -Duse64bitint nor -Duse64bitall.

Last but not least: note that due to Perl's habit of always using floating point numbers, the quads are still not true integers. When quads overflow their limits (0...18_446_744_073_709_551_615 unsigned, -9_223_372_036_854_775_808...9_223_372_036_854_775_807 signed), they are silently promoted to floating point numbers, after which they will start losing precision (in their lower digits).

```
    NOTE: 64-bit support is still experimental on most platforms.
    Existing support only covers the LP64 data model.  In particular, the
    LLP64 data model is not yet supported.  64-bit libraries and system
    APIs on many platforms have not stabilized--your mileage may vary.
```

92.2.12 Large file support

If you have filesystems that support "large files" (files larger than 2 gigabytes), you may now also be able to create and access them from Perl.

```
    NOTE: The default action is to enable large file support, if
    available on the platform.
```

If the large file support is on, and you have a Fcntl constant O_LARGEFILE, the O_LARGEFILE is automatically added to the flags of sysopen().

Beware that unless your filesystem also supports "sparse files" seeking to umpteen petabytes may be inadvisable.

Note that in addition to requiring a proper file system to do large files you may also need to adjust your per-process (or your per-system, or per-process-group, or per-user-group) maximum filesize limits before running Perl scripts that try to handle large files, especially if you intend to write such files.

Finally, in addition to your process/process group maximum filesize limits, you may have quota limits on your filesystems that stop you (your user id or your user group id) from using large files.

Adjusting your process/user/group/file system/operating system limits is outside the scope of Perl core language. For process limits, you may try increasing the limits using your shell's limits/limit/ulimit command before running Perl. The BSD::Resource extension (not included with the standard Perl distribution) may also be of use, it offers the getrlimit/setrlimit interface that can be used to adjust process resource usage limits, including the maximum filesize limit.

92.2.13 Long doubles

In some systems you may be able to use long doubles to enhance the range and precision of your double precision floating point numbers (that is, Perl's numbers). Use Configure -Duselongdouble to enable this support (if it is available).

92.2.14 "more bits"

You can "Configure -Dusemorebits" to turn on both the 64-bit support and the long double support.

92.2.15 Enhanced support for sort() subroutines

Perl subroutines with a prototype of `($$)`, and XSUBs in general, can now be used as sort subroutines. In either case, the two elements to be compared are passed as normal parameters in @_. See sort in *perlfunc*.

For unprototyped sort subroutines, the historical behavior of passing the elements to be compared as the global variables $a and $b remains unchanged.

92.2.16 `sort $coderef @foo` allowed

sort() did not accept a subroutine reference as the comparison function in earlier versions. This is now permitted.

92.2.17 File globbing implemented internally

Perl now uses the File::Glob implementation of the glob() operator automatically. This avoids using an external csh process and the problems associated with it.

```
    NOTE: This is currently an experimental feature.  Interfaces and
    implementation are subject to change.
```

92.2.18 Support for CHECK blocks

In addition to `BEGIN`, `INIT`, `END`, `DESTROY` and `AUTOLOAD`, subroutines named `CHECK` are now special. These are queued up during compilation and behave similar to END blocks, except they are called at the end of compilation rather than at the end of execution. They cannot be called directly.

92.2.19 POSIX character class syntax [: :] supported

For example to match alphabetic characters use /[[:alpha:]]/. See *perlre* for details.

92.2.20 Better pseudo-random number generator

In 5.005_0x and earlier, perl's rand() function used the C library rand(3) function. As of 5.005_52, Configure tests for drand48(), random(), and rand() (in that order) and picks the first one it finds.

These changes should result in better random numbers from rand().

92.2.21 Improved `qw//` operator

The `qw//` operator is now evaluated at compile time into a true list instead of being replaced with a run time call to `split()`. This removes the confusing misbehaviour of `qw//` in scalar context, which had inherited that behaviour from split().

Thus:

```
    $foo = ($bar) = qw(a b c); print "$foo|$bar\n";
```

now correctly prints "3|a", instead of "2|a".

92.2.22 Better worst-case behavior of hashes

Small changes in the hashing algorithm have been implemented in order to improve the distribution of lower order bits in the hashed value. This is expected to yield better performance on keys that are repeated sequences.

92.2.23 pack() format 'Z' supported

The new format type 'Z' is useful for packing and unpacking null-terminated strings. See pack in *perlfunc*.

92.2.24 pack() format modifier '!' supported

The new format type modifier '!' is useful for packing and unpacking native shorts, ints, and longs. See pack in *perlfunc*.

92.2.25 pack() and unpack() support counted strings

The template character '/' can be used to specify a counted string type to be packed or unpacked. See pack in *perlfunc*.

92.2.26 Comments in pack() templates

The '#' character in a template introduces a comment up to end of the line. This facilitates documentation of pack() templates.

92.2.27 Weak references

In previous versions of Perl, you couldn't cache objects so as to allow them to be deleted if the last reference from outside the cache is deleted. The reference in the cache would hold a reference count on the object and the objects would never be destroyed.

Another familiar problem is with circular references. When an object references itself, its reference count would never go down to zero, and it would not get destroyed until the program is about to exit.

Weak references solve this by allowing you to "weaken" any reference, that is, make it not count towards the reference count. When the last non-weak reference to an object is deleted, the object is destroyed and all the weak references to the object are automatically undef-ed.

To use this feature, you need the Devel::WeakRef package from CPAN, which contains additional documentation.

```
    NOTE: This is an experimental feature.  Details are subject to change.
```

92.2.28 Binary numbers supported

Binary numbers are now supported as literals, in s?printf formats, and `oct()`:

```
    $answer = 0b101010;
    printf "The answer is: %b\n", oct("0b101010");
```

92.2.29 Lvalue subroutines

Subroutines can now return modifiable lvalues. See Lvalue subroutines in *perlsub*.

```
    NOTE: This is an experimental feature.  Details are subject to change.
```

92.2.30 Some arrows may be omitted in calls through references

Perl now allows the arrow to be omitted in many constructs involving subroutine calls through references. For example, `$foo[10]->('foo')` may now be written `$foo[10]('foo')`. This is rather similar to how the arrow may be omitted from `$foo[10]->{'foo'}`. Note however, that the arrow is still required for `foo(10)->('bar')`.

92.2.31 Boolean assignment operators are legal lvalues

Constructs such as `($a ||= 2) += 1` are now allowed.

92.2.32 exists() is supported on subroutine names

The exists() builtin now works on subroutine names. A subroutine is considered to exist if it has been declared (even if implicitly). See exists in *perlfunc* for examples.

92.2.33 exists() and delete() are supported on array elements

The exists() and delete() builtins now work on simple arrays as well. The behavior is similar to that on hash elements.

exists() can be used to check whether an array element has been initialized. This avoids autovivifying array elements that don't exist. If the array is tied, the EXISTS() method in the corresponding tied package will be invoked.

delete() may be used to remove an element from the array and return it. The array element at that position returns to its uninitialized state, so that testing for the same element with exists() will return false. If the element happens to be the one at the end, the size of the array also shrinks up to the highest element that tests true for exists(), or 0 if none such is found. If the array is tied, the DELETE() method in the corresponding tied package will be invoked.

See exists in *perlfunc* and delete in *perlfunc* for examples.

92.2.34 Pseudo-hashes work better

Dereferencing some types of reference values in a pseudo-hash, such as `$ph->{foo}[1]`, was accidentally disallowed. This has been corrected.

When applied to a pseudo-hash element, exists() now reports whether the specified value exists, not merely if the key is valid.

delete() now works on pseudo-hashes. When given a pseudo-hash element or slice it deletes the values corresponding to the keys (but not the keys themselves). See Pseudo-hashes: Using an array as a hash in *perlref*.

Pseudo-hash slices with constant keys are now optimized to array lookups at compile-time.

List assignments to pseudo-hash slices are now supported.

The `fields` pragma now provides ways to create pseudo-hashes, via fields::new() and fields::phash(). See *fields*.

```
    NOTE: The pseudo-hash data type continues to be experimental.
    Limiting oneself to the interface elements provided by the
    fields pragma will provide protection from any future changes.
```

92.2.35 Automatic flushing of output buffers

fork(), exec(), system(), qx//, and pipe open()s now flush buffers of all files opened for output when the operation was attempted. This mostly eliminates confusing buffering mishaps suffered by users unaware of how Perl internally handles I/O.

This is not supported on some platforms like Solaris where a suitably correct implementation of fflush(NULL) isn't available.

92.2.36 Better diagnostics on meaningless filehandle operations

Constructs such as `open(<FH>)` and `close(<FH>)` are compile time errors. Attempting to read from filehandles that were opened only for writing will now produce warnings (just as writing to read-only filehandles does).

92.2.37 Where possible, buffered data discarded from duped input filehandle

`open(NEW, "<&OLD")` now attempts to discard any data that was previously read and buffered in `OLD` before duping the handle. On platforms where doing this is allowed, the next read operation on `NEW` will return the same data as the corresponding operation on `OLD`. Formerly, it would have returned the data from the start of the following disk block instead.

92.2.38 eof() has the same old magic as <>

`eof()` would return true if no attempt to read from <> had yet been made. `eof()` has been changed to have a little magic of its own, it now opens the <> files.

92.2.39 binmode() can be used to set :crlf and :raw modes

binmode() now accepts a second argument that specifies a discipline for the handle in question. The two pseudo-disciplines ":raw" and ":crlf" are currently supported on DOS-derivative platforms. See binmode in *perlfunc* and *open*.

92.2.40 `-T` filetest recognizes UTF-8 encoded files as "text"

The algorithm used for the `-T` filetest has been enhanced to correctly identify UTF-8 content as "text".

92.2.41 system(), backticks and pipe open now reflect exec() failure

On Unix and similar platforms, system(), qx() and open(FOO, "cmd |") etc., are implemented via fork() and exec(). When the underlying exec() fails, earlier versions did not report the error properly, since the exec() happened to be in a different process.

The child process now communicates with the parent about the error in launching the external command, which allows these constructs to return with their usual error value and set $!.

92.2.42 Improved diagnostics

Line numbers are no longer suppressed (under most likely circumstances) during the global destruction phase.

Diagnostics emitted from code running in threads other than the main thread are now accompanied by the thread ID.

Embedded null characters in diagnostics now actually show up. They used to truncate the message in prior versions.

$foo::a and $foo::b are now exempt from "possible typo" warnings only if sort() is encountered in package `foo`.

Unrecognized alphabetic escapes encountered when parsing quote constructs now generate a warning, since they may take on new semantics in later versions of Perl.

Many diagnostics now report the internal operation in which the warning was provoked, like so:

```
    Use of uninitialized value in concatenation (.) at (eval 1) line 1.
    Use of uninitialized value in print at (eval 1) line 1.
```

Diagnostics that occur within eval may also report the file and line number where the eval is located, in addition to the eval sequence number and the line number within the evaluated text itself. For example:

```
    Not enough arguments for scalar at (eval 4)[newlib/perl5db.pl:1411] line 2, at EOF
```

92.2.43 Diagnostics follow STDERR

Diagnostic output now goes to whichever file the `STDERR` handle is pointing at, instead of always going to the underlying C runtime library's `stderr`.

92.2.44 More consistent close-on-exec behavior

On systems that support a close-on-exec flag on filehandles, the flag is now set for any handles created by pipe(), socketpair(), socket(), and accept(), if that is warranted by the value of $^F that may be in effect. Earlier versions neglected to set the flag for handles created with these operators. See pipe in *perlfunc*, socketpair in *perlfunc*, socket in *perlfunc*, accept in *perlfunc*, and $^F in *perlvar*.

92.2.45 syswrite() ease-of-use

The length argument of `syswrite()` has become optional.

92.2.46 Better syntax checks on parenthesized unary operators

Expressions such as:

```
    print defined(&foo,&bar,&baz);
    print uc("foo","bar","baz");
    undef($foo,&bar);
```

used to be accidentally allowed in earlier versions, and produced unpredictable behaviour. Some produced ancillary warnings when used in this way; others silently did the wrong thing.

The parenthesized forms of most unary operators that expect a single argument now ensure that they are not called with more than one argument, making the cases shown above syntax errors. The usual behaviour of:

```
    print defined &foo, &bar, &baz;
    print uc "foo", "bar", "baz";
    undef $foo, &bar;
```

remains unchanged. See *perlop*.

92.2.47 Bit operators support full native integer width

The bit operators (& | ˆ ˜ << >>) now operate on the full native integral width (the exact size of which is available in $Config{ivsize}). For example, if your platform is either natively 64-bit or if Perl has been configured to use 64-bit integers, these operations apply to 8 bytes (as opposed to 4 bytes on 32-bit platforms). For portability, be sure to mask off the excess bits in the result of unary ˜, e.g., `˜$x & 0xffffffff`.

92.2.48 Improved security features

More potentially unsafe operations taint their results for improved security.

The `passwd` and `shell` fields returned by the getpwent(), getpwnam(), and getpwuid() are now tainted, because the user can affect their own encrypted password and login shell.

The variable modified by shmread(), and messages returned by msgrcv() (and its object-oriented interface IPC::SysV::Msg::rcv) are also tainted, because other untrusted processes can modify messages and shared memory segments for their own nefarious purposes.

92.2.49 More functional bareword prototype (*)

Bareword prototypes have been rationalized to enable them to be used to override builtins that accept barewords and interpret them in a special way, such as `require` or `do`.

Arguments prototyped as * will now be visible within the subroutine as either a simple scalar or as a reference to a typeglob. See Prototypes in *perlsub*.

92.2.50 `require` and do may be overridden

`require` and `do 'file'` operations may be overridden locally by importing subroutines of the same name into the current package (or globally by importing them into the CORE::GLOBAL:: namespace). Overriding `require` will also affect `use`, provided the override is visible at compile-time. See Overriding Built-in Functions in *perlsub*.

92.2.51 $ ˆX variables may now have names longer than one character

Formerly, $ˆX was synonymous with ${"\cX"}, but $ˆXY was a syntax error. Now variable names that begin with a control character may be arbitrarily long. However, for compatibility reasons, these variables *must* be written with explicit braces, as `${ˆXY}` for example. `${ˆXYZ}` is synonymous with ${"\cXYZ"}. Variable names with more than one control character, such as `${ˆXYˆZ}`, are illegal.

The old syntax has not changed. As before, 'ˆX' may be either a literal control-X character or the two-character sequence 'caret' plus 'X'. When braces are omitted, the variable name stops after the control character. Thus `"$ˆXYZ"` continues to be synonymous with `$ˆX . "YZ"` as before.

As before, lexical variables may not have names beginning with control characters. As before, variables whose names begin with a control character are always forced to be in package 'main'. All such variables are reserved for future extensions, except those that begin with `ˆ_`, which may be used by user programs and are guaranteed not to acquire special meaning in any future version of Perl.

92.2.52 New variable $ ˆC reflects `-c` switch

`$^C` has a boolean value that reflects whether perl is being run in compile-only mode (i.e. via the `-c` switch). Since BEGIN blocks are executed under such conditions, this variable enables perl code to determine whether actions that make sense only during normal running are warranted. See *perlvar*.

92.2.53 New variable $ ˆV contains Perl version as a string

`$^V` contains the Perl version number as a string composed of characters whose ordinals match the version numbers, i.e. v5.6.0. This may be used in string comparisons.

See `Support for strings represented as a vector of ordinals` for an example.

92.2.54 Optional Y2K warnings

If Perl is built with the cpp macro `PERL_Y2KWARN` defined, it emits optional warnings when concatenating the number 19 with another number.

This behavior must be specifically enabled when running Configure. See *INSTALL* and *README.Y2K*.

92.2.55 Arrays now always interpolate into double-quoted strings

In double-quoted strings, arrays now interpolate, no matter what. The behavior in earlier versions of perl 5 was that arrays would interpolate into strings if the array had been mentioned before the string was compiled, and otherwise Perl would raise a fatal compile-time error. In versions 5.000 through 5.003, the error was

```
        Literal @example now requires backslash
```

In versions 5.004_01 through 5.6.0, the error was

```
        In string, @example now must be written as \@example
```

The idea here was to get people into the habit of writing `"fred\@example.com"` when they wanted a literal `@` sign, just as they have always written `"Give me back my \$5"` when they wanted a literal `$` sign.

Starting with 5.6.1, when Perl now sees an `@` sign in a double-quoted string, it *always* attempts to interpolate an array, regardless of whether or not the array has been used or declared already. The fatal error has been downgraded to an optional warning:

```
        Possible unintended interpolation of @example in string
```

This warns you that `"fred@example.com"` is going to turn into `fred.com` if you don't backslash the `@`. See http://www.plover.com/˜mjd/perl/at-error.html for more details about the history here.

92.3 Modules and Pragmata

92.3.1 Modules

attributes

While used internally by Perl as a pragma, this module also provides a way to fetch subroutine and variable attributes. See *attributes*.

B

The Perl Compiler suite has been extensively reworked for this release. More of the standard Perl testsuite passes when run under the Compiler, but there is still a significant way to go to achieve production quality compiled executables.

```
    NOTE: The Compiler suite remains highly experimental.  The
    generated code may not be correct, even when it manages to execute
    without errors.
```

Benchmark

Overall, Benchmark results exhibit lower average error and better timing accuracy.

You can now run tests for *n* seconds instead of guessing the right number of tests to run: e.g., timethese(-5, ...) will run each code for at least 5 CPU seconds. Zero as the "number of repetitions" means "for at least 3 CPU seconds". The output format has also changed. For example:

```
   use Benchmark;$x=3;timethese(-5,{a=>sub{$x*$x},b=>sub{$x**2}})
```

will now output something like this:

```
   Benchmark: running a, b, each for at least 5 CPU seconds...
            a:  5 wallclock secs ( 5.77 usr +  0.00 sys =  5.77 CPU) @ 200551.91/s (n=1156516)
            b:  4 wallclock secs ( 5.00 usr +  0.02 sys =  5.02 CPU) @ 159605.18/s (n=800686)
```

New features: "each for at least N CPU seconds...", "wallclock secs", and the "@ operations/CPU second (n=operations)".

timethese() now returns a reference to a hash of Benchmark objects containing the test results, keyed on the names of the tests.

timethis() now returns the iterations field in the Benchmark result object instead of 0.

timethese(), timethis(), and the new cmpthese() (see below) can also take a format specifier of 'none' to suppress output.

A new function countit() is just like timeit() except that it takes a TIME instead of a COUNT.

A new function cmpthese() prints a chart comparing the results of each test returned from a timethese() call. For each possible pair of tests, the percentage speed difference (iters/sec or seconds/iter) is shown.

For other details, see *Benchmark*.

ByteLoader

The ByteLoader is a dedicated extension to generate and run Perl bytecode. See *ByteLoader*.

constant

References can now be used.

The new version also allows a leading underscore in constant names, but disallows a double leading underscore (as in "__LINE__"). Some other names are disallowed or warned against, including BEGIN, END, etc. Some names which were forced into main:: used to fail silently in some cases; now they're fatal (outside of main::) and an optional warning (inside of main::). The ability to detect whether a constant had been set with a given name has been added.

See *constant*.

charnames

This pragma implements the `\N` string escape. See *charnames*.

Data::Dumper

A `Maxdepth` setting can be specified to avoid venturing too deeply into deep data structures. See *Data::Dumper*.

The XSUB implementation of Dump() is now automatically called if the `Useqq` setting is not in use.

Dumping `qr//` objects works correctly.

DB

`DB` is an experimental module that exposes a clean abstraction to Perl's debugging API.

DB_File

DB_File can now be built with Berkeley DB versions 1, 2 or 3. See `ext/DB_File/Changes`.

Devel::DProf

Devel::DProf, a Perl source code profiler has been added. See *Devel::DProf* and *dprofpp*.

Devel::Peek

The Devel::Peek module provides access to the internal representation of Perl variables and data. It is a data debugging tool for the XS programmer.

Dumpvalue

The Dumpvalue module provides screen dumps of Perl data.

DynaLoader

DynaLoader now supports a dl_unload_file() function on platforms that support unloading shared objects using dlclose().

Perl can also optionally arrange to unload all extension shared objects loaded by Perl. To enable this, build Perl with the Configure option `-Accflags=-DDL_UNLOAD_ALL_AT_EXIT`. (This maybe useful if you are using Apache with mod_perl.)

English

$PERL_VERSION now stands for `$^V` (a string value) rather than for `$]` (a numeric value).

Env

Env now supports accessing environment variables like PATH as array variables.

Fcntl

More Fcntl constants added: F_SETLK64, F_SETLKW64, O_LARGEFILE for large file (more than 4GB) access (NOTE: the O_LARGEFILE is automatically added to sysopen() flags if large file support has been configured, as is the default), Free/Net/OpenBSD locking behaviour flags F_FLOCK, F_POSIX, Linux F_SHLCK, and O_ACCMODE: the combined mask of O_RDONLY, O_WRONLY, and O_RDWR. The seek()/sysseek() constants SEEK_SET, SEEK_CUR, and SEEK_END are available via the `:seek` tag. The chmod()/stat() S_IF* constants and S_IS* functions are available via the `:mode` tag.

File::Compare

A compare_text() function has been added, which allows custom comparison functions. See *File::Compare*.

File::Find

File::Find now works correctly when the wanted() function is either autoloaded or is a symbolic reference.

A bug that caused File::Find to lose track of the working directory when pruning top-level directories has been fixed.

File::Find now also supports several other options to control its behavior. It can follow symbolic links if the `follow` option is specified. Enabling the `no_chdir` option will make File::Find skip changing the current directory when walking directories. The `untaint` flag can be useful when running with taint checks enabled.

See *File::Find*.

File::Glob

This extension implements BSD-style file globbing. By default, it will also be used for the internal implementation of the glob() operator. See *File::Glob*.

File::Spec

New methods have been added to the File::Spec module: devnull() returns the name of the null device (/dev/null on Unix) and tmpdir() the name of the temp directory (normally /tmp on Unix). There are now also methods to convert between absolute and relative filenames: abs2rel() and rel2abs(). For compatibility with operating systems that specify volume names in file paths, the splitpath(), splitdir(), and catdir() methods have been added.

File::Spec::Functions

The new File::Spec::Functions modules provides a function interface to the File::Spec module. Allows shorthand

```
    $fullname = catfile($dir1, $dir2, $file);
```

instead of

```
    $fullname = File::Spec->catfile($dir1, $dir2, $file);
```

Getopt::Long

Getopt::Long licensing has changed to allow the Perl Artistic License as well as the GPL. It used to be GPL only, which got in the way of non-GPL applications that wanted to use Getopt::Long.

Getopt::Long encourages the use of Pod::Usage to produce help messages. For example:

```
    use Getopt::Long;
    use Pod::Usage;
    my $man = 0;
    my $help = 0;
    GetOptions('help|?' => \$help, man => \$man) or pod2usage(2);
    pod2usage(1) if $help;
    pod2usage(-exitstatus => 0, -verbose => 2) if $man;

    __END__

    =head1 NAME

    sample - Using Getopt::Long and Pod::Usage

    =head1 SYNOPSIS

    sample [options] [file ...]

     Options:
       -help            brief help message
       -man             full documentation

    =head1 OPTIONS

    =over 8

    =item B<-help>

    Print a brief help message and exits.

    =item B<-man>

    Prints the manual page and exits.

    =back

    =head1 DESCRIPTION
    B<This program> will read the given input file(s) and do something
    useful with the contents thereof.

    =cut
```

See *Pod::Usage* for details.

A bug that prevented the non-option call-back <> from being specified as the first argument has been fixed.

To specify the characters < and > as option starters, use ><. Note, however, that changing option starters is strongly deprecated.

IO

write() and syswrite() will now accept a single-argument form of the call, for consistency with Perl's syswrite().

You can now create a TCP-based IO::Socket::INET without forcing a connect attempt. This allows you to configure its options (like making it non-blocking) and then call connect() manually.

A bug that prevented the IO::Socket::protocol() accessor from ever returning the correct value has been corrected.

IO::Socket::connect now uses non-blocking IO instead of alarm() to do connect timeouts.

IO::Socket::accept now uses select() instead of alarm() for doing timeouts.

IO::Socket::INET->new now sets $! correctly on failure. $@ is still set for backwards compatibility.

JPL

Java Perl Lingo is now distributed with Perl. See jpl/README for more information.

lib

`use lib` now weeds out any trailing duplicate entries. `no lib` removes all named entries.

Math::BigInt

The bitwise operations <<, >>, &, |, and ˜ are now supported on bigints.

Math::Complex

The accessor methods Re, Im, arg, abs, rho, and theta can now also act as mutators (accessor $z->Re(), mutator $z->Re(3)).

The class method `display_format` and the corresponding object method `display_format`, in addition to accepting just one argument, now can also accept a parameter hash. Recognized keys of a parameter hash are `"style"`, which corresponds to the old one parameter case, and two new parameters: `"format"`, which is a printf()-style format string (defaults usually to `"%.15g"`, you can revert to the default by setting the format string to `undef`) used for both parts of a complex number, and `"polar_pretty_print"` (defaults to true), which controls whether an attempt is made to try to recognize small multiples and rationals of pi (2pi, pi/2) at the argument (angle) of a polar complex number.

The potentially disruptive change is that in list context both methods now *return the parameter hash*, instead of only the value of the `"style"` parameter.

Math::Trig

A little bit of radial trigonometry (cylindrical and spherical), radial coordinate conversions, and the great circle distance were added.

Pod::Parser, Pod::InputObjects

Pod::Parser is a base class for parsing and selecting sections of pod documentation from an input stream. This module takes care of identifying pod paragraphs and commands in the input and hands off the parsed paragraphs and commands to user-defined methods which are free to interpret or translate them as they see fit.

Pod::InputObjects defines some input objects needed by Pod::Parser, and for advanced users of Pod::Parser that need more about a command besides its name and text.

As of release 5.6.0 of Perl, Pod::Parser is now the officially sanctioned "base parser code" recommended for use by all pod2xxx translators. Pod::Text (pod2text) and Pod::Man (pod2man) have already been converted to use

Pod::Parser and efforts to convert Pod::HTML (pod2html) are already underway. For any questions or comments about pod parsing and translating issues and utilities, please use the pod-people@perl.org mailing list.

For further information, please see *Pod::Parser* and *Pod::InputObjects*.

Pod::Checker, podchecker

This utility checks pod files for correct syntax, according to *perlpod*. Obvious errors are flagged as such, while warnings are printed for mistakes that can be handled gracefully. The checklist is not complete yet. See *Pod::Checker*.

Pod::ParseUtils, Pod::Find

These modules provide a set of gizmos that are useful mainly for pod translators. Pod::Find traverses directory structures and returns found pod files, along with their canonical names (like `File::Spec::Unix`). Pod::ParseUtils contains **Pod::List** (useful for storing pod list information), **Pod::Hyperlink** (for parsing the contents of `L<>` sequences) and **Pod::Cache** (for caching information about pod files, e.g., link nodes).

Pod::Select, podselect

Pod::Select is a subclass of Pod::Parser which provides a function named "podselect()" to filter out user-specified sections of raw pod documentation from an input stream. podselect is a script that provides access to Pod::Select from other scripts to be used as a filter. See *Pod::Select*.

Pod::Usage, pod2usage

Pod::Usage provides the function "pod2usage()" to print usage messages for a Perl script based on its embedded pod documentation. The pod2usage() function is generally useful to all script authors since it lets them write and maintain a single source (the pods) for documentation, thus removing the need to create and maintain redundant usage message text consisting of information already in the pods.

There is also a pod2usage script which can be used from other kinds of scripts to print usage messages from pods (even for non-Perl scripts with pods embedded in comments).

For details and examples, please see *Pod::Usage*.

Pod::Text and Pod::Man

Pod::Text has been rewritten to use Pod::Parser. While pod2text() is still available for backwards compatibility, the module now has a new preferred interface. See *Pod::Text* for the details. The new Pod::Text module is easily subclassed for tweaks to the output, and two such subclasses (Pod::Text::Termcap for man-page-style bold and underlining using termcap information, and Pod::Text::Color for markup with ANSI color sequences) are now standard.

pod2man has been turned into a module, Pod::Man, which also uses Pod::Parser. In the process, several outstanding bugs related to quotes in section headers, quoting of code escapes, and nested lists have been fixed. pod2man is now a wrapper script around this module.

SDBM_File

An EXISTS method has been added to this module (and sdbm_exists() has been added to the underlying sdbm library), so one can now call exists on an SDBM_File tied hash and get the correct result, rather than a runtime error.

A bug that may have caused data loss when more than one disk block happens to be read from the database in a single FETCH() has been fixed.

Sys::Syslog

Sys::Syslog now uses XSUBs to access facilities from syslog.h so it no longer requires syslog.ph to exist.

Sys::Hostname

Sys::Hostname now uses XSUBs to call the C library's gethostname() or uname() if they exist.

Term::ANSIColor

Term::ANSIColor is a very simple module to provide easy and readable access to the ANSI color and highlighting escape sequences, supported by most ANSI terminal emulators. It is now included standard.

Time::Local

The timelocal() and timegm() functions used to silently return bogus results when the date fell outside the machine's integer range. They now consistently croak() if the date falls in an unsupported range.

Win32

The error return value in list context has been changed for all functions that return a list of values. Previously these functions returned a list with a single element `undef` if an error occurred. Now these functions return the empty list in these situations. This applies to the following functions:

```
Win32::FsType
Win32::GetOSVersion
```

The remaining functions are unchanged and continue to return `undef` on error even in list context.

The Win32::SetLastError(ERROR) function has been added as a complement to the Win32::GetLastError() function.

The new Win32::GetFullPathName(FILENAME) returns the full absolute pathname for FILENAME in scalar context. In list context it returns a two-element list containing the fully qualified directory name and the filename. See *Win32*.

XSLoader

The XSLoader extension is a simpler alternative to DynaLoader. See *XSLoader*.

DBM Filters

A new feature called "DBM Filters" has been added to all the DBM modules–DB_File, GDBM_File, NDBM_File, ODBM_File, and SDBM_File. DBM Filters add four new methods to each DBM module:

```
filter_store_key
filter_store_value
filter_fetch_key
filter_fetch_value
```

These can be used to filter key-value pairs before the pairs are written to the database or just after they are read from the database. See *perldbmfilter* for further information.

92.3.2 Pragmata

`use attrs` is now obsolete, and is only provided for backward-compatibility. It's been replaced by the `sub : attributes` syntax. See Subroutine Attributes in *perlsub* and *attributes*.

Lexical warnings pragma, `use warnings;`, to control optional warnings. See *perllexwarn*.

`use filetest` to control the behaviour of filetests (`-r` `-w` ...). Currently only one subpragma implemented, "use filetest 'access';", that uses access(2) or equivalent to check permissions instead of using stat(2) as usual. This matters in filesystems where there are ACLs (access control lists): the stat(2) might lie, but access(2) knows better.

The `open` pragma can be used to specify default disciplines for handle constructors (e.g. open()) and for qx//. The two pseudo-disciplines `:raw` and `:crlf` are currently supported on DOS-derivative platforms (i.e. where binmode is not a no-op). See also §92.2.39.

92.4 Utility Changes

92.4.1 dprofpp

`dprofpp` is used to display profile data generated using `Devel::DProf`. See *dprofpp*.

92.4.2 find2perl

The `find2perl` utility now uses the enhanced features of the File::Find module. The -depth and -follow options are supported. Pod documentation is also included in the script.

92.4.3 h2xs

The `h2xs` tool can now work in conjunction with `C::Scan` (available from CPAN) to automatically parse real-life header files. The `-M`, `-a`, `-k`, and `-o` options are new.

92.4.4 perlcc

`perlcc` now supports the C and Bytecode backends. By default, it generates output from the simple C backend rather than the optimized C backend.

Support for non-Unix platforms has been improved.

92.4.5 perldoc

`perldoc` has been reworked to avoid possible security holes. It will not by default let itself be run as the superuser, but you may still use the **-U** switch to try to make it drop privileges first.

92.4.6 The Perl Debugger

Many bug fixes and enhancements were added to *perl5db.pl*, the Perl debugger. The help documentation was rearranged. New commands include `< ?`, `> ?`, and `{ ?` to list out current actions, `man` *`docpage`* to run your doc viewer on some perl docset, and support for quoted options. The help information was rearranged, and should be viewable once again if you're using **less** as your pager. A serious security hole was plugged–you should immediately remove all older versions of the Perl debugger as installed in previous releases, all the way back to perl3, from your system to avoid being bitten by this.

92.5 Improved Documentation

Many of the platform-specific README files are now part of the perl installation. See *perl* for the complete list.

perlapi.pod

The official list of public Perl API functions.

perlboot.pod

A tutorial for beginners on object-oriented Perl.

perlcompile.pod

An introduction to using the Perl Compiler suite.

perldbmfilter.pod

A howto document on using the DBM filter facility.

perldebug.pod

All material unrelated to running the Perl debugger, plus all low-level guts-like details that risked crushing the casual user of the debugger, have been relocated from the old manpage to the next entry below.

perldebguts.pod

This new manpage contains excessively low-level material not related to the Perl debugger, but slightly related to debugging Perl itself. It also contains some arcane internal details of how the debugging process works that may only be of interest to developers of Perl debuggers.

perlfork.pod

Notes on the fork() emulation currently available for the Windows platform.

perlfilter.pod

An introduction to writing Perl source filters.

perlhack.pod

Some guidelines for hacking the Perl source code.

perlintern.pod

A list of internal functions in the Perl source code. (List is currently empty.)

perllexwarn.pod

Introduction and reference information about lexically scoped warning categories.

perlnumber.pod

Detailed information about numbers as they are represented in Perl.

perlopentut.pod

A tutorial on using open() effectively.

perlreftut.pod

A tutorial that introduces the essentials of references.

perltootc.pod

A tutorial on managing class data for object modules.

perltodo.pod

Discussion of the most often wanted features that may someday be supported in Perl.

perlunicode.pod

An introduction to Unicode support features in Perl.

92.6 Performance enhancements

92.6.1 Simple sort() using { $ a <=> $ b } and the like are optimized

Many common sort() operations using a simple inlined block are now optimized for faster performance.

92.6.2 Optimized assignments to lexical variables

Certain operations in the RHS of assignment statements have been optimized to directly set the lexical variable on the LHS, eliminating redundant copying overheads.

92.6.3 Faster subroutine calls

Minor changes in how subroutine calls are handled internally provide marginal improvements in performance.

92.6.4 delete(), each(), values() and hash iteration are faster

The hash values returned by delete(), each(), values() and hashes in a list context are the actual values in the hash, instead of copies. This results in significantly better performance, because it eliminates needless copying in most situations.

92.7 Installation and Configuration Improvements

92.7.1 -Dusethreads means something different

The -Dusethreads flag now enables the experimental interpreter-based thread support by default. To get the flavor of experimental threads that was in 5.005 instead, you need to run Configure with "-Dusethreads -Duse5005threads".

As of v5.6.0, interpreter-threads support is still lacking a way to create new threads from Perl (i.e., `use Thread;` will not work with interpreter threads). `use Thread;` continues to be available when you specify the -Duse5005threads option to Configure, bugs and all.

```
    NOTE: Support for threads continues to be an experimental feature.
    Interfaces and implementation are subject to sudden and drastic changes.
```

92.7.2 New Configure flags

The following new flags may be enabled on the Configure command line by running Configure with `-Dflag`.

```
    usemultiplicity
    usethreads useithreads      (new interpreter threads: no Perl API yet)
    usethreads use5005threads   (threads as they were in 5.005)

    use64bitint                 (equal to now deprecated 'use64bits')
    use64bitall

    uselongdouble
    usemorebits
    uselargefiles
    usesocks                    (only SOCKS v5 supported)
```

92.7.3 Threadedness and 64-bitness now more daring

The Configure options enabling the use of threads and the use of 64-bitness are now more daring in the sense that they no more have an explicit list of operating systems of known threads/64-bit capabilities. In other words: if your operating system has the necessary APIs and datatypes, you should be able just to go ahead and use them, for threads by Configure -Dusethreads, and for 64 bits either explicitly by Configure -Duse64bitint or implicitly if your system has 64-bit wide datatypes. See also §92.2.11.

92.7.4 Long Doubles

Some platforms have "long doubles", floating point numbers of even larger range than ordinary "doubles". To enable using long doubles for Perl's scalars, use -Duselongdouble.

92.7.5 -Dusemorebits

You can enable both -Duse64bitint and -Duselongdouble with -Dusemorebits. See also §92.2.11.

92.7.6 -Duselargefiles

Some platforms support system APIs that are capable of handling large files (typically, files larger than two gigabytes). Perl will try to use these APIs if you ask for -Duselargefiles.

See §92.2.12 for more information.

92.7.7 installusrbinperl

You can use "Configure -Uinstallusrbinperl" which causes installperl to skip installing perl also as /usr/bin/perl. This is useful if you prefer not to modify /usr/bin for some reason or another but harmful because many scripts assume to find Perl in /usr/bin/perl.

92.7.8 SOCKS support

You can use "Configure -Dusesocks" which causes Perl to probe for the SOCKS proxy protocol library (v5, not v4). For more information on SOCKS, see:

```
    http://www.socks.nec.com/
```

92.7.9 `-A` flag

You can "post-edit" the Configure variables using the Configure `-A` switch. The editing happens immediately after the platform specific hints files have been processed but before the actual configuration process starts. Run `Configure -h` to find out the full `-A` syntax.

92.7.10 Enhanced Installation Directories

The installation structure has been enriched to improve the support for maintaining multiple versions of perl, to provide locations for vendor-supplied modules, scripts, and manpages, and to ease maintenance of locally-added modules, scripts, and manpages. See the section on Installation Directories in the INSTALL file for complete details. For most users building and installing from source, the defaults should be fine.

If you previously used `Configure -Dsitelib` or `-Dsitearch` to set special values for library directories, you might wish to consider using the new `-Dsiteprefix` setting instead. Also, if you wish to re-use a config.sh file from an earlier version of perl, you should be sure to check that Configure makes sensible choices for the new directories. See INSTALL for complete details.

92.8 Platform specific changes

92.8.1 Supported platforms

- The Mach CThreads (NEXTSTEP, OPENSTEP) are now supported by the Thread extension.
- GNU/Hurd is now supported.
- Rhapsody/Darwin is now supported.
- EPOC is now supported (on Psion 5).
- The cygwin port (formerly cygwin32) has been greatly improved.

92.8.2 DOS

- Perl now works with djgpp 2.02 (and 2.03 alpha).
- Environment variable names are not converted to uppercase any more.
- Incorrect exit codes from backticks have been fixed.
- This port continues to use its own builtin globbing (not File::Glob).

92.8.3 OS390 (OpenEdition MVS)

Support for this EBCDIC platform has not been renewed in this release. There are difficulties in reconciling Perl's standardization on UTF-8 as its internal representation for characters with the EBCDIC character set, because the two are incompatible.

It is unclear whether future versions will renew support for this platform, but the possibility exists.

92.8.4 VMS

Numerous revisions and extensions to configuration, build, testing, and installation process to accommodate core changes and VMS-specific options.

Expand %ENV-handling code to allow runtime mapping to logical names, CLI symbols, and CRTL environ array.

Extension of subprocess invocation code to accept filespecs as command "verbs".

Add to Perl command line processing the ability to use default file types and to recognize Unix-style `2>&1`.

Expansion of File::Spec::VMS routines, and integration into ExtUtils::MM_VMS.

Extension of ExtUtils::MM_VMS to handle complex extensions more flexibly.

Barewords at start of Unix-syntax paths may be treated as text rather than only as logical names.

Optional secure translation of several logical names used internally by Perl.

Miscellaneous bugfixing and porting of new core code to VMS.

Thanks are gladly extended to the many people who have contributed VMS patches, testing, and ideas.

92.8.5 Win32

Perl can now emulate fork() internally, using multiple interpreters running in different concurrent threads. This support must be enabled at build time. See *perlfork* for detailed information.

When given a pathname that consists only of a drivename, such as `A:`, opendir() and stat() now use the current working directory for the drive rather than the drive root.

The builtin XSUB functions in the Win32:: namespace are documented. See *Win32*.

$^X now contains the full path name of the running executable.

A Win32::GetLongPathName() function is provided to complement Win32::GetFullPathName() and Win32::GetShortPathName(). See *Win32*.

POSIX::uname() is supported.

system(1,...) now returns true process IDs rather than process handles. kill() accepts any real process id, rather than strictly return values from system(1,...).

For better compatibility with Unix, `kill(0, $pid)` can now be used to test whether a process exists.

The `Shell` module is supported.

Better support for building Perl under command.com in Windows 95 has been added.

Scripts are read in binary mode by default to allow ByteLoader (and the filter mechanism in general) to work properly. For compatibility, the DATA filehandle will be set to text mode if a carriage return is detected at the end of the line containing the __END__ or __DATA__ token; if not, the DATA filehandle will be left open in binary mode. Earlier versions always opened the DATA filehandle in text mode.

The glob() operator is implemented via the `File::Glob` extension, which supports glob syntax of the C shell. This increases the flexibility of the glob() operator, but there may be compatibility issues for programs that relied on the older globbing syntax. If you want to preserve compatibility with the older syntax, you might want to run perl with `-MFile::DosGlob`. For details and compatibility information, see *File::Glob*.

92.9 Significant bug fixes

92.9.1 <HANDLE> on empty files

With `$/` set to `undef`, "slurping" an empty file returns a string of zero length (instead of `undef`, as it used to) the first time the HANDLE is read after `$/` is set to `undef`. Further reads yield `undef`.

This means that the following will append "foo" to an empty file (it used to do nothing):

```
    perl -0777 -pi -e 's/^/foo/' empty_file
```

The behaviour of:

```
    perl -pi -e 's/^/foo/' empty_file
```

is unchanged (it continues to leave the file empty).

92.9.2 `eval '...'` improvements

Line numbers (as reflected by caller() and most diagnostics) within `eval '...'` were often incorrect where here documents were involved. This has been corrected.

Lexical lookups for variables appearing in `eval '...'` within functions that were themselves called within an `eval '...'` were searching the wrong place for lexicals. The lexical search now correctly ends at the subroutine's block boundary.

The use of `return` within `eval {...}` caused $@ not to be reset correctly when no exception occurred within the eval. This has been fixed.

Parsing of here documents used to be flawed when they appeared as the replacement expression in `eval 's/.../.../e'`. This has been fixed.

92.9.3 All compilation errors are true errors

Some "errors" encountered at compile time were by necessity generated as warnings followed by eventual termination of the program. This enabled more such errors to be reported in a single run, rather than causing a hard stop at the first error that was encountered.

The mechanism for reporting such errors has been reimplemented to queue compile-time errors and report them at the end of the compilation as true errors rather than as warnings. This fixes cases where error messages leaked through in the form of warnings when code was compiled at run time using `eval STRING`, and also allows such errors to be reliably trapped using `eval "..."`.

92.9.4 Implicitly closed filehandles are safer

Sometimes implicitly closed filehandles (as when they are localized, and Perl automatically closes them on exiting the scope) could inadvertently set $? or $!. This has been corrected.

92.9.5 Behavior of list slices is more consistent

When taking a slice of a literal list (as opposed to a slice of an array or hash), Perl used to return an empty list if the result happened to be composed of all undef values.

The new behavior is to produce an empty list if (and only if) the original list was empty. Consider the following example:

```
    @a = (1,undef,undef,2)[2,1,2];
```

The old behavior would have resulted in @a having no elements. The new behavior ensures it has three undefined elements.

Note in particular that the behavior of slices of the following cases remains unchanged:

```
    @a = ()[1,2];
    @a = (getpwent)[7,0];
    @a = (anything_returning_empty_list())[2,1,2];
    @a = @b[2,1,2];
    @a = @c{'a','b','c'};
```

See *perldata*.

92.9.6 `(\$)` prototype and `$foo{a}`

A scalar reference prototype now correctly allows a hash or array element in that slot.

92.9.7 `goto &sub` and AUTOLOAD

The `goto &sub` construct works correctly when `&sub` happens to be autoloaded.

92.9.8 `-bareword` allowed under `use integer`

The autoquoting of barewords preceded by `-` did not work in prior versions when the `integer` pragma was enabled. This has been fixed.

92.9.9 Failures in DESTROY()

When code in a destructor threw an exception, it went unnoticed in earlier versions of Perl, unless someone happened to be looking in $@ just after the point the destructor happened to run. Such failures are now visible as warnings when warnings are enabled.

92.9.10 Locale bugs fixed

printf() and sprintf() previously reset the numeric locale back to the default "C" locale. This has been fixed.

Numbers formatted according to the local numeric locale (such as using a decimal comma instead of a decimal dot) caused "isn't numeric" warnings, even while the operations accessing those numbers produced correct results. These warnings have been discontinued.

92.9.11 Memory leaks

The `eval 'return sub {...}'` construct could sometimes leak memory. This has been fixed.

Operations that aren't filehandle constructors used to leak memory when used on invalid filehandles. This has been fixed.

Constructs that modified `@_` could fail to deallocate values in `@_` and thus leak memory. This has been corrected.

92.9.12 Spurious subroutine stubs after failed subroutine calls

Perl could sometimes create empty subroutine stubs when a subroutine was not found in the package. Such cases stopped later method lookups from progressing into base packages. This has been corrected.

92.9.13 Taint failures under `-U`

When running in unsafe mode, taint violations could sometimes cause silent failures. This has been fixed.

92.9.14 END blocks and the `-c` switch

Prior versions used to run BEGIN **and** END blocks when Perl was run in compile-only mode. Since this is typically not the expected behavior, END blocks are not executed anymore when the `-c` switch is used, or if compilation fails.

See §92.2.18 for how to run things when the compile phase ends.

92.9.15 Potential to leak DATA filehandles

Using the `__DATA__` token creates an implicit filehandle to the file that contains the token. It is the program's responsibility to close it when it is done reading from it.

This caveat is now better explained in the documentation. See *perldata*.

92.10 New or Changed Diagnostics

"%s" variable %s masks earlier declaration in same %s

(W misc) A "my" or "our" variable has been redeclared in the current scope or statement, effectively eliminating all access to the previous instance. This is almost always a typographical error. Note that the earlier variable will still exist until the end of the scope or until all closure referents to it are destroyed.

"my sub" not yet implemented

(F) Lexically scoped subroutines are not yet implemented. Don't try that yet.

"our" variable %s redeclared

(W misc) You seem to have already declared the same global once before in the current lexical scope.

'!' allowed only after types %s

(F) The '!' is allowed in pack() and unpack() only after certain types. See pack in *perlfunc*.

/ cannot take a count

(F) You had an unpack template indicating a counted-length string, but you have also specified an explicit size for the string. See pack in *perlfunc*.

/ must be followed by a, A or Z

(F) You had an unpack template indicating a counted-length string, which must be followed by one of the letters a, A or Z to indicate what sort of string is to be unpacked. See pack in *perlfunc*.

/ must be followed by a*, A* or Z*

(F) You had a pack template indicating a counted-length string, Currently the only things that can have their length counted are a*, A* or Z*. See pack in *perlfunc*.

/ must follow a numeric type

(F) You had an unpack template that contained a '#', but this did not follow some numeric unpack specification. See pack in *perlfunc*.

/%s/: Unrecognized escape \\%c passed through

(W regexp) You used a backslash-character combination which is not recognized by Perl. This combination appears in an interpolated variable or a '-delimited regular expression. The character was understood literally.

/%s/: Unrecognized escape \\%c in character class passed through

(W regexp) You used a backslash-character combination which is not recognized by Perl inside character classes. The character was understood literally.

/%s/ should probably be written as "%s"

(W syntax) You have used a pattern where Perl expected to find a string, as in the first argument to `join`. Perl will treat the true or false result of matching the pattern against $_ as the string, which is probably not what you had in mind.

%s() called too early to check prototype

(W prototype) You've called a function that has a prototype before the parser saw a definition or declaration for it, and Perl could not check that the call conforms to the prototype. You need to either add an early prototype declaration for the subroutine in question, or move the subroutine definition ahead of the call to get proper prototype checking. Alternatively, if you are certain that you're calling the function correctly, you may put an ampersand before the name to avoid the warning. See *perlsub*.

%s argument is not a HASH or ARRAY element

(F) The argument to exists() must be a hash or array element, such as:

```
$foo{$bar}
$ref->{"susie"}[12]
```

%s argument is not a HASH or ARRAY element or slice

(F) The argument to delete() must be either a hash or array element, such as:

```
$foo{$bar}
$ref->{"susie"}[12]
```

or a hash or array slice, such as:

```
@foo[$bar, $baz, $xyzzy]
@{$ref->[12]}{"susie", "queue"}
```

%s argument is not a subroutine name

(F) The argument to exists() for `exists &sub` must be a subroutine name, and not a subroutine call. `exists &sub()` will generate this error.

%s package attribute may clash with future reserved word: %s

(W reserved) A lowercase attribute name was used that had a package-specific handler. That name might have a meaning to Perl itself some day, even though it doesn't yet. Perhaps you should use a mixed-case attribute name, instead. See *attributes*.

(in cleanup) %s

(W misc) This prefix usually indicates that a DESTROY() method raised the indicated exception. Since destructors are usually called by the system at arbitrary points during execution, and often a vast number of times, the warning is issued only once for any number of failures that would otherwise result in the same message being repeated.

Failure of user callbacks dispatched using the `G_KEEPERR` flag could also result in this warning. See G_KEEPERR in *perlcall*.

<> should be quotes

(F) You wrote `require <file>` when you should have written `require 'file'`.

Attempt to join self

(F) You tried to join a thread from within itself, which is an impossible task. You may be joining the wrong thread, or you may need to move the join() to some other thread.

Bad evalled substitution pattern

(F) You've used the /e switch to evaluate the replacement for a substitution, but perl found a syntax error in the code to evaluate, most likely an unexpected right brace '}'.

Bad realloc() ignored

(S) An internal routine called realloc() on something that had never been malloc()ed in the first place. Mandatory, but can be disabled by setting environment variable `PERL_BADFREE` to 1.

Bareword found in conditional

(W bareword) The compiler found a bareword where it expected a conditional, which often indicates that an || or && was parsed as part of the last argument of the previous construct, for example:

```
open FOO || die;
```

It may also indicate a misspelled constant that has been interpreted as a bareword:

```
use constant TYPO => 1;
if (TYOP) { print "foo" }
```

The `strict` pragma is useful in avoiding such errors.

Binary number > 0b11111111111111111111111111111111 non-portable

(W portable) The binary number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

Bit vector size > 32 non-portable

(W portable) Using bit vector sizes larger than 32 is non-portable.

Buffer overflow in prime_env_iter: %s

(W internal) A warning peculiar to VMS. While Perl was preparing to iterate over %ENV, it encountered a logical name or symbol definition which was too long, so it was truncated to the string shown.

Can't check filesystem of script "%s"

(P) For some reason you can't check the filesystem of the script for nosuid.

Can't declare class for non-scalar %s in "%s"

(S) Currently, only scalar variables can declared with a specific class qualifier in a "my" or "our" declaration. The semantics may be extended for other types of variables in future.

Can't declare %s in "%s"

(F) Only scalar, array, and hash variables may be declared as "my" or "our" variables. They must have ordinary identifiers as names.

Can't ignore signal CHLD, forcing to default

(W signal) Perl has detected that it is being run with the SIGCHLD signal (sometimes known as SIGCLD) disabled. Since disabling this signal will interfere with proper determination of exit status of child processes, Perl has reset the signal to its default value. This situation typically indicates that the parent program under which Perl may be running (e.g., cron) is being very careless.

Can't modify non-lvalue subroutine call

(F) Subroutines meant to be used in lvalue context should be declared as such, see Lvalue subroutines in *perlsub*.

Can't read CRTL environ

(S) A warning peculiar to VMS. Perl tried to read an element of %ENV from the CRTL's internal environment array and discovered the array was missing. You need to figure out where your CRTL misplaced its environ or define *PERL_ENV_TABLES* (see *perlvms*) so that environ is not searched.

Can't remove %s: %s, skipping file

(S) You requested an inplace edit without creating a backup file. Perl was unable to remove the original file to replace it with the modified file. The file was left unmodified.

Can't return %s from lvalue subroutine

(F) Perl detected an attempt to return illegal lvalues (such as temporary or readonly values) from a subroutine used as an lvalue. This is not allowed.

Can't weaken a nonreference

(F) You attempted to weaken something that was not a reference. Only references can be weakened.

Character class [:%s: unknown]

(F) The class in the character class [: :] syntax is unknown. See *perlre*.

Character class syntax [%s belongs inside] **character classes**

(W unsafe) The character class constructs [: :], [= =], and [. .] go *inside* character classes, the [] are part of the construct, for example: /[012[:alpha:]345]/. Note that [= =] and [. .] are not currently implemented; they are simply placeholders for future extensions.

Constant is not %s reference

(F) A constant value (perhaps declared using the `use constant` pragma) is being dereferenced, but it amounts to the wrong type of reference. The message indicates the type of reference that was expected. This usually indicates a syntax error in dereferencing the constant value. See Constant Functions in *perlsub* and *constant*.

constant(%s): %s

(F) The parser found inconsistencies either while attempting to define an overloaded constant, or when trying to find the character name specified in the `\N{...}` escape. Perhaps you forgot to load the corresponding `overload` or `charnames` pragma? See *charnames* and *overload*.

CORE::%s is not a keyword

(F) The CORE:: namespace is reserved for Perl keywords.

defined(@array) is deprecated

(D) defined() is not usually useful on arrays because it checks for an undefined *scalar* value. If you want to see if the array is empty, just use `if (@array) { # not empty }` for example.

defined(%hash) is deprecated

(D) defined() is not usually useful on hashes because it checks for an undefined *scalar* value. If you want to see if the hash is empty, just use `if (%hash) { # not empty }` for example.

Did not produce a valid header

See Server error.

(Did you mean "local" instead of "our"?)

(W misc) Remember that "our" does not localize the declared global variable. You have declared it again in the same lexical scope, which seems superfluous.

Document contains no data

See Server error.

entering effective %s failed

(F) While under the `use filetest` pragma, switching the real and effective uids or gids failed.

false [range "%s" in regexp]

(W regexp) A character class range must start and end at a literal character, not another character class like `\d` or `[:alpha:]`. The "-" in your false range is interpreted as a literal "-". Consider quoting the "-", "\-". See *perlre*.

Filehandle %s opened only for output

(W io) You tried to read from a filehandle opened only for writing. If you intended it to be a read/write filehandle, you needed to open it with "+<" or "+>" or "+>>" instead of with "<" or nothing. If you intended only to read from the file, use "<". See open in *perlfunc*.

flock() on closed filehandle %s

(W closed) The filehandle you're attempting to flock() got itself closed some time before now. Check your logic flow. flock() operates on filehandles. Are you attempting to call flock() on a dirhandle by the same name?

Global symbol "%s" requires explicit package name

(F) You've said "use strict vars", which indicates that all variables must either be lexically scoped (using "my"), declared beforehand using "our", or explicitly qualified to say which package the global variable is in (using "::").

Hexadecimal number > 0xffffffff non-portable

(W portable) The hexadecimal number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

Ill-formed CRTL environ value "%s"

(W internal) A warning peculiar to VMS. Perl tried to read the CRTL's internal environ array, and encountered an element without the = delimiter used to separate keys from values. The element is ignored.

Ill-formed message in prime_env_iter: |%s|

(W internal) A warning peculiar to VMS. Perl tried to read a logical name or CLI symbol definition when preparing to iterate over %ENV, and didn't see the expected delimiter between key and value, so the line was ignored.

Illegal binary digit %s

(F) You used a digit other than 0 or 1 in a binary number.

Illegal binary digit %s ignored

(W digit) You may have tried to use a digit other than 0 or 1 in a binary number. Interpretation of the binary number stopped before the offending digit.

Illegal number of bits in vec

(F) The number of bits in vec() (the third argument) must be a power of two from 1 to 32 (or 64, if your platform supports that).

Integer overflow in %s number

(W overflow) The hexadecimal, octal or binary number you have specified either as a literal or as an argument to hex() or oct() is too big for your architecture, and has been converted to a floating point number. On a 32-bit architecture the largest hexadecimal, octal or binary number representable without overflow is 0xFFFFFFFF, 037777777777, or 0b11111111111111111111111111111111 respectively. Note that Perl transparently promotes all numbers to a floating point representation internally–subject to loss of precision errors in subsequent operations.

Invalid %s attribute: %s

The indicated attribute for a subroutine or variable was not recognized by Perl or by a user-supplied handler. See *attributes*.

Invalid %s attributes: %s

The indicated attributes for a subroutine or variable were not recognized by Perl or by a user-supplied handler. See *attributes*.

invalid [range "%s" in regexp]

The offending range is now explicitly displayed.

Invalid separator character %s in attribute list

(F) Something other than a colon or whitespace was seen between the elements of an attribute list. If the previous attribute had a parenthesised parameter list, perhaps that list was terminated too soon. See *attributes*.

Invalid separator character %s in subroutine attribute list

(F) Something other than a colon or whitespace was seen between the elements of a subroutine attribute list. If the previous attribute had a parenthesised parameter list, perhaps that list was terminated too soon.

leaving effective %s failed

(F) While under the `use filetest` pragma, switching the real and effective uids or gids failed.

Lvalue subs returning %s not implemented yet

(F) Due to limitations in the current implementation, array and hash values cannot be returned in subroutines used in lvalue context. See Lvalue subroutines in *perlsub*.

Method %s not permitted

See Server error.

Missing %sbrace%s on \N{}

(F) Wrong syntax of character name literal `\N{charname}` within double-quotish context.

Missing command in piped open

(W pipe) You used the `open(FH, "| command")` or `open(FH, "command |")` construction, but the command was missing or blank.

Missing name in "my sub"

(F) The reserved syntax for lexically scoped subroutines requires that they have a name with which they can be found.

No %s specified for -%c

(F) The indicated command line switch needs a mandatory argument, but you haven't specified one.

No package name allowed for variable %s in "our"

(F) Fully qualified variable names are not allowed in "our" declarations, because that doesn't make much sense under existing semantics. Such syntax is reserved for future extensions.

No space allowed after -%c

(F) The argument to the indicated command line switch must follow immediately after the switch, without intervening spaces.

no UTC offset information; assuming local time is UTC

(S) A warning peculiar to VMS. Perl was unable to find the local timezone offset, so it's assuming that local system time is equivalent to UTC. If it's not, define the logical name *SYS$ TIMEZONE_DIFFERENTIAL* to translate to the number of seconds which need to be added to UTC to get local time.

Octal number > 037777777777 non-portable

(W portable) The octal number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

See also *perlport* for writing portable code.

panic: del_backref

(P) Failed an internal consistency check while trying to reset a weak reference.

panic: kid popen errno read

(F) forked child returned an incomprehensible message about its errno.

panic: magic_killbackrefs

(P) Failed an internal consistency check while trying to reset all weak references to an object.

Parentheses missing around "%s" list

(W parenthesis) You said something like

```
my $foo, $bar = @_;
```

when you meant

```
my ($foo, $bar) = @_;
```

Remember that "my", "our", and "local" bind tighter than comma.

Possible unintended interpolation of %s in string

(W ambiguous) It used to be that Perl would try to guess whether you wanted an array interpolated or a literal @. It no longer does this; arrays are now *always* interpolated into strings. This means that if you try something like:

```
    print "fred@example.com";
```

and the array `@example` doesn't exist, Perl is going to print `fred.com`, which is probably not what you wanted. To get a literal `@` sign in a string, put a backslash before it, just as you would to get a literal `$` sign.

Possible Y2K bug: %s

(W y2k) You are concatenating the number 19 with another number, which could be a potential Year 2000 problem.

pragma "attrs" is deprecated, use "sub NAME : ATTRS" instead

(W deprecated) You have written something like this:

```
sub doit
{
    use attrs qw(locked);
}
```

You should use the new declaration syntax instead.

```
sub doit : locked
{
    ...
```

The `use attrs` pragma is now obsolete, and is only provided for backward-compatibility. See Subroutine Attributes in *perlsub*.

Premature end of script headers

See Server error.

Repeat count in pack overflows

(F) You can't specify a repeat count so large that it overflows your signed integers. See pack in *perlfunc*.

Repeat count in unpack overflows

(F) You can't specify a repeat count so large that it overflows your signed integers. See unpack in *perlfunc*.

realloc() of freed memory ignored

(S) An internal routine called realloc() on something that had already been freed.

Reference is already weak

(W misc) You have attempted to weaken a reference that is already weak. Doing so has no effect.

setpgrp can't take arguments

(F) Your system has the setpgrp() from BSD 4.2, which takes no arguments, unlike POSIX setpgid(), which takes a process ID and process group ID.

Strange *+?{} on zero-length expression

(W regexp) You applied a regular expression quantifier in a place where it makes no sense, such as on a zero-width assertion. Try putting the quantifier inside the assertion instead. For example, the way to match "abc" provided that it is followed by three repetitions of "xyz" is `/abc(?=(?:xyz){3})/`, not `/abc(?=xyz){3}/`.

switching effective %s is not implemented

(F) While under the `use filetest` pragma, we cannot switch the real and effective uids or gids.

This Perl can't reset CRTL environ elements (%s)

This Perl can't set CRTL environ elements (%s=%s)

(W internal) Warnings peculiar to VMS. You tried to change or delete an element of the CRTL's internal environ array, but your copy of Perl wasn't built with a CRTL that contained the setenv() function. You'll need to rebuild Perl with a CRTL that does, or redefine *PERL_ENV_TABLES* (see *perlvms*) so that the environ array isn't the target of the change to %ENV which produced the warning.

Too late to run %s block

(W void) A CHECK or INIT block is being defined during run time proper, when the opportunity to run them has already passed. Perhaps you are loading a file with `require` or `do` when you should be using `use` instead. Or perhaps you should put the `require` or `do` inside a BEGIN block.

Unknown open() mode '%s'

(F) The second argument of 3-argument open() is not among the list of valid modes: <, >, >>, +<, +>, +>>, -|, |-.

Unknown process %x sent message to prime_env_iter: %s

(P) An error peculiar to VMS. Perl was reading values for %ENV before iterating over it, and someone else stuck a message in the stream of data Perl expected. Someone's very confused, or perhaps trying to subvert Perl's population of %ENV for nefarious purposes.

Unrecognized escape \\%c passed through

(W misc) You used a backslash-character combination which is not recognized by Perl. The character was understood literally.

Unterminated attribute parameter in attribute list

(F) The lexer saw an opening (left) parenthesis character while parsing an attribute list, but the matching closing (right) parenthesis character was not found. You may need to add (or remove) a backslash character to get your parentheses to balance. See *attributes*.

Unterminated attribute list

(F) The lexer found something other than a simple identifier at the start of an attribute, and it wasn't a semicolon or the start of a block. Perhaps you terminated the parameter list of the previous attribute too soon. See *attributes*.

Unterminated attribute parameter in subroutine attribute list

(F) The lexer saw an opening (left) parenthesis character while parsing a subroutine attribute list, but the matching closing (right) parenthesis character was not found. You may need to add (or remove) a backslash character to get your parentheses to balance.

Unterminated subroutine attribute list

(F) The lexer found something other than a simple identifier at the start of a subroutine attribute, and it wasn't a semicolon or the start of a block. Perhaps you terminated the parameter list of the previous attribute too soon.

Value of CLI symbol "`%s`" too long

(W misc) A warning peculiar to VMS. Perl tried to read the value of an %ENV element from a CLI symbol table, and found a resultant string longer than 1024 characters. The return value has been truncated to 1024 characters.

Version number must be a constant number

(P) The attempt to translate a `use Module n.n LIST` statement into its equivalent `BEGIN` block found an internal inconsistency with the version number.

92.11 New tests

lib/attrs

Compatibility tests for `sub : attrs` vs the older `use attrs`.

lib/env

Tests for new environment scalar capability (e.g., `use Env qw($BAR);`).

lib/env-array

Tests for new environment array capability (e.g., `use Env qw(@PATH);`).

lib/io_const

IO constants (SEEK_*, _IO*).

lib/io_dir

Directory-related IO methods (new, read, close, rewind, tied delete).

lib/io_multihomed

INET sockets with multi-homed hosts.

lib/io_poll

IO poll().

lib/io_unix

UNIX sockets.

op/attrs

Regression tests for `my ($x,@y,%z) : attrs` and <sub : attrs>.

op/filetest

File test operators.

op/lex_assign

Verify operations that access pad objects (lexicals and temporaries).

op/exists_sub

Verify `exists &sub` operations.

92.12 Incompatible Changes

92.12.1 Perl Source Incompatibilities

Beware that any new warnings that have been added or old ones that have been enhanced are **not** considered incompatible changes.

Since all new warnings must be explicitly requested via the `-w` switch or the `warnings` pragma, it is ultimately the programmer's responsibility to ensure that warnings are enabled judiciously.

CHECK is a new keyword

All subroutine definitions named CHECK are now special. See `/"Support for CHECK blocks"` for more information.

Treatment of list slices of undef has changed

There is a potential incompatibility in the behavior of list slices that are comprised entirely of undefined values. See §92.9.5.

Format of $ English::PERL_VERSION is different

The English module now sets $PERL_VERSION to $^V (a string value) rather than `$]` (a numeric value). This is a potential incompatibility. Send us a report via perlbug if you are affected by this.

See §92.2.7 for the reasons for this change.

Literals of the form `1.2.3` parse differently

Previously, numeric literals with more than one dot in them were interpreted as a floating point number concatenated with one or more numbers. Such "numbers" are now parsed as strings composed of the specified ordinals.

For example, `print 97.98.99` used to output `97.9899` in earlier versions, but now prints `abc`.

See §92.2.6.

Possibly changed pseudo-random number generator

Perl programs that depend on reproducing a specific set of pseudo-random numbers may now produce different output due to improvements made to the rand() builtin. You can use `sh Configure -Drandfunc=rand` to obtain the old behavior.

See §92.2.20.

Hashing function for hash keys has changed

Even though Perl hashes are not order preserving, the apparently random order encountered when iterating on the contents of a hash is actually determined by the hashing algorithm used. Improvements in the algorithm may yield a random order that is **different** from that of previous versions, especially when iterating on hashes.

See §92.2.22 for additional information.

`undef` fails on read only values

Using the `undef` operator on a readonly value (such as $1) has the same effect as assigning `undef` to the readonly value–it throws an exception.

Close-on-exec bit may be set on pipe and socket handles

Pipe and socket handles are also now subject to the close-on-exec behavior determined by the special variable $^F.

See §92.2.44.

Writing `"$$1"` to mean `"${$}1"` is unsupported

Perl 5.004 deprecated the interpretation of `$$1` and similar within interpolated strings to mean `$$ . "1"`, but still allowed it.

In Perl 5.6.0 and later, `"$$1"` always means `"${$1}"`.

delete(), each(), values() and `\(%h)`

operate on aliases to values, not copies

delete(), each(), values() and hashes (e.g. `\(%h)`) in a list context return the actual values in the hash, instead of copies (as they used to in earlier versions). Typical idioms for using these constructs copy the returned values, but this can make a significant difference when creating references to the returned values. Keys in the hash are still returned as copies when iterating on a hash.

See also §92.6.4.

vec(EXPR,OFFSET,BITS) enforces powers-of-two BITS

vec() generates a run-time error if the BITS argument is not a valid power-of-two integer.

Text of some diagnostic output has changed

Most references to internal Perl operations in diagnostics have been changed to be more descriptive. This may be an issue for programs that may incorrectly rely on the exact text of diagnostics for proper functioning.

`%@` has been removed

The undocumented special variable `%@` that used to accumulate "background" errors (such as those that happen in DESTROY()) has been removed, because it could potentially result in memory leaks.

Parenthesized not() behaves like a list operator

The `not` operator now falls under the "if it looks like a function, it behaves like a function" rule.

As a result, the parenthesized form can be used with `grep` and `map`. The following construct used to be a syntax error before, but it works as expected now:

```
grep not($_), @things;
```

On the other hand, using `not` with a literal list slice may not work. The following previously allowed construct:

```
print not (1,2,3)[0];
```

needs to be written with additional parentheses now:

```
print not((1,2,3)[0]);
```

The behavior remains unaffected when `not` is not followed by parentheses.

Semantics of bareword prototype `(*)` have changed

The semantics of the bareword prototype * have changed. Perl 5.005 always coerced simple scalar arguments to a typeglob, which wasn't useful in situations where the subroutine must distinguish between a simple scalar and a typeglob. The new behavior is to not coerce bareword arguments to a typeglob. The value will always be visible as either a simple scalar or as a reference to a typeglob.

See §92.2.49.

Semantics of bit operators may have changed on 64-bit platforms

If your platform is either natively 64-bit or if Perl has been configured to used 64-bit integers, i.e., $Config{ivsize} is 8, there may be a potential incompatibility in the behavior of bitwise numeric operators (& | ^ ~ << >>). These operators used to strictly operate on the lower 32 bits of integers in previous versions, but now operate over the entire native integral width. In particular, note that unary ~ will produce different results on platforms that have different $Config{ivsize}. For portability, be sure to mask off the excess bits in the result of unary ~, e.g., `~$x & 0xffffffff`.

See §92.2.47.

More builtins taint their results

As described in §92.2.48, there may be more sources of taint in a Perl program.

To avoid these new tainting behaviors, you can build Perl with the Configure option `-Accflags=-DINCOMPLETE_TAINTS`. Beware that the ensuing perl binary may be insecure.

92.12.2 C Source Incompatibilities

`PERL_POLLUTE`

Release 5.005 grandfathered old global symbol names by providing preprocessor macros for extension source compatibility. As of release 5.6.0, these preprocessor definitions are not available by default. You need to explicitly compile perl with `-DPERL_POLLUTE` to get these definitions. For extensions still using the old symbols, this option can be specified via MakeMaker:

```
perl Makefile.PL POLLUTE=1
```

`PERL_IMPLICIT_CONTEXT`

This new build option provides a set of macros for all API functions such that an implicit interpreter/thread context argument is passed to every API function. As a result of this, something like `sv_setsv(foo,bar)` amounts to a macro invocation that actually translates to something like `Perl_sv_setsv(my_perl,foo,bar)`. While this is generally expected to not have any significant source compatibility issues, the difference between a macro and a real function call will need to be considered.

This means that there **is** a source compatibility issue as a result of this if your extensions attempt to use pointers to any of the Perl API functions.

Note that the above issue is not relevant to the default build of Perl, whose interfaces continue to match those of prior versions (but subject to the other options described here).

See The Perl API in *perlguts* for detailed information on the ramifications of building Perl with this option.

```
NOTE: PERL_IMPLICIT_CONTEXT is automatically enabled whenever Perl is built
with one of -Dusethreads, -Dusemultiplicity, or both.  It is not
intended to be enabled by users at this time.
```

`PERL_POLLUTE_MALLOC`

Enabling Perl's malloc in release 5.005 and earlier caused the namespace of the system's malloc family of functions to be usurped by the Perl versions, since by default they used the same names. Besides causing problems on platforms that do not allow these functions to be cleanly replaced, this also meant that the system versions could not be called in programs that used Perl's malloc. Previous versions of Perl have allowed this behaviour to be suppressed with the HIDEMYMALLOC and EMBEDMYMALLOC preprocessor definitions.

As of release 5.6.0, Perl's malloc family of functions have default names distinct from the system versions. You need to explicitly compile perl with `-DPERL_POLLUTE_MALLOC` to get the older behaviour. HIDEMYMALLOC and EMBEDMYMALLOC have no effect, since the behaviour they enabled is now the default.

Note that these functions do **not** constitute Perl's memory allocation API. See Memory Allocation in *perlguts* for further information about that.

92.12.3 Compatible C Source API Changes

`PATCHLEVEL` is now `PERL_VERSION`

The cpp macros `PERL_REVISION`, `PERL_VERSION`, and `PERL_SUBVERSION` are now available by default from perl.h, and reflect the base revision, patchlevel, and subversion respectively. `PERL_REVISION` had no prior equivalent, while `PERL_VERSION` and `PERL_SUBVERSION` were previously available as `PATCHLEVEL` and `SUBVERSION`.

The new names cause less pollution of the **cpp** namespace and reflect what the numbers have come to stand for in common practice. For compatibility, the old names are still supported when *patchlevel.h* is explicitly included (as required before), so there is no source incompatibility from the change.

92.12.4 Binary Incompatibilities

In general, the default build of this release is expected to be binary compatible for extensions built with the 5.005 release or its maintenance versions. However, specific platforms may have broken binary compatibility due to changes in the defaults used in hints files. Therefore, please be sure to always check the platform-specific README files for any notes to the contrary.

The usethreads or usemultiplicity builds are **not** binary compatible with the corresponding builds in 5.005.

On platforms that require an explicit list of exports (AIX, OS/2 and Windows, among others), purely internal symbols such as parser functions and the run time opcodes are not exported by default. Perl 5.005 used to export all functions irrespective of whether they were considered part of the public API or not.

For the full list of public API functions, see *perlapi*.

92.13 Known Problems

92.13.1 Thread test failures

The subtests 19 and 20 of lib/thr5005.t test are known to fail due to fundamental problems in the 5.005 threading implementation. These are not new failures–Perl 5.005_0x has the same bugs, but didn't have these tests.

92.13.2 EBCDIC platforms not supported

In earlier releases of Perl, EBCDIC environments like OS390 (also known as Open Edition MVS) and VM-ESA were supported. Due to changes required by the UTF-8 (Unicode) support, the EBCDIC platforms are not supported in Perl 5.6.0.

92.13.3 In 64-bit HP-UX the lib/io_multihomed test may hang

The lib/io_multihomed test may hang in HP-UX if Perl has been configured to be 64-bit. Because other 64-bit platforms do not hang in this test, HP-UX is suspect. All other tests pass in 64-bit HP-UX. The test attempts to create and connect to "multihomed" sockets (sockets which have multiple IP addresses).

92.13.4 NEXTSTEP 3.3 POSIX test failure

In NEXTSTEP 3.3p2 the implementation of the strftime(3) in the operating system libraries is buggy: the %j format numbers the days of a month starting from zero, which, while being logical to programmers, will cause the subtests 19 to 27 of the lib/posix test may fail.

92.13.5 Tru64 (aka Digital UNIX, aka DEC OSF/1) lib/sdbm test failure with gcc

If compiled with gcc 2.95 the lib/sdbm test will fail (dump core). The cure is to use the vendor cc, it comes with the operating system and produces good code.

92.13.6 UNICOS/mk CC failures during Configure run

In UNICOS/mk the following errors may appear during the Configure run:

```
Guessing which symbols your C compiler and preprocessor define...
CC-20 cc: ERROR File = try.c, Line = 3
...
  bad switch yylook 79bad switch yylook 79bad switch yylook 79bad switch yylook 79#ifdef A29K
...
4 errors detected in the compilation of "try.c".
```

The culprit is the broken awk of UNICOS/mk. The effect is fortunately rather mild: Perl itself is not adversely affected by the error, only the h2ph utility coming with Perl, and that is rather rarely needed these days.

92.13.7 Arrow operator and arrays

When the left argument to the arrow operator `->` is an array, or the `scalar` operator operating on an array, the result of the operation must be considered erroneous. For example:

```
    @x->[2]
    scalar(@x)->[2]
```

These expressions will get run-time errors in some future release of Perl.

92.13.8 Experimental features

As discussed above, many features are still experimental. Interfaces and implementation of these features are subject to change, and in extreme cases, even subject to removal in some future release of Perl. These features include the following:

Threads

Unicode

64-bit support

Lvalue subroutines

Weak references

The pseudo-hash data type

The Compiler suite

Internal implementation of file globbing

The DB module

The regular expression code constructs:
`(?{ code })` and `(??{ code })`

92.14 Obsolete Diagnostics

Character class syntax [: : is reserved] **for future extensions**
(W) Within regular expression character classes ([]) the syntax beginning with "[:" and ending with ":]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[:" and ":\]".

Ill-formed logical name |%s| in prime_env_iter
(W) A warning peculiar to VMS. A logical name was encountered when preparing to iterate over %ENV which violates the syntactic rules governing logical names. Because it cannot be translated normally, it is skipped, and will not appear in %ENV. This may be a benign occurrence, as some software packages might directly modify logical name tables and introduce nonstandard names, or it may indicate that a logical name table has been corrupted.

In string, @%s now must be written as \@%s
The description of this error used to say:

```
        (Someday it will simply assume that an unbackslashed @
         interpolates an array.)
```

That day has come, and this fatal error has been removed. It has been replaced by a non-fatal warning instead. See Arrays now always interpolate into double-quoted strings for details.

Probable precedence problem on %s

(W) The compiler found a bareword where it expected a conditional, which often indicates that an || or && was parsed as part of the last argument of the previous construct, for example:

```
    open FOO || die;
```

regexp too big

(F) The current implementation of regular expressions uses shorts as address offsets within a string. Unfortunately this means that if the regular expression compiles to longer than 32767, it'll blow up. Usually when you want a regular expression this big, there is a better way to do it with multiple statements. See *perlre*.

Use of "$ $ <digit>" to mean "$ {$ }<digit>" is deprecated

(D) Perl versions before 5.004 misinterpreted any type marker followed by "$" and a digit. For example, "$$0" was incorrectly taken to mean "${$}0" instead of "${$0}". This bug is (mostly) fixed in Perl 5.004.

However, the developers of Perl 5.004 could not fix this bug completely, because at least two widely-used modules depend on the old meaning of "$$0" in a string. So Perl 5.004 still interprets "$$<digit>" in the old (broken) way inside strings; but it generates this message as a warning. And in Perl 5.005, this special treatment will cease.

92.15 Reporting Bugs

If you find what you think is a bug, you might check the articles recently posted to the comp.lang.perl.misc newsgroup. There may also be information at http://www.perl.com/perl/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Be sure to trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to perlbug@perl.org to be analysed by the Perl porting team.

Chapter 93

perl5005delta

What's new for perl5.005

93.1 DESCRIPTION

This document describes differences between the 5.004 release and this one.

93.2 About the new versioning system

Perl is now developed on two tracks: a maintenance track that makes small, safe updates to released production versions with emphasis on compatibility; and a development track that pursues more aggressive evolution. Maintenance releases (which should be considered production quality) have subversion numbers that run from `1` to `49`, and development releases (which should be considered "alpha" quality) run from `50` to `99`.

Perl 5.005 is the combined product of the new dual-track development scheme.

93.3 Incompatible Changes

93.3.1 WARNING: This version is not binary compatible with Perl 5.004.

Starting with Perl 5.004_50 there were many deep and far-reaching changes to the language internals. If you have dynamically loaded extensions that you built under perl 5.003 or 5.004, you can continue to use them with 5.004, but you will need to rebuild and reinstall those extensions to use them 5.005. See *INSTALL* for detailed instructions on how to upgrade.

93.3.2 Default installation structure has changed

The new Configure defaults are designed to allow a smooth upgrade from 5.004 to 5.005, but you should read *INSTALL* for a detailed discussion of the changes in order to adapt them to your system.

93.3.3 Perl Source Compatibility

When none of the experimental features are enabled, there should be very few user-visible Perl source compatibility issues.

If threads are enabled, then some caveats apply. `@_` and `$_` become lexical variables. The effect of this should be largely transparent to the user, but there are some boundary conditions under which user will need to be aware of the issues. For example, `local(@_)` results in a "Can't localize lexical variable @_ ..." message. This may be enabled in a future version.

Some new keywords have been introduced. These are generally expected to have very little impact on compatibility. See New `INIT` keyword, New `lock` keyword, and New `qr//` operator.

Certain barewords are now reserved. Use of these will provoke a warning if you have asked for them with the `-w` switch. See `our` is now a reserved word.

93.3.4 C Source Compatibility

There have been a large number of changes in the internals to support the new features in this release.

- Core sources now require ANSI C compiler

  An ANSI C compiler is now **required** to build perl. See *INSTALL*.

- All Perl global variables must now be referenced with an explicit prefix

  All Perl global variables that are visible for use by extensions now have a `PL_` prefix. New extensions should `not` refer to perl globals by their unqualified names. To preserve sanity, we provide limited backward compatibility for globals that are being widely used like `sv_undef` and `na` (which should now be written as `PL_sv_undef`, `PL_na` etc.)

  If you find that your XS extension does not compile anymore because a perl global is not visible, try adding a `PL_` prefix to the global and rebuild.

  It is strongly recommended that all functions in the Perl API that don't begin with `perl` be referenced with a `Perl_` prefix. The bare function names without the `Perl_` prefix are supported with macros, but this support may cease in a future release.

  See *perlapi*.

- Enabling threads has source compatibility issues

  Perl built with threading enabled requires extensions to use the new `dTHR` macro to initialize the handle to access per-thread data. If you see a compiler error that talks about the variable `thr` not being declared (when building a module that has XS code), you need to add `dTHR;` at the beginning of the block that elicited the error.

  The API function `perl_get_sv("@",FALSE)` should be used instead of directly accessing perl globals as `GvSV(errgv)`. The API call is backward compatible with existing perls and provides source compatibility with threading is enabled.

  See §93.3.4 for more information.

93.3.5 Binary Compatibility

This version is NOT binary compatible with older versions. All extensions will need to be recompiled. Further binaries built with threads enabled are incompatible with binaries built without. This should largely be transparent to the user, as all binary incompatible configurations have their own unique architecture name, and extension binaries get installed at unique locations. This allows coexistence of several configurations in the same directory hierarchy. See *INSTALL*.

93.3.6 Security fixes may affect compatibility

A few taint leaks and taint omissions have been corrected. This may lead to "failure" of scripts that used to work with older versions. Compiling with -DINCOMPLETE_TAINTS provides a perl with minimal amounts of changes to the tainting behavior. But note that the resulting perl will have known insecurities.

Oneliners with the `-e` switch do not create temporary files anymore.

93.3.7 Relaxed new mandatory warnings introduced in 5.004

Many new warnings that were introduced in 5.004 have been made optional. Some of these warnings are still present, but perl's new features make them less often a problem. See New Diagnostics.

93.3.8 Licensing

Perl has a new Social Contract for contributors. See *Porting/Contract*.

The license included in much of the Perl documentation has changed. Most of the Perl documentation was previously under the implicit GNU General Public License or the Artistic License (at the user's choice). Now much of the documentation unambiguously states the terms under which it may be distributed. Those terms are in general much less restrictive than the GNU GPL. See *perl* and the individual perl manpages listed therein.

93.4 Core Changes

93.4.1 Threads

WARNING: Threading is considered an **experimental** feature. Details of the implementation may change without notice. There are known limitations and some bugs. These are expected to be fixed in future versions.

See *README.threads*.

93.4.2 Compiler

WARNING: The Compiler and related tools are considered **experimental**. Features may change without notice, and there are known limitations and bugs. Since the compiler is fully external to perl, the default configuration will build and install it.

The Compiler produces three different types of transformations of a perl program. The C backend generates C code that captures perl's state just before execution begins. It eliminates the compile-time overheads of the regular perl interpreter, but the run-time performance remains comparatively the same. The CC backend generates optimized C code equivalent to the code path at run-time. The CC backend has greater potential for big optimizations, but only a few optimizations are implemented currently. The Bytecode backend generates a platform independent bytecode representation of the interpreter's state just before execution. Thus, the Bytecode back end also eliminates much of the compilation overhead of the interpreter.

The compiler comes with several valuable utilities.

`B::Lint` is an experimental module to detect and warn about suspicious code, especially the cases that the `-w` switch does not detect.

`B::Deparse` can be used to demystify perl code, and understand how perl optimizes certain constructs.

`B::Xref` generates cross reference reports of all definition and use of variables, subroutines and formats in a program.

`B::Showlex` show the lexical variables used by a subroutine or file at a glance.

`perlcc` is a simple frontend for compiling perl.

See `ext/B/README`, *B*, and the respective compiler modules.

93.4.3 Regular Expressions

Perl's regular expression engine has been seriously overhauled, and many new constructs are supported. Several bugs have been fixed.

Here is an itemized summary:

Many new and improved optimizations

Changes in the RE engine:

```
Unneeded nodes removed;
Substrings merged together;
New types of nodes to process (SUBEXPR)* and similar expressions
    quickly, used if the SUBEXPR has no side effects and matches
    strings of the same length;
Better optimizations by lookup for constant substrings;
Better search for constants substrings anchored by $ ;
```

Changes in Perl code using RE engine:

```
More optimizations to s/longer/short/;
study() was not working;
/blah/ may be optimized to an analogue of index() if $& $‘ $’ not seen;
Unneeded copying of matched-against string removed;
Only matched part of the string is copying if $‘ $’ were not seen;
```

Many bug fixes

Note that only the major bug fixes are listed here. See *Changes* for others.

```
Backtracking might not restore start of $3.
No feedback if max count for * or + on "complex" subexpression
    was reached, similarly (but at compile time) for {3,34567}
Primitive restrictions on max count introduced to decrease a
    possibility of a segfault;
(ZERO-LENGTH)* could segfault;
(ZERO-LENGTH)* was prohibited;
Long REs were not allowed;
/RE/g could skip matches at the same position after a
  zero-length match;
```

New regular expression constructs

The following new syntax elements are supported:

```
(?<=RE)
(?<!RE)
(?{ CODE })
(?i-x)
(?i:RE)
(?(COND)YES_RE|NO_RE)
(?>RE)
\z
```

New operator for precompiled regular expressions

See New `qr//` operator.

Other improvements

```
Better debugging output (possibly with colors),
    even from non-debugging Perl;
RE engine code now looks like C, not like assembler;
Behaviour of RE modifiable by ‘use re’ directive;
Improved documentation;
Test suite significantly extended;
Syntax [:^upper:] etc., reserved inside character classes;
```

Incompatible changes

```
(?i) localized inside enclosing group;
$( is not interpolated into RE any more;
/RE/g may match at the same position (with non-zero length)
    after a zero-length match (bug fix).
```

See *perlre* and *perlop*.

93.4.4 Improved malloc()

See banner at the beginning of `malloc.c` for details.

93.4.5 Quicksort is internally implemented

Perl now contains its own highly optimized qsort() routine. The new qsort() is resistant to inconsistent comparison functions, so Perl's `sort()` will not provoke coredumps any more when given poorly written sort subroutines. (Some C library `qsort()`s that were being used before used to have this problem.) In our testing, the new `qsort()` required the minimal number of pair-wise compares on average, among all known `qsort()` implementations.

See `perlfunc/sort`.

93.4.6 Reliable signals

Perl's signal handling is susceptible to random crashes, because signals arrive asynchronously, and the Perl runtime is not reentrant at arbitrary times.

However, one experimental implementation of reliable signals is available when threads are enabled. See `Thread::Signal`. Also see *INSTALL* for how to build a Perl capable of threads.

93.4.7 Reliable stack pointers

The internals now reallocate the perl stack only at predictable times. In particular, magic calls never trigger reallocations of the stack, because all reentrancy of the runtime is handled using a "stack of stacks". This should improve reliability of cached stack pointers in the internals and in XSUBs.

93.4.8 More generous treatment of carriage returns

Perl used to complain if it encountered literal carriage returns in scripts. Now they are mostly treated like whitespace within program text. Inside string literals and here documents, literal carriage returns are ignored if they occur paired with linefeeds, or get interpreted as whitespace if they stand alone. This behavior means that literal carriage returns in files should be avoided. You can get the older, more compatible (but less generous) behavior by defining the preprocessor symbol `PERL_STRICT_CR` when building perl. Of course, all this has nothing whatever to do with how escapes like `\r` are handled within strings.

Note that this doesn't somehow magically allow you to keep all text files in DOS format. The generous treatment only applies to files that perl itself parses. If your C compiler doesn't allow carriage returns in files, you may still be unable to build modules that need a C compiler.

93.4.9 Memory leaks

`substr`, `pos` and `vec` don't leak memory anymore when used in lvalue context. Many small leaks that impacted applications that embed multiple interpreters have been fixed.

93.4.10 Better support for multiple interpreters

The build-time option `-DMULTIPLICITY` has had many of the details reworked. Some previously global variables that should have been per-interpreter now are. With care, this allows interpreters to call each other. See the `PerlInterp` extension on CPAN.

93.4.11 Behavior of local() on array and hash elements is now well-defined

See Temporary Values via local() in *perlsub*.

93.4.12 `%!` is transparently tied to the *Errno* module

See *perlvar*, and *Errno*.

93.4.13 Pseudo-hashes are supported

See *perlref*.

93.4.14 `EXPR foreach EXPR` is supported

See *perlsyn*.

93.4.15 Keywords can be globally overridden

See *perlsub*.

93.4.16 `$^E` is meaningful on Win32

See *perlvar*.

93.4.17 `foreach (1..1000000)` optimized

`foreach (1..1000000)` is now optimized into a counting loop. It does not try to allocate a 1000000-size list anymore.

93.4.18 `Foo::` can be used as implicitly quoted package name

Barewords caused unintuitive behavior when a subroutine with the same name as a package happened to be defined. Thus, `new Foo @args`, use the result of the call to `Foo()` instead of `Foo` being treated as a literal. The recommended way to write barewords in the indirect object slot is `new Foo:: @args`. Note that the method `new()` is called with a first argument of `Foo`, not `Foo::` when you do that.

93.4.19 `exists $Foo::{Bar::}` tests existence of a package

It was impossible to test for the existence of a package without actually creating it before. Now `exists $Foo::{Bar::}` can be used to test if the `Foo::Bar` namespace has been created.

93.4.20 Better locale support

See *perllocale*.

93.4.21 Experimental support for 64-bit platforms

Perl5 has always had 64-bit support on systems with 64-bit longs. Starting with 5.005, the beginnings of experimental support for systems with 32-bit long and 64-bit 'long long' integers has been added. If you add -DUSE_LONG_LONG to your ccflags in config.sh (or manually define it in perl.h) then perl will be built with 'long long' support. There will be many compiler warnings, and the resultant perl may not work on all systems. There are many other issues related to third-party extensions and libraries. This option exists to allow people to work on those issues.

93.4.22 prototype() returns useful results on builtins

See prototype in *perlfunc*.

93.4.23 Extended support for exception handling

`die()` now accepts a reference value, and `$@` gets set to that value in exception traps. This makes it possible to propagate exception objects. This is an undocumented **experimental** feature.

93.4.24 Re-blessing in DESTROY() supported for chaining DESTROY() methods

See Destructors in *perlobj*.

93.4.25 All `printf` format conversions are handled internally

See printf in *perlfunc*.

93.4.26 New `INIT` keyword

`INIT` subs are like `BEGIN` and `END`, but they get run just before the perl runtime begins execution. e.g., the Perl Compiler makes use of `INIT` blocks to initialize and resolve pointers to XSUBs.

93.4.27 New `lock` keyword

The `lock` keyword is the fundamental synchronization primitive in threaded perl. When threads are not enabled, it is currently a noop.

To minimize impact on source compatibility this keyword is "weak", i.e., any user-defined subroutine of the same name overrides it, unless a `use Thread` has been seen.

93.4.28 New `qr//` operator

The `qr//` operator, which is syntactically similar to the other quote-like operators, is used to create precompiled regular expressions. This compiled form can now be explicitly passed around in variables, and interpolated in other regular expressions. See *perlop*.

93.4.29 `our` is now a reserved word

Calling a subroutine with the name `our` will now provoke a warning when using the `-w` switch.

93.4.30 Tied arrays are now fully supported

See *Tie::Array*.

93.4.31 Tied handles support is better

Several missing hooks have been added. There is also a new base class for TIEARRAY implementations. See *Tie::Array*.

93.4.32 4th argument to substr

substr() can now both return and replace in one operation. The optional 4th argument is the replacement string. See substr in *perlfunc*.

93.4.33 Negative LENGTH argument to splice

splice() with a negative LENGTH argument now work similar to what the LENGTH did for substr(). Previously a negative LENGTH was treated as 0. See splice in *perlfunc*.

93.4.34 Magic lvalues are now more magical

When you say something like `substr($x, 5) = "hi"`, the scalar returned by substr() is special, in that any modifications to it affect $x. (This is called a 'magic lvalue' because an 'lvalue' is something on the left side of an assignment.) Normally, this is exactly what you would expect to happen, but Perl uses the same magic if you use substr(), pos(), or vec() in a context where they might be modified, like taking a reference with \ or as an argument to a sub that modifies `@_`. In previous versions, this 'magic' only went one way, but now changes to the scalar the magic refers to ($x in the above example) affect the magic lvalue too. For instance, this code now acts differently:

```
    $x = "hello";
    sub printit {
        $x = "g'bye";
        print $_[0], "\n";
    }
    printit(substr($x, 0, 5));
```

In previous versions, this would print "hello", but it now prints "g'bye".

93.4.35 <> now reads in records

If `$/` is a reference to an integer, or a scalar that holds an integer, <> will read in records instead of lines. For more info, see $/ in *perlvar*.

93.5 Supported Platforms

Configure has many incremental improvements. Site-wide policy for building perl can now be made persistent, via Policy.sh. Configure also records the command-line arguments used in *config.sh*.

93.5.1 New Platforms

BeOS is now supported. See *README.beos*.

DOS is now supported under the DJGPP tools. See *README.dos* (installed as *perldos* on some systems).

MiNT is now supported. See *README.mint*.

MPE/iX is now supported. See *README.mpeix*.

MVS (aka OS390, aka Open Edition) is now supported. See *README.os390* (installed as *perlos390* on some systems).

Stratus VOS is now supported. See *README.vos*.

93.5.2 Changes in existing support

Win32 support has been vastly enhanced. Support for Perl Object, a C++ encapsulation of Perl. GCC and EGCS are now supported on Win32. See *README.win32*, aka *perlwin32*.

VMS configuration system has been rewritten. See *README.vms* (installed as README_vms on some systems).

The hints files for most Unix platforms have seen incremental improvements.

93.6 Modules and Pragmata

93.6.1 New Modules

B

Perl compiler and tools. See *B*.

Data::Dumper

A module to pretty print Perl data. See *Data::Dumper*.

Dumpvalue

A module to dump perl values to the screen. See *Dumpvalue*.

Errno

A module to look up errors more conveniently. See *Errno*.

File::Spec

A portable API for file operations.

ExtUtils::Installed

Query and manage installed modules.

ExtUtils::Packlist

Manipulate .packlist files.

Fatal

Make functions/builtins succeed or die.

IPC::SysV

Constants and other support infrastructure for System V IPC operations in perl.

Test

A framework for writing testsuites.

Tie::Array

Base class for tied arrays.

Tie::Handle

Base class for tied handles.

Thread

Perl thread creation, manipulation, and support.

attrs

Set subroutine attributes.

fields

Compile-time class fields.

re

Various pragmata to control behavior of regular expressions.

93.6.2 Changes in existing modules

Benchmark

You can now run tests for *x* seconds instead of guessing the right number of tests to run.

Keeps better time.

Carp

Carp has a new function cluck(). cluck() warns, like carp(), but also adds a stack backtrace to the error message, like confess().

CGI

CGI has been updated to version 2.42.

Fcntl

More Fcntl constants added: F_SETLK64, F_SETLKW64, O_LARGEFILE for large (more than 4G) file access (the 64-bit support is not yet working, though, so no need to get overly excited), Free/Net/OpenBSD locking behaviour flags F_FLOCK, F_POSIX, Linux F_SHLCK, and O_ACCMODE: the mask of O_RDONLY, O_WRONLY, and O_RDWR.

Math::Complex

The accessors methods Re, Im, arg, abs, rho, theta, methods can ($z->Re()) now also act as mutators ($z->Re(3)).

Math::Trig

A little bit of radial trigonometry (cylindrical and spherical) added, for example the great circle distance.

POSIX

POSIX now has its own platform-specific hints files.

DB_File

DB_File supports version 2.x of Berkeley DB. See `ext/DB_File/Changes`.

MakeMaker

MakeMaker now supports writing empty makefiles, provides a way to specify that site umask() policy should be honored. There is also better support for manipulation of .packlist files, and getting information about installed modules.

Extensions that have both architecture-dependent and architecture-independent files are now always installed completely in the architecture-dependent locations. Previously, the shareable parts were shared both across architectures and across perl versions and were therefore liable to be overwritten with newer versions that might have subtle incompatibilities.

CPAN

See *perlmodinstall* and *CPAN*.

Cwd

Cwd::cwd is faster on most platforms.

93.7 Utility Changes

`h2ph` and related utilities have been vastly overhauled.

`perlcc`, a new experimental front end for the compiler is available.

The crude GNU `configure` emulator is now called `configure.gnu` to avoid trampling on `Configure` under case-insensitive filesystems.

`perldoc` used to be rather slow. The slower features are now optional. In particular, case-insensitive searches need the `-i` switch, and recursive searches need `-r`. You can set these switches in the `PERLDOC` environment variable to get the old behavior.

93.8 Documentation Changes

Config.pm now has a glossary of variables.

Porting/patching.pod has detailed instructions on how to create and submit patches for perl.

perlport specifies guidelines on how to write portably.

perlmodinstall describes how to fetch and install modules from `CPAN` sites.

Some more Perl traps are documented now. See *perltrap*.

perlopentut gives a tutorial on using open().

perlreftut gives a tutorial on references.

perlthrtut gives a tutorial on threads.

93.9 New Diagnostics

Ambiguous call resolved as CORE::%s(), qualify as such or use &

(W) A subroutine you have declared has the same name as a Perl keyword, and you have used the name without qualification for calling one or the other. Perl decided to call the builtin because the subroutine is not imported.

To force interpretation as a subroutine call, either put an ampersand before the subroutine name, or qualify the name with its package. Alternatively, you can import the subroutine (or pretend that it's imported with the `use subs` pragma).

To silently interpret it as the Perl operator, use the `CORE::` prefix on the operator (e.g. `CORE::log($x)`) or by declaring the subroutine to be an object method (see *attrs*).

Bad index while coercing array into hash

(F) The index looked up in the hash found as the 0'th element of a pseudo-hash is not legal. Index values must be at 1 or greater. See *perlref*.

Bareword "%s" refers to nonexistent package

(W) You used a qualified bareword of the form `Foo::`, but the compiler saw no other uses of that namespace before that point. Perhaps you need to predeclare a package?

Can't call method "%s" on an undefined value

(F) You used the syntax of a method call, but the slot filled by the object reference or package name contains an undefined value. Something like this will reproduce the error:

```
$BADREF = 42;
process $BADREF 1,2,3;
$BADREF->process(1,2,3);
```

Can't check filesystem of script "%s" for nosuid

(P) For some reason you can't check the filesystem of the script for nosuid.

Can't coerce array into hash

(F) You used an array where a hash was expected, but the array has no information on how to map from keys to array indices. You can do that only with arrays that have a hash reference at index 0.

Can't goto subroutine from an eval-string

(F) The "goto subroutine" call can't be used to jump out of an eval "string". (You can use it to jump out of an eval {BLOCK}, but you probably don't want to.)

Can't localize pseudo-hash element

(F) You said something like `local $ar->{'key'}`, where $ar is a reference to a pseudo-hash. That hasn't been implemented yet, but you can get a similar effect by localizing the corresponding array element directly – `local $ar->[$ar->[0]{'key'}]`.

Can't use %%! because Errno.pm is not available

(F) The first time the %! hash is used, perl automatically loads the Errno.pm module. The Errno module is expected to tie the %! hash to provide symbolic names for `$!` errno values.

Cannot find an opnumber for "%s"

(F) A string of a form `CORE::word` was given to prototype(), but there is no builtin with the name `word`.

Character class syntax [. . is reserved] for future extensions

(W) Within regular expression character classes ([]) the syntax beginning with "[." and ending with ".]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[." and ".\]".

Character class syntax [: : is reserved] for future extensions

(W) Within regular expression character classes ([]) the syntax beginning with "[:" and ending with ":]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[:" and ":\]".

Character class syntax [= = is reserved] for future extensions

(W) Within regular expression character classes ([]) the syntax beginning with "[=" and ending with "=]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[=" and "=\]".

%s: Eval-group in insecure regular expression

(F) Perl detected tainted data when trying to compile a regular expression that contains the `(?{ ... })` zero-width assertion, which is unsafe. See (?{ code }) in *perlre*, and *perlsec*.

%s: Eval-group not allowed, use re 'eval'

(F) A regular expression contained the `(?{ ... })` zero-width assertion, but that construct is only allowed when the `use re 'eval'` pragma is in effect. See (?{ code }) in *perlre*.

%s: Eval-group not allowed at run time

(F) Perl tried to compile a regular expression containing the `(?{ ... })` zero-width assertion at run time, as it would when the pattern contains interpolated values. Since that is a security risk, it is not allowed. If you insist, you may still do this by explicitly building the pattern from an interpolated string at run time and using that in an eval(). See (?{ code }) in *perlre*.

Explicit blessing to " (assuming package main)

(W) You are blessing a reference to a zero length string. This has the effect of blessing the reference into the package main. This is usually not what you want. Consider providing a default target package, e.g. bless($ref, $p || 'MyPackage');

Illegal hex digit ignored

(W) You may have tried to use a character other than 0 - 9 or A - F in a hexadecimal number. Interpretation of the hexadecimal number stopped before the illegal character.

No such array field

(F) You tried to access an array as a hash, but the field name used is not defined. The hash at index 0 should map all valid field names to array indices for that to work.

No such field "%s" in variable %s of type %s

(F) You tried to access a field of a typed variable where the type does not know about the field name. The field names are looked up in the %FIELDS hash in the type package at compile time. The %FIELDS hash is usually set up with the 'fields' pragma.

Out of memory during ridiculously large request

(F) You can't allocate more than 2ˆ31+"small amount" bytes. This error is most likely to be caused by a typo in the Perl program. e.g., `$arr[time]` instead of `$arr[$time]`.

Range iterator outside integer range

(F) One (or both) of the numeric arguments to the range operator ".." are outside the range which can be represented by integers internally. One possible workaround is to force Perl to use magical string increment by prepending "0" to your numbers.

Recursive inheritance detected while looking for method '%s' %s

(F) More than 100 levels of inheritance were encountered while invoking a method. Probably indicates an unintended loop in your inheritance hierarchy.

Reference found where even-sized list expected

(W) You gave a single reference where Perl was expecting a list with an even number of elements (for assignment to a hash). This usually means that you used the anon hash constructor when you meant to use parens. In any case, a hash requires key/value **pairs**.

```
%hash = { one => 1, two => 2, };   # WRONG
%hash = [ qw/ an anon array / ];   # WRONG
%hash = ( one => 1, two => 2, );   # right
%hash = qw( one 1 two 2 );                 # also fine
```

Undefined value assigned to typeglob

(W) An undefined value was assigned to a typeglob, a la `*foo = undef`. This does nothing. It's possible that you really mean `undef *foo`.

Use of reserved word "%s" is deprecated

(D) The indicated bareword is a reserved word. Future versions of perl may use it as a keyword, so you're better off either explicitly quoting the word in a manner appropriate for its context of use, or using a different name altogether. The warning can be suppressed for subroutine names by either adding a & prefix, or using a package qualifier, e.g. `&our()`, or `Foo::our()`.

perl: warning: Setting locale failed.

(S) The whole warning message will look something like:

```
perl: warning: Setting locale failed.
perl: warning: Please check that your locale settings:
        LC_ALL = "En_US",
        LANG = (unset)
    are supported and installed on your system.
perl: warning: Falling back to the standard locale ("C").
```

Exactly what were the failed locale settings varies. In the above the settings were that the LC_ALL was "En_US" and the LANG had no value. This error means that Perl detected that you and/or your system administrator have set up the so-called variable system but Perl could not use those settings. This was not dead serious, fortunately: there is a "default locale" called "C" that Perl can and will use, the script will be run. Before you really fix the problem, however, you will get the same error message each time you run Perl. How to really fix the problem can be found in LOCALE PROBLEMS in *perllocale*.

93.10 Obsolete Diagnostics

Can't mktemp()

(F) The mktemp() routine failed for some reason while trying to process a **-e** switch. Maybe your /tmp partition is full, or clobbered.

Removed because **-e** doesn't use temporary files any more.

Can't write to temp file for -e: %s

(F) The write routine failed for some reason while trying to process a **-e** switch. Maybe your /tmp partition is full, or clobbered.

Removed because **-e** doesn't use temporary files any more.

Cannot open temporary file

(F) The create routine failed for some reason while trying to process a **-e** switch. Maybe your /tmp partition is full, or clobbered.

Removed because **-e** doesn't use temporary files any more.

regexp too big

(F) The current implementation of regular expressions uses shorts as address offsets within a string. Unfortunately this means that if the regular expression compiles to longer than 32767, it'll blow up. Usually when you want a regular expression this big, there is a better way to do it with multiple statements. See *perlre*.

93.11 Configuration Changes

You can use "Configure -Uinstallusrbinperl" which causes installperl to skip installing perl also as /usr/bin/perl. This is useful if you prefer not to modify /usr/bin for some reason or another but harmful because many scripts assume to find Perl in /usr/bin/perl.

93.12 BUGS

If you find what you think is a bug, you might check the headers of recently posted articles in the comp.lang.perl.misc newsgroup. There may also be information at http://www.perl.com/perl/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Make sure you trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to <*perlbug@perl.com*> to be analysed by the Perl porting team.

93.13 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl.

The *README* file for general stuff.

The *Artistic* and *Copying* files for copyright information.

93.14 HISTORY

Written by Gurusamy Sarathy <*gsar@activestate.com*>, with many contributions from The Perl Porters.

Send omissions or corrections to <*perlbug@perl.com*>.

Chapter 94

perl5004delta

What's new for perl5.004

94.1 DESCRIPTION

This document describes differences between the 5.003 release (as documented in *Programming Perl*, second edition–the Camel Book) and this one.

94.2 Supported Environments

Perl5.004 builds out of the box on Unix, Plan 9, LynxOS, VMS, OS/2, QNX, AmigaOS, and Windows NT. Perl runs on Windows 95 as well, but it cannot be built there, for lack of a reasonable command interpreter.

94.3 Core Changes

Most importantly, many bugs were fixed, including several security problems. See the *Changes* file in the distribution for details.

94.3.1 List assignment to %ENV works

`%ENV = ()` and `%ENV = @list` now work as expected (except on VMS where it generates a fatal error).

94.3.2 Change to "Can't locate Foo.pm in @INC" error

The error "Can't locate Foo.pm in @INC" now lists the contents of @INC for easier debugging.

94.3.3 Compilation option: Binary compatibility with 5.003

There is a new Configure question that asks if you want to maintain binary compatibility with Perl 5.003. If you choose binary compatibility, you do not have to recompile your extensions, but you might have symbol conflicts if you embed Perl in another application, just as in the 5.003 release. By default, binary compatibility is preserved at the expense of symbol table pollution.

94.3.4 $ PERL5OPT environment variable

You may now put Perl options in the $PERL5OPT environment variable. Unless Perl is running with taint checks, it will interpret this variable as if its contents had appeared on a "#!perl" line at the beginning of your script, except that hyphens are optional. PERL5OPT may only be used to set the following switches: **-[DIMUdmw]**.

94.3.5 Limitations on -M, -m, and -T options

The `-M` and `-m` options are no longer allowed on the `#!` line of a script. If a script needs a module, it should invoke it with the `use` pragma.

The **-T** option is also forbidden on the `#!` line of a script, unless it was present on the Perl command line. Due to the way `#!` works, this usually means that **-T** must be in the first argument. Thus:

```
#!/usr/bin/perl -T -w
```

will probably work for an executable script invoked as `scriptname`, while:

```
#!/usr/bin/perl -w -T
```

will probably fail under the same conditions. (Non-Unix systems will probably not follow this rule.) But `perl scriptname` is guaranteed to fail, since then there is no chance of **-T** being found on the command line before it is found on the `#!` line.

94.3.6 More precise warnings

If you removed the **-w** option from your Perl 5.003 scripts because it made Perl too verbose, we recommend that you try putting it back when you upgrade to Perl 5.004. Each new perl version tends to remove some undesirable warnings, while adding new warnings that may catch bugs in your scripts.

94.3.7 Deprecated: Inherited `AUTOLOAD` for non-methods

Before Perl 5.004, `AUTOLOAD` functions were looked up as methods (using the `@ISA` hierarchy), even when the function to be autoloaded was called as a plain function (e.g. `Foo::bar()`), not a method (e.g. `Foo->bar()` or `$obj->bar()`).

Perl 5.005 will use method lookup only for methods' `AUTOLOAD`s. However, there is a significant base of existing code that may be using the old behavior. So, as an interim step, Perl 5.004 issues an optional warning when a non-method uses an inherited `AUTOLOAD`.

The simple rule is: Inheritance will not work when autoloading non-methods. The simple fix for old code is: In any module that used to depend on inheriting `AUTOLOAD` for non-methods from a base class named `BaseClass`, execute `*AUTOLOAD = \&BaseClass::AUTOLOAD` during startup.

94.3.8 Previously deprecated %OVERLOAD is no longer usable

Using %OVERLOAD to define overloading was deprecated in 5.003. Overloading is now defined using the overload pragma. %OVERLOAD is still used internally but should not be used by Perl scripts. See *overload* for more details.

94.3.9 Subroutine arguments created only when they're modified

In Perl 5.004, nonexistent array and hash elements used as subroutine parameters are brought into existence only if they are actually assigned to (via `@_`).

Earlier versions of Perl vary in their handling of such arguments. Perl versions 5.002 and 5.003 always brought them into existence. Perl versions 5.000 and 5.001 brought them into existence only if they were not the first argument (which was almost certainly a bug). Earlier versions of Perl never brought them into existence.

For example, given this code:

```
undef @a; undef %a;
sub show { print $_[0] };
sub change { $_[0]++ };
show($a[2]);
change($a{b});
```

After this code executes in Perl 5.004, $a{b} exists but $a[2] does not. In Perl 5.002 and 5.003, both $a{b} and $a[2] would have existed (but $a[2]'s value would have been undefined).

94.3.10 Group vector changeable with `$)`

The `$)` special variable has always (well, in Perl 5, at least) reflected not only the current effective group, but also the group list as returned by the `getgroups()` C function (if there is one). However, until this release, there has not been a way to call the `setgroups()` C function from Perl.

In Perl 5.004, assigning to `$)` is exactly symmetrical with examining it: The first number in its string value is used as the effective gid; if there are any numbers after the first one, they are passed to the `setgroups()` C function (if there is one).

94.3.11 Fixed parsing of $ $ <digit>, &$ <digit>, etc.

Perl versions before 5.004 misinterpreted any type marker followed by "$" and a digit. For example, "$$0" was incorrectly taken to mean "${$}0" instead of "${$0}". This bug is (mostly) fixed in Perl 5.004.

However, the developers of Perl 5.004 could not fix this bug completely, because at least two widely-used modules depend on the old meaning of "$$0" in a string. So Perl 5.004 still interprets "$$<digit>" in the old (broken) way inside strings; but it generates this message as a warning. And in Perl 5.005, this special treatment will cease.

94.3.12 Fixed localization of $ <digit>, $ &, etc.

Perl versions before 5.004 did not always properly localize the regex-related special variables. Perl 5.004 does localize them, as the documentation has always said it should. This may result in $1, $2, etc. no longer being set where existing programs use them.

94.3.13 No resetting of $. on implicit close

The documentation for Perl 5.0 has always stated that `$.` is *not* reset when an already-open file handle is reopened with no intervening call to `close`. Due to a bug, perl versions 5.000 through 5.003 *did* reset `$.` under that circumstance; Perl 5.004 does not.

94.3.14 `wantarray` may return undef

The `wantarray` operator returns true if a subroutine is expected to return a list, and false otherwise. In Perl 5.004, `wantarray` can also return the undefined value if a subroutine's return value will not be used at all, which allows subroutines to avoid a time-consuming calculation of a return value if it isn't going to be used.

94.3.15 `eval EXPR` determines value of EXPR in scalar context

Perl (version 5) used to determine the value of EXPR inconsistently, sometimes incorrectly using the surrounding context for the determination. Now, the value of EXPR (before being parsed by eval) is always determined in a scalar context. Once parsed, it is executed as before, by providing the context that the scope surrounding the eval provided. This change makes the behavior Perl4 compatible, besides fixing bugs resulting from the inconsistent behavior. This program:

```
    @a = qw(time now is time);
    print eval @a;
    print '|', scalar eval @a;
```

used to print something like "timenowis881399109|4", but now (and in perl4) prints "4|4".

94.3.16 Changes to tainting checks

A bug in previous versions may have failed to detect some insecure conditions when taint checks are turned on. (Taint checks are used in setuid or setgid scripts, or when explicitly turned on with the `-T` invocation option.) Although it's unlikely, this may cause a previously-working script to now fail – which should be construed as a blessing, since that indicates a potentially-serious security hole was just plugged.

The new restrictions when tainting include:

No glob() or <*>

These operators may spawn the C shell (csh), which cannot be made safe. This restriction will be lifted in a future version of Perl when globbing is implemented without the use of an external program.

No spawning if tainted $ CDPATH, $ ENV, $ BASH_ENV

These environment variables may alter the behavior of spawned programs (especially shells) in ways that subvert security. So now they are treated as dangerous, in the manner of $IFS and $PATH.

No spawning if tainted $ TERM doesn't look like a terminal name

Some termcap libraries do unsafe things with $TERM. However, it would be unnecessarily harsh to treat all $TERM values as unsafe, since only shell metacharacters can cause trouble in $TERM. So a tainted $TERM is considered to be safe if it contains only alphanumerics, underscores, dashes, and colons, and unsafe if it contains other characters (including whitespace).

94.3.17 New Opcode module and revised Safe module

A new Opcode module supports the creation, manipulation and application of opcode masks. The revised Safe module has a new API and is implemented using the new Opcode module. Please read the new Opcode and Safe documentation.

94.3.18 Embedding improvements

In older versions of Perl it was not possible to create more than one Perl interpreter instance inside a single process without leaking like a sieve and/or crashing. The bugs that caused this behavior have all been fixed. However, you still must take care when embedding Perl in a C program. See the updated perlembed manpage for tips on how to manage your interpreters.

94.3.19 Internal change: FileHandle class based on IO::* classes

File handles are now stored internally as type IO::Handle. The FileHandle module is still supported for backwards compatibility, but it is now merely a front end to the IO::* modules – specifically, IO::Handle, IO::Seekable, and IO::File. We suggest, but do not require, that you use the IO::* modules in new code.

In harmony with this change, `*GLOB{FILEHANDLE}` is now just a backward-compatible synonym for `*GLOB{IO}`.

94.3.20 Internal change: PerlIO abstraction interface

It is now possible to build Perl with AT&T's sfio IO package instead of stdio. See *perlapio* for more details, and the *INSTALL* file for how to use it.

94.3.21 New and changed syntax

$ coderef->(PARAMS)

A subroutine reference may now be suffixed with an arrow and a (possibly empty) parameter list. This syntax denotes a call of the referenced subroutine, with the given parameters (if any).

This new syntax follows the pattern of `$hashref->{FOO}` and `$aryref->[$foo]`: You may now write `&$subref($foo)` as `$subref->($foo)`. All these arrow terms may be chained; thus, `&{$table->{FOO}}($bar)` may now be written `$table->{FOO}->($bar)`.

94.3.22 New and changed builtin constants

__PACKAGE__

The current package name at compile time, or the undefined value if there is no current package (due to a `package;` directive). Like `__FILE__` and `__LINE__`, `__PACKAGE__` does *not* interpolate into strings.

94.3.23 New and changed builtin variables

$ ˆE

Extended error message on some platforms. (Also known as $EXTENDED_OS_ERROR if you `use English`).

$ ˆH

The current set of syntax checks enabled by `use strict`. See the documentation of `strict` for more details. Not actually new, but newly documented. Because it is intended for internal use by Perl core components, there is no `use English` long name for this variable.

$ ˆM

By default, running out of memory it is not trappable. However, if compiled for this, Perl may use the contents of `$ˆM` as an emergency pool after die()ing with this message. Suppose that your Perl were compiled with -DPERL_EMERGENCY_SBRK and used Perl's malloc. Then

```
    $^M = 'a' x (1<<16);
```

would allocate a 64K buffer for use when in emergency. See the *INSTALL* file for information on how to enable this option. As a disincentive to casual use of this advanced feature, there is no `use English` long name for this variable.

94.3.24 New and changed builtin functions

delete on slices

This now works. (e.g. `delete @ENV{'PATH', 'MANPATH'}`)

flock

is now supported on more platforms, prefers fcntl to lockf when emulating, and always flushes before (un)locking.

printf and sprintf

Perl now implements these functions itself; it doesn't use the C library function sprintf() any more, except for floating-point numbers, and even then only known flags are allowed. As a result, it is now possible to know which conversions and flags will work, and what they will do.

The new conversions in Perl's sprintf() are:

```
   %i   a synonym for %d
   %p   a pointer (the address of the Perl value, in hexadecimal)
   %n   special: *stores* the number of characters output so far
        into the next variable in the parameter list
```

The new flags that go between the `%` and the conversion are:

```
   #    prefix octal with "0", hex with "0x"
   h    interpret integer as C type "short" or "unsigned short"
   V    interpret integer as Perl's standard integer type
```

Also, where a number would appear in the flags, an asterisk ("*") may be used instead, in which case Perl uses the next item in the parameter list as the given number (that is, as the field width or precision). If a field width obtained through "*" is negative, it has the same effect as the '-' flag: left-justification.

See sprintf in *perlfunc* for a complete list of conversion and flags.

keys as an lvalue

As an lvalue, `keys` allows you to increase the number of hash buckets allocated for the given hash. This can gain you a measure of efficiency if you know the hash is going to get big. (This is similar to pre-extending an array by assigning a larger number to $#array.) If you say

```
keys %hash = 200;
```

then `%hash` will have at least 200 buckets allocated for it. These buckets will be retained even if you do `%hash = ()`; use `undef %hash` if you want to free the storage while `%hash` is still in scope. You can't shrink the number of buckets allocated for the hash using `keys` in this way (but you needn't worry about doing this by accident, as trying has no effect).

my() in Control Structures

You can now use my() (with or without the parentheses) in the control expressions of control structures such as:

```
while (defined(my $line = <>)) {
    $line = lc $line;
} continue {
    print $line;
}

if ((my $answer = <STDIN>) =~ /^y(es)?$/i) {
    user_agrees();
} elsif ($answer =~ /^n(o)?$/i) {
    user_disagrees();
} else {
    chomp $answer;
    die "'$answer' is neither 'yes' nor 'no'";
}
```

Also, you can declare a foreach loop control variable as lexical by preceding it with the word "my". For example, in:

```
foreach my $i (1, 2, 3) {
    some_function();
}
```

$i is a lexical variable, and the scope of $i extends to the end of the loop, but not beyond it.

Note that you still cannot use my() on global punctuation variables such as $_ and the like.

pack() and unpack()

A new format 'w' represents a BER compressed integer (as defined in ASN.1). Its format is a sequence of one or more bytes, each of which provides seven bits of the total value, with the most significant first. Bit eight of each byte is set, except for the last byte, in which bit eight is clear.

If 'p' or 'P' are given undef as values, they now generate a NULL pointer.

Both pack() and unpack() now fail when their templates contain invalid types. (Invalid types used to be ignored.)

sysseek()

The new sysseek() operator is a variant of seek() that sets and gets the file's system read/write position, using the lseek(2) system call. It is the only reliable way to seek before using sysread() or syswrite(). Its return value is the new position, or the undefined value on failure.

use VERSION

If the first argument to `use` is a number, it is treated as a version number instead of a module name. If the version of the Perl interpreter is less than VERSION, then an error message is printed and Perl exits immediately. Because `use` occurs at compile time, this check happens immediately during the compilation process, unlike `require VERSION`, which waits until runtime for the check. This is often useful if you need to check the current Perl version before `use`ing library modules which have changed in incompatible ways from older versions of Perl. (We try not to do this more than we have to.)

use Module VERSION LIST

If the VERSION argument is present between Module and LIST, then the `use` will call the VERSION method in class Module with the given version as an argument. The default VERSION method, inherited from the UNIVERSAL class, croaks if the given version is larger than the value of the variable $Module::VERSION. (Note that there is not a comma after VERSION!)

This version-checking mechanism is similar to the one currently used in the Exporter module, but it is faster and can be used with modules that don't use the Exporter. It is the recommended method for new code.

prototype(FUNCTION)

Returns the prototype of a function as a string (or `undef` if the function has no prototype). FUNCTION is a reference to or the name of the function whose prototype you want to retrieve. (Not actually new; just never documented before.)

srand

The default seed for `srand`, which used to be `time`, has been changed. Now it's a heady mix of difficult-to-predict system-dependent values, which should be sufficient for most everyday purposes.

Previous to version 5.004, calling `rand` without first calling `srand` would yield the same sequence of random numbers on most or all machines. Now, when perl sees that you're calling `rand` and haven't yet called `srand`, it calls `srand` with the default seed. You should still call `srand` manually if your code might ever be run on a pre-5.004 system, of course, or if you want a seed other than the default.

$ _ as Default

Functions documented in the Camel to default to $_ now in fact do, and all those that do are so documented in *perlfunc*.

`m//gc` does not reset search position on failure

The `m//g` match iteration construct has always reset its target string's search position (which is visible through the `pos` operator) when a match fails; as a result, the next `m//g` match after a failure starts again at the beginning of the string. With Perl 5.004, this reset may be disabled by adding the "c" (for "continue") modifier, i.e. `m//gc`. This feature, in conjunction with the `\G` zero-width assertion, makes it possible to chain matches together. See *perlop* and *perlre*.

`m//x` ignores whitespace before ?*+{}

The `m//x` construct has always been intended to ignore all unescaped whitespace. However, before Perl 5.004, whitespace had the effect of escaping repeat modifiers like "*" or "?"; for example, `/a *b/x` was (mis)interpreted as `/a\*b/x`. This bug has been fixed in 5.004.

nested `sub{}` closures work now

Prior to the 5.004 release, nested anonymous functions didn't work right. They do now.

formats work right on changing lexicals

Just like anonymous functions that contain lexical variables that change (like a lexical index variable for a `foreach` loop), formats now work properly. For example, this silently failed before (printed only zeros), but is fine now:

```
    my $i;
    foreach $i ( 1 .. 10 ) {
        write;
    }
    format =
        my i is @#
        $i
    .
```

However, it still fails (without a warning) if the foreach is within a subroutine:

```
    my $i;
    sub foo {
      foreach $i ( 1 .. 10 ) {
        write;
      }
    }
    foo;
    format =
        my i is @#
        $i
    .
```

94.3.25 New builtin methods

The `UNIVERSAL` package automatically contains the following methods that are inherited by all other classes:

isa(CLASS)

`isa` returns *true* if its object is blessed into a subclass of `CLASS`

`isa` is also exportable and can be called as a sub with two arguments. This allows the ability to check what a reference points to. Example:

```
    use UNIVERSAL qw(isa);

    if(isa($ref, 'ARRAY')) {
       ...
    }
```

can(METHOD)

`can` checks to see if its object has a method called `METHOD`, if it does then a reference to the sub is returned; if it does not then *undef* is returned.

VERSION([NEED)]

`VERSION` returns the version number of the class (package). If the NEED argument is given then it will check that the current version (as defined by the $VERSION variable in the given package) not less than NEED; it will die if this is not the case. This method is normally called as a class method. This method is called automatically by the `VERSION` form of `use`.

```
    use A 1.2 qw(some imported subs);
    # implies:
    A->VERSION(1.2);
```

NOTE: `can` directly uses Perl's internal code for method lookup, and `isa` uses a very similar method and caching strategy. This may cause strange effects if the Perl code dynamically changes @ISA in any package.

You may add other methods to the UNIVERSAL class via Perl or XS code. You do not need to `use UNIVERSAL` in order to make these methods available to your program. This is necessary only if you wish to have `isa` available as a plain subroutine in the current package.

94.3.26 TIEHANDLE now supported

See *perltie* for other kinds of tie()s.

TIEHANDLE classname, LIST

This is the constructor for the class. That means it is expected to return an object of some sort. The reference can be used to hold some internal information.

```
sub TIEHANDLE {
    print "<shout>\n";
    my $i;
    return bless \$i, shift;
}
```

PRINT this, LIST

This method will be triggered every time the tied handle is printed to. Beyond its self reference it also expects the list that was passed to the print function.

```
sub PRINT {
    $r = shift;
    $$r++;
    return print join( $, => map {uc} @_), $\;
}
```

PRINTF this, LIST

This method will be triggered every time the tied handle is printed to with the `printf()` function. Beyond its self reference it also expects the format and list that was passed to the printf function.

```
sub PRINTF {
    shift;
      my $fmt = shift;
    print sprintf($fmt, @_)."\n";
}
```

READ this LIST

This method will be called when the handle is read from via the `read` or `sysread` functions.

```
sub READ {
    $r = shift;
    my($buf,$len,$offset) = @_;
    print "READ called, \$buf=$buf, \$len=$len, \$offset=$offset";
}
```

READLINE this

This method will be called when the handle is read from. The method should return undef when there is no more data.

```
sub READLINE {
    $r = shift;
    return "PRINT called $$r times\n"
}
```

GETC this

This method will be called when the `getc` function is called.

```
        sub GETC { print "Don't GETC, Get Perl"; return "a"; }
```

DESTROY this

As with the other types of ties, this method will be called when the tied handle is about to be destroyed. This is useful for debugging and possibly for cleaning up.

```
        sub DESTROY {
            print "</shout>\n";
        }
```

94.3.27 Malloc enhancements

If perl is compiled with the malloc included with the perl distribution (that is, if `perl -V:d_mymalloc` is 'define') then you can print memory statistics at runtime by running Perl thusly:

```
  env PERL_DEBUG_MSTATS=2 perl your_script_here
```

The value of 2 means to print statistics after compilation and on exit; with a value of 1, the statistics are printed only on exit. (If you want the statistics at an arbitrary time, you'll need to install the optional module Devel::Peek.)

Three new compilation flags are recognized by malloc.c. (They have no effect if perl is compiled with system malloc().)

-DPERL_EMERGENCY_SBRK

If this macro is defined, running out of memory need not be a fatal error: a memory pool can allocated by assigning to the special variable `$^M`. See §**??**.

-DPACK_MALLOC

Perl memory allocation is by bucket with sizes close to powers of two. Because of these malloc overhead may be big, especially for data of size exactly a power of two. If `PACK_MALLOC` is defined, perl uses a slightly different algorithm for small allocations (up to 64 bytes long), which makes it possible to have overhead down to 1 byte for allocations which are powers of two (and appear quite often).

Expected memory savings (with 8-byte alignment in `alignbytes`) is about 20% for typical Perl usage. Expected slowdown due to additional malloc overhead is in fractions of a percent (hard to measure, because of the effect of saved memory on speed).

-DTWO_POT_OPTIMIZE

Similarly to `PACK_MALLOC`, this macro improves allocations of data with size close to a power of two; but this works for big allocations (starting with 16K by default). Such allocations are typical for big hashes and special-purpose scripts, especially image processing.

On recent systems, the fact that perl requires 2M from system for 1M allocation will not affect speed of execution, since the tail of such a chunk is not going to be touched (and thus will not require real memory). However, it may result in a premature out-of-memory error. So if you will be manipulating very large blocks with sizes close to powers of two, it would be wise to define this macro.

Expected saving of memory is 0-100% (100% in applications which require most memory in such 2**n chunks); expected slowdown is negligible.

94.3.28 Miscellaneous efficiency enhancements

Functions that have an empty prototype and that do nothing but return a fixed value are now inlined (e.g. `sub PI () { 3.14159 }`).

Each unique hash key is only allocated once, no matter how many hashes have an entry with that key. So even if you have 100 copies of the same hash, the hash keys never have to be reallocated.

94.4 Support for More Operating Systems

Support for the following operating systems is new in Perl 5.004.

94.4.1 Win32

Perl 5.004 now includes support for building a "native" perl under Windows NT, using the Microsoft Visual C++ compiler (versions 2.0 and above) or the Borland C++ compiler (versions 5.02 and above). The resulting perl can be used under Windows 95 (if it is installed in the same directory locations as it got installed in Windows NT). This port includes support for perl extension building tools like *MakeMaker* and *h2xs*, so that many extensions available on the Comprehensive Perl Archive Network (CPAN) can now be readily built under Windows NT. See http://www.perl.com/ for more information on CPAN and *README.win32* in the perl distribution for more details on how to get started with building this port.

There is also support for building perl under the Cygwin32 environment. Cygwin32 is a set of GNU tools that make it possible to compile and run many Unix programs under Windows NT by providing a mostly Unix-like interface for compilation and execution. See *README.cygwin32* in the perl distribution for more details on this port and how to obtain the Cygwin32 toolkit.

94.4.2 Plan 9

See *README.plan9* in the perl distribution.

94.4.3 QNX

See *README.qnx* in the perl distribution.

94.4.4 AmigaOS

See *README.amigaos* in the perl distribution.

94.5 Pragmata

Six new pragmatic modules exist:

use autouse MODULE => qw(sub1 sub2 sub3)

Defers `require MODULE` until someone calls one of the specified subroutines (which must be exported by MODULE). This pragma should be used with caution, and only when necessary.

use blib

use blib 'dir'

Looks for MakeMaker-like *'blib'* directory structure starting in *dir* (or current directory) and working back up to five levels of parent directories.

Intended for use on command line with **-M** option as a way of testing arbitrary scripts against an uninstalled version of a package.

use constant NAME => VALUE

Provides a convenient interface for creating compile-time constants, See Constant Functions in *perlsub*.

use locale

Tells the compiler to enable (or disable) the use of POSIX locales for builtin operations.

When `use locale` is in effect, the current LC_CTYPE locale is used for regular expressions and case mapping; LC_COLLATE for string ordering; and LC_NUMERIC for numeric formatting in printf and sprintf (but **not** in print). LC_NUMERIC is always used in write, since lexical scoping of formats is problematic at best.

Each `use locale` or `no locale` affects statements to the end of the enclosing BLOCK or, if not inside a BLOCK, to the end of the current file. Locales can be switched and queried with POSIX::setlocale().

See *perllocale* for more information.

use ops

Disable unsafe opcodes, or any named opcodes, when compiling Perl code.

use vmsish

Enable VMS-specific language features. Currently, there are three VMS-specific features available: 'status', which makes `$?` and `system` return genuine VMS status values instead of emulating POSIX; 'exit', which makes `exit` take a genuine VMS status value instead of assuming that `exit 1` is an error; and 'time', which makes all times relative to the local time zone, in the VMS tradition.

94.6 Modules

94.6.1 Required Updates

Though Perl 5.004 is compatible with almost all modules that work with Perl 5.003, there are a few exceptions:

```
    Module   Required Version for Perl 5.004
    ------   -------------------------------
    Filter   Filter-1.12
    LWP      libwww-perl-5.08
    Tk       Tk400.202 (-w makes noise)
```

Also, the majordomo mailing list program, version 1.94.1, doesn't work with Perl 5.004 (nor with perl 4), because it executes an invalid regular expression. This bug is fixed in majordomo version 1.94.2.

94.6.2 Installation directories

The *installperl* script now places the Perl source files for extensions in the architecture-specific library directory, which is where the shared libraries for extensions have always been. This change is intended to allow administrators to keep the Perl 5.004 library directory unchanged from a previous version, without running the risk of binary incompatibility between extensions' Perl source and shared libraries.

94.6.3 Module information summary

Brand new modules, arranged by topic rather than strictly alphabetically:

```
    CGI.pm              Web server interface ("Common Gateway Interface")
    CGI/Apache.pm       Support for Apache's Perl module
    CGI/Carp.pm         Log server errors with helpful context
    CGI/Fast.pm         Support for FastCGI (persistent server process)
    CGI/Push.pm         Support for server push
    CGI/Switch.pm       Simple interface for multiple server types
    CPAN                Interface to Comprehensive Perl Archive Network
    CPAN::FirstTime     Utility for creating CPAN configuration file
    CPAN::Nox           Runs CPAN while avoiding compiled extensions

    IO.pm               Top-level interface to IO::* classes
    IO/File.pm          IO::File extension Perl module
    IO/Handle.pm        IO::Handle extension Perl module
    IO/Pipe.pm          IO::Pipe extension Perl module
    IO/Seekable.pm      IO::Seekable extension Perl module
    IO/Select.pm        IO::Select extension Perl module
    IO/Socket.pm        IO::Socket extension Perl module

    Opcode.pm           Disable named opcodes when compiling Perl code

    ExtUtils/Embed.pm   Utilities for embedding Perl in C programs
    ExtUtils/testlib.pm Fixes up @INC to use just-built extension

    FindBin.pm          Find path of currently executing program

    Class/Struct.pm     Declare struct-like datatypes as Perl classes
    File/stat.pm        By-name interface to Perl's builtin stat
    Net/hostent.pm      By-name interface to Perl's builtin gethost*
    Net/netent.pm       By-name interface to Perl's builtin getnet*
    Net/protoent.pm     By-name interface to Perl's builtin getproto*
    Net/servent.pm      By-name interface to Perl's builtin getserv*
    Time/gmtime.pm      By-name interface to Perl's builtin gmtime
    Time/localtime.pm   By-name interface to Perl's builtin localtime
    Time/tm.pm          Internal object for Time::{gm,local}time
    User/grent.pm       By-name interface to Perl's builtin getgr*
    User/pwent.pm       By-name interface to Perl's builtin getpw*

    Tie/RefHash.pm      Base class for tied hashes with references as keys

    UNIVERSAL.pm        Base class for *ALL* classes
```

94.6.4 Fcntl

New constants in the existing Fcntl modules are now supported, provided that your operating system happens to support them:

```
    F_GETOWN F_SETOWN
    O_ASYNC O_DEFER O_DSYNC O_FSYNC O_SYNC
    O_EXLOCK O_SHLOCK
```

These constants are intended for use with the Perl operators sysopen() and fcntl() and the basic database modules like SDBM_File. For the exact meaning of these and other Fcntl constants please refer to your operating system's documentation for fcntl() and open().

In addition, the Fcntl module now provides these constants for use with the Perl operator flock():

```
        LOCK_SH LOCK_EX LOCK_NB LOCK_UN
```

These constants are defined in all environments (because where there is no flock() system call, Perl emulates it). However, for historical reasons, these constants are not exported unless they are explicitly requested with the ":flock" tag (e.g. `use Fcntl ':flock'`).

94.6.5 IO

The IO module provides a simple mechanism to load all the IO modules at one go. Currently this includes:

```
     IO::Handle
     IO::Seekable
     IO::File
     IO::Pipe
     IO::Socket
```

For more information on any of these modules, please see its respective documentation.

94.6.6 Math::Complex

The Math::Complex module has been totally rewritten, and now supports more operations. These are overloaded:

```
     + - * / ** <=> neg ~ abs sqrt exp log sin cos atan2 "" (stringify)
```

And these functions are now exported:

```
    pi i Re Im arg
    log10 logn ln cbrt root
    tan
    csc sec cot
    asin acos atan
    acsc asec acot
    sinh cosh tanh
    csch sech coth
    asinh acosh atanh
    acsch asech acoth
    cplx cplxe
```

94.6.7 Math::Trig

This new module provides a simpler interface to parts of Math::Complex for those who need trigonometric functions only for real numbers.

94.6.8 DB_File

There have been quite a few changes made to DB_File. Here are a few of the highlights:

- Fixed a handful of bugs.
- By public demand, added support for the standard hash function exists().
- Made it compatible with Berkeley DB 1.86.
- Made negative subscripts work with RECNO interface.
- Changed the default flags from O_RDWR to O_CREAT|O_RDWR and the default mode from 0640 to 0666.
- Made DB_File automatically import the open() constants (O_RDWR, O_CREAT etc.) from Fcntl, if available.
- Updated documentation.

Refer to the HISTORY section in DB_File.pm for a complete list of changes. Everything after DB_File 1.01 has been added since 5.003.

94.6.9 Net::Ping

Major rewrite - support added for both udp echo and real icmp pings.

94.6.10 Object-oriented overrides for builtin operators

Many of the Perl builtins returning lists now have object-oriented overrides. These are:

```
    File::stat
    Net::hostent
    Net::netent
    Net::protoent
    Net::servent
    Time::gmtime
    Time::localtime
    User::grent
    User::pwent
```

For example, you can now say

```
    use File::stat;
    use User::pwent;
    $his = (stat($filename)->st_uid == pwent($whoever)->pw_uid);
```

94.7 Utility Changes

94.7.1 pod2html

Sends converted HTML to standard output

The *pod2html* utility included with Perl 5.004 is entirely new. By default, it sends the converted HTML to its standard output, instead of writing it to a file like Perl 5.003's *pod2html* did. Use the **–outfile=FILENAME** option to write to a file.

94.7.2 xsubpp

`void` XSUBs now default to returning nothing

Due to a documentation/implementation bug in previous versions of Perl, XSUBs with a return type of `void` have actually been returning one value. Usually that value was the GV for the XSUB, but sometimes it was some already freed or reused value, which would sometimes lead to program failure.

In Perl 5.004, if an XSUB is declared as returning `void`, it actually returns no value, i.e. an empty list (though there is a backward-compatibility exception; see below). If your XSUB really does return an SV, you should give it a return type of `SV *`.

For backward compatibility, *xsubpp* tries to guess whether a `void` XSUB is really `void` or if it wants to return an `SV *`. It does so by examining the text of the XSUB: if *xsubpp* finds what looks like an assignment to `ST(0)`, it assumes that the XSUB's return type is really `SV *`.

94.8 C Language API Changes

`gv_fetchmethod` and `perl_call_sv`

The `gv_fetchmethod` function finds a method for an object, just like in Perl 5.003. The GV it returns may be a method cache entry. However, in Perl 5.004, method cache entries are not visible to users; therefore, they can no longer be passed directly to `perl_call_sv`. Instead, you should use the `GvCV` macro on the GV to extract its CV, and pass the CV to `perl_call_sv`.

The most likely symptom of passing the result of `gv_fetchmethod` to `perl_call_sv` is Perl's producing an "Undefined subroutine called" error on the *second* call to a given method (since there is no cache on the first call).

`perl_eval_pv`

A new function handy for eval'ing strings of Perl code inside C code. This function returns the value from the eval statement, which can be used instead of fetching globals from the symbol table. See *perlguts*, *perlembed* and *perlcall* for details and examples.

Extended API for manipulating hashes

Internal handling of hash keys has changed. The old hashtable API is still fully supported, and will likely remain so. The additions to the API allow passing keys as `SV*`s, so that `tied` hashes can be given real scalars as keys rather than plain strings (nontied hashes still can only use strings as keys). New extensions must use the new hash access functions and macros if they wish to use `SV*` keys. These additions also make it feasible to manipulate `HE*`s (hash entries), which can be more efficient. See *perlguts* for details.

94.9 Documentation Changes

Many of the base and library pods were updated. These new pods are included in section 1:

perldelta

This document.

perlfaq

Frequently asked questions.

perllocale

Locale support (internationalization and localization).

perltoot

Tutorial on Perl OO programming.

perlapio

Perl internal IO abstraction interface.

perlmodlib

Perl module library and recommended practice for module creation. Extracted from *perlmod* (which is much smaller as a result).

perldebug

Although not new, this has been massively updated.

perlsec

Although not new, this has been massively updated.

94.10 New Diagnostics

Several new conditions will trigger warnings that were silent before. Some only affect certain platforms. The following new warnings and errors outline these. These messages are classified as follows (listed in increasing order of desperation):

```
(W) A warning (optional).
(D) A deprecation (optional).
(S) A severe warning (mandatory).
(F) A fatal error (trappable).
(P) An internal error you should never see (trappable).
(X) A very fatal error (nontrappable).
(A) An alien error message (not generated by Perl).
```

"my" variable %s masks earlier declaration in same scope

(W) A lexical variable has been redeclared in the same scope, effectively eliminating all access to the previous instance. This is almost always a typographical error. Note that the earlier variable will still exist until the end of the scope or until all closure referents to it are destroyed.

%s argument is not a HASH element or slice

(F) The argument to delete() must be either a hash element, such as

```
$foo{$bar}
$ref->[12]->{"susie"}
```

or a hash slice, such as

```
@foo{$bar, $baz, $xyzzy}
@{$ref->[12]}{"susie", "queue"}
```

Allocation too large: %lx

(X) You can't allocate more than 64K on an MS-DOS machine.

Allocation too large

(F) You can't allocate more than 2ˆ31+"small amount" bytes.

Applying %s to %s will act on scalar(%s)

(W) The pattern match (//), substitution (s///), and transliteration (tr///) operators work on scalar values. If you apply one of them to an array or a hash, it will convert the array or hash to a scalar value – the length of an array, or the population info of a hash – and then work on that scalar value. This is probably not what you meant to do. See grep in *perlfunc* and map in *perlfunc* for alternatives.

Attempt to free nonexistent shared string

(P) Perl maintains a reference counted internal table of strings to optimize the storage and access of hash keys and other strings. This indicates someone tried to decrement the reference count of a string that can no longer be found in the table.

Attempt to use reference as lvalue in substr

(W) You supplied a reference as the first argument to substr() used as an lvalue, which is pretty strange. Perhaps you forgot to dereference it first. See substr in *perlfunc*.

Bareword "%s" refers to nonexistent package

(W) You used a qualified bareword of the form `Foo::`, but the compiler saw no other uses of that namespace before that point. Perhaps you need to predeclare a package?

Can’t redefine active sort subroutine %s

(F) Perl optimizes the internal handling of sort subroutines and keeps pointers into them. You tried to redefine one such sort subroutine when it was currently active, which is not allowed. If you really want to do this, you should write `sort { &func } @x` instead of `sort func @x`.

Can’t use bareword ("%s") as %s ref while "strict refs" in use

(F) Only hard references are allowed by "strict refs". Symbolic references are disallowed. See *perlref*.

Cannot resolve method ‘%s’ overloading ‘%s’ in package ‘%s’

(P) Internal error trying to resolve overloading specified by a method name (as opposed to a subroutine reference).

Constant subroutine %s redefined

(S) You redefined a subroutine which had previously been eligible for inlining. See Constant Functions in *perlsub* for commentary and workarounds.

Constant subroutine %s undefined

(S) You undefined a subroutine which had previously been eligible for inlining. See Constant Functions in *perlsub* for commentary and workarounds.

Copy method did not return a reference

(F) The method which overloads "=" is buggy. See Copy Constructor in *overload*.

Died

(F) You passed die() an empty string (the equivalent of `die ""`) or you called it with no args and both `$@` and `$_` were empty.

Exiting pseudo-block via %s

(W) You are exiting a rather special block construct (like a sort block or subroutine) by unconventional means, such as a goto, or a loop control statement. See sort in *perlfunc*.

Identifier too long

(F) Perl limits identifiers (names for variables, functions, etc.) to 252 characters for simple names, somewhat more for compound names (like `$A::B`). You’ve exceeded Perl’s limits. Future versions of Perl are likely to eliminate these arbitrary limitations.

Illegal character %s (carriage return)

(F) A carriage return character was found in the input. This is an error, and not a warning, because carriage return characters can break multi-line strings, including here documents (e.g., `print <<EOF;`).

Illegal switch in PERL5OPT: %s

(X) The PERL5OPT environment variable may only be used to set the following switches: **-[DIMUdmw]**.

Integer overflow in hex number

(S) The literal hex number you have specified is too big for your architecture. On a 32-bit architecture the largest hex literal is 0xFFFFFFFF.

Integer overflow in octal number

(S) The literal octal number you have specified is too big for your architecture. On a 32-bit architecture the largest octal literal is 037777777777.

internal error: glob failed

(P) Something went wrong with the external program(s) used for `glob` and `<*.c>`. This may mean that your csh (C shell) is broken. If so, you should change all of the csh-related variables in config.sh: If you have tcsh, make the variables refer to it as if it were csh (e.g. `full_csh='/usr/bin/tcsh'`); otherwise, make them all empty (except that `d_csh` should be `'undef'`) so that Perl will think csh is missing. In either case, after editing config.sh, run `./Configure -S` and rebuild Perl.

Invalid conversion in %s: "%s"

(W) Perl does not understand the given format conversion. See sprintf in *perlfunc*.

Invalid type in pack: '%s'

(F) The given character is not a valid pack type. See pack in *perlfunc*.

Invalid type in unpack: '%s'

(F) The given character is not a valid unpack type. See unpack in *perlfunc*.

Name "%s::%s" used only once: possible typo

(W) Typographical errors often show up as unique variable names. If you had a good reason for having a unique name, then just mention it again somehow to suppress the message (the `use vars` pragma is provided for just this purpose).

Null picture in formline

(F) The first argument to formline must be a valid format picture specification. It was found to be empty, which probably means you supplied it an uninitialized value. See *perlform*.

Offset outside string

(F) You tried to do a read/write/send/recv operation with an offset pointing outside the buffer. This is difficult to imagine. The sole exception to this is that `sysread()`ing past the buffer will extend the buffer and zero pad the new area.

Out of memory!

(X|F) The malloc() function returned 0, indicating there was insufficient remaining memory (or virtual memory) to satisfy the request.

The request was judged to be small, so the possibility to trap it depends on the way Perl was compiled. By default it is not trappable. However, if compiled for this, Perl may use the contents of `$^M` as an emergency pool after die()ing with this message. In this case the error is trappable *once*.

Out of memory during request for %s

(F) The malloc() function returned 0, indicating there was insufficient remaining memory (or virtual memory) to satisfy the request. However, the request was judged large enough (compile-time default is 64K), so a possibility to shut down by trapping this error is granted.

panic: frexp

(P) The library function frexp() failed, making printf("%f") impossible.

Possible attempt to put comments in qw() list

(W) qw() lists contain items separated by whitespace; as with literal strings, comment characters are not ignored, but are instead treated as literal data. (You may have used different delimiters than the parentheses shown here; braces are also frequently used.)

You probably wrote something like this:

```
@list = qw(
    a # a comment
    b # another comment
);
```

when you should have written this:

```
@list = qw(
    a
    b
);
```

If you really want comments, build your list the old-fashioned way, with quotes and commas:

```
@list = (
    'a',    # a comment
    'b',    # another comment
);
```

Possible attempt to separate words with commas

(W) qw() lists contain items separated by whitespace; therefore commas aren't needed to separate the items. (You may have used different delimiters than the parentheses shown here; braces are also frequently used.)

You probably wrote something like this:

```
qw! a, b, c !;
```

which puts literal commas into some of the list items. Write it without commas if you don't want them to appear in your data:

```
qw! a b c !;
```

Scalar value @%s{%s} better written as $ %s{%s}

(W) You've used a hash slice (indicated by @) to select a single element of a hash. Generally it's better to ask for a scalar value (indicated by $). The difference is that `$foo{&bar}` always behaves like a scalar, both when assigning to it and when evaluating its argument, while `@foo{&bar}` behaves like a list when you assign to it, and provides a list context to its subscript, which can do weird things if you're expecting only one subscript.

Stub found while resolving method '%s' overloading '%s' in %s

(P) Overloading resolution over @ISA tree may be broken by importing stubs. Stubs should never be implicitly created, but explicit calls to `can` may break this.

Too late for "-T" option

(X) The #! line (or local equivalent) in a Perl script contains the **-T** option, but Perl was not invoked with **-T** in its argument list. This is an error because, by the time Perl discovers a **-T** in a script, it's too late to properly taint everything from the environment. So Perl gives up.

untie attempted while %d inner references still exist

(W) A copy of the object returned from `tie` (or `tied`) was still valid when `untie` was called.

Unrecognized character %s

(F) The Perl parser has no idea what to do with the specified character in your Perl script (or eval). Perhaps you tried to run a compressed script, a binary program, or a directory as a Perl program.

Unsupported function fork

(F) Your version of executable does not support forking.

Note that under some systems, like OS/2, there may be different flavors of Perl executables, some of which may support fork, some not. Try changing the name you call Perl by to `perl_`, `perl__`, and so on.

Use of "$ $ <digit>" to mean "$ {$ }<digit>" is deprecated

(D) Perl versions before 5.004 misinterpreted any type marker followed by "$" and a digit. For example, "$$0" was incorrectly taken to mean "${$}0" instead of "${$0}". This bug is (mostly) fixed in Perl 5.004.

However, the developers of Perl 5.004 could not fix this bug completely, because at least two widely-used modules depend on the old meaning of "$$0" in a string. So Perl 5.004 still interprets "$$<digit>" in the old (broken) way inside strings; but it generates this message as a warning. And in Perl 5.005, this special treatment will cease.

Value of %s can be "0"; test with defined()

(W) In a conditional expression, you used <HANDLE>, <*> (glob), `each()`, or `readdir()` as a boolean value. Each of these constructs can return a value of "0"; that would make the conditional expression false, which is probably not what you intended. When using these constructs in conditional expressions, test their values with the `defined` operator.

Variable "%s" may be unavailable

(W) An inner (nested) *anonymous* subroutine is inside a *named* subroutine, and outside that is another subroutine; and the anonymous (innermost) subroutine is referencing a lexical variable defined in the outermost subroutine. For example:

```
sub outermost { my $a; sub middle { sub { $a } } }
```

If the anonymous subroutine is called or referenced (directly or indirectly) from the outermost subroutine, it will share the variable as you would expect. But if the anonymous subroutine is called or referenced when the outermost subroutine is not active, it will see the value of the shared variable as it was before and during the *first* call to the outermost subroutine, which is probably not what you want.

In these circumstances, it is usually best to make the middle subroutine anonymous, using the `sub {}` syntax. Perl has specific support for shared variables in nested anonymous subroutines; a named subroutine in between interferes with this feature.

Variable "%s" will not stay shared

(W) An inner (nested) *named* subroutine is referencing a lexical variable defined in an outer subroutine.

When the inner subroutine is called, it will probably see the value of the outer subroutine's variable as it was before and during the *first* call to the outer subroutine; in this case, after the first call to the outer subroutine is complete, the inner and outer subroutines will no longer share a common value for the variable. In other words, the variable will no longer be shared.

Furthermore, if the outer subroutine is anonymous and references a lexical variable outside itself, then the outer and inner subroutines will *never* share the given variable.

This problem can usually be solved by making the inner subroutine anonymous, using the `sub {}` syntax. When inner anonymous subs that reference variables in outer subroutines are called or referenced, they are automatically rebound to the current values of such variables.

Warning: something's wrong

(W) You passed warn() an empty string (the equivalent of `warn ""`) or you called it with no args and `$_` was empty.

Ill-formed logical name |%s| in prime_env_iter

(W) A warning peculiar to VMS. A logical name was encountered when preparing to iterate over %ENV which violates the syntactic rules governing logical names. Since it cannot be translated normally, it is skipped, and will not appear in %ENV. This may be a benign occurrence, as some software packages might directly modify logical name tables and introduce nonstandard names, or it may indicate that a logical name table has been corrupted.

Got an error from DosAllocMem

(P) An error peculiar to OS/2. Most probably you're using an obsolete version of Perl, and this should not happen anyway.

Malformed PERLLIB_PREFIX

(F) An error peculiar to OS/2. PERLLIB_PREFIX should be of the form

```
prefix1;prefix2
```

or

```
prefix1 prefix2
```

with nonempty prefix1 and prefix2. If `prefix1` is indeed a prefix of a builtin library search path, prefix2 is substituted. The error may appear if components are not found, or are too long. See "PERLLIB_PREFIX" in *README.os2*.

PERL_SH_DIR too long

(F) An error peculiar to OS/2. PERL_SH_DIR is the directory to find the `sh`-shell in. See "PERL_SH_DIR" in *README.os2*.

Process terminated by SIG%s

(W) This is a standard message issued by OS/2 applications, while *nix applications die in silence. It is considered a feature of the OS/2 port. One can easily disable this by appropriate sighandlers, see Signals in *perlipc*. See also "Process terminated by SIGTERM/SIGINT" in *README.os2*.

94.11 BUGS

If you find what you think is a bug, you might check the headers of recently posted articles in the comp.lang.perl.misc newsgroup. There may also be information at http://www.perl.com/perl/ , the Perl Home Page.

If you believe you have an unreported bug, please run the **perlbug** program included with your release. Make sure you trim your bug down to a tiny but sufficient test case. Your bug report, along with the output of `perl -V`, will be sent off to <*perlbug@perl.com*> to be analysed by the Perl porting team.

94.12 SEE ALSO

The *Changes* file for exhaustive details on what changed.

The *INSTALL* file for how to build Perl. This file has been significantly updated for 5.004, so even veteran users should look through it.

The *README* file for general stuff.

The *Copying* file for copyright information.

94.13 HISTORY

Constructed by Tom Christiansen, grabbing material with permission from innumerable contributors, with kibitzing by more than a few Perl porters.

Chapter 95

perlartistic

The Perl Artistic License

95.1 SYNOPSIS

```
 You can refer to this document in Pod via "L<perlartistic>"
 Or you can see this document by entering "perldoc perlartistic"
```

95.2 DESCRIPTION

This is **"The Artistic License"**. It's here so that modules, programs, etc., that want to declare this as their distribution license, can link to it.

It is also one of the two licenses Perl allows itself to be redistributed and/or modified; for the other one, the GNU General Public License, see the *perlgpl*.

95.3 The "Artistic License"

95.3.1 Preamble

The intent of this document is to state the conditions under which a Package may be copied, such that the Copyright Holder maintains some semblance of artistic control over the development of the package, while giving the users of the package the right to use and distribute the Package in a more-or-less customary fashion, plus the right to make reasonable modifications.

95.3.2 Definitions

"Package"

refers to the collection of files distributed by the Copyright Holder, and derivatives of that collection of files created through textual modification.

"Standard Version"

refers to such a Package if it has not been modified, or has been modified in accordance with the wishes of the Copyright Holder as specified below.

"Copyright Holder"

is whoever is named in the copyright or copyrights for the package.

"You"

is you, if you’re thinking about copying or distributing this Package.

"Reasonable copying fee"

is whatever you can justify on the basis of media cost, duplication charges, time of people involved, and so on. (You will not be required to justify it to the Copyright Holder, but only to the computing community at large as a market that must bear the fee.)

"Freely Available"

means that no fee is charged for the item itself, though there may be fees involved in handling the item. It also means that recipients of the item may redistribute it under the same conditions they received it.

95.3.3 Conditions

1. You may make and give away verbatim copies of the source form of the Standard Version of this Package without restriction, provided that you duplicate all of the original copyright notices and associated disclaimers.
2. You may apply bug fixes, portability fixes and other modifications derived from the Public Domain or from the Copyright Holder. A Package modified in such a way shall still be considered the Standard Version.
3. You may otherwise modify your copy of this Package in any way, provided that you insert a prominent notice in each changed file stating how and when you changed that file, and provided that you do at least ONE of the following:

   a)

   place your modifications in the Public Domain or otherwise make them Freely Available, such as by posting said modifications to Usenet or an equivalent medium, or placing the modifications on a major archive site such as uunet.uu.net, or by allowing the Copyright Holder to include your modifications in the Standard Version of the Package.

   b)

   use the modified Package only within your corporation or organization.

   c)

   rename any non-standard executables so the names do not conflict with standard executables, which must also be provided, and provide a separate manual page for each non-standard executable that clearly documents how it differs from the Standard Version.

   d)

   make other distribution arrangements with the Copyright Holder.

4. You may distribute the programs of this Package in object code or executable form, provided that you do at least ONE of the following:

   a)

   distribute a Standard Version of the executables and library files, together with instructions (in the manual page or equivalent) on where to get the Standard Version.

   b)

   accompany the distribution with the machine-readable source of the Package with your modifications.

   c)

   give non-standard executables non-standard names, and clearly document the differences in manual pages (or equivalent), together with instructions on where to get the Standard Version.

   d)

   make other distribution arrangements with the Copyright Holder.

5. You may charge a reasonable copying fee for any distribution of this Package. You may charge any fee you choose for support of this Package. You may not charge a fee for this Package itself. However, you may distribute this Package in aggregate with other (possibly commercial) programs as part of a larger (possibly commercial) software distribution provided that you do not advertise this Package as a product of your own. You may embed this Package's interpreter within an executable of yours (by linking); this shall be construed as a mere form of aggregation, provided that the complete Standard Version of the interpreter is so embedded.
6. The scripts and library files supplied as input to or produced as output from the programs of this Package do not automatically fall under the copyright of this Package, but belong to whoever generated them, and may be sold commercially, and may be aggregated with this Package. If such scripts or library files are aggregated with this Package via the so-called "undump" or "unexec" methods of producing a binary executable image, then distribution of such an image shall neither be construed as a distribution of this Package nor shall it fall under the restrictions of Paragraphs 3 and 4, provided that you do not represent such an executable image as a Standard Version of this Package.
7. C subroutines (or comparably compiled subroutines in other languages) supplied by you and linked into this Package in order to emulate subroutines and variables of the language defined by this Package shall not be considered part of this Package, but are the equivalent of input as in Paragraph 6, provided these subroutines do not change the language in any way that would cause it to fail the regression tests for the language.
8. Aggregation of this Package with a commercial distribution is always permitted provided that the use of this Package is embedded; that is, when no overt attempt is made to make this Package's interfaces visible to the end user of the commercial distribution. Such use shall not be construed as a distribution of this Package.
9. The name of the Copyright Holder may not be used to endorse or promote products derived from this software without specific prior written permission.
10. THIS PACKAGE IS PROVIDED "AS IS" AND WITHOUT ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, WITHOUT LIMITATION, THE IMPLIED WARRANTIES OF MERCHANTIBILITY AND FITNESS FOR A PARTICULAR PURPOSE.

The End

Chapter 96

perlgpl

The GNU General Public License, version 2

96.1 SYNOPSIS

```
 You can refer to this document in Pod via "L<perlgpl>"
 Or you can see this document by entering "perldoc perlgpl"
```

96.2 DESCRIPTION

This is **"The GNU General Public License, version 2"**. It's here so that modules, programs, etc., that want to declare this as their distribution license, can link to it.

It is also one of the two licenses Perl allows itself to be redistributed and/or modified; for the other one, the Perl Artistic License, see the *perlartistic*.

96.3 GNU GENERAL PUBLIC LICENSE

```
                    GNU GENERAL PUBLIC LICENSE
                       Version 2, June 1991

 Copyright (C) 1989, 1991 Free Software Foundation, Inc.
                          59 Temple Place - Suite 330, Boston, MA
                          02111-1307, USA.
 Everyone is permitted to copy and distribute verbatim copies
 of this license document, but changing it is not allowed.

                            Preamble
```

The licenses for most software are designed to take away your freedom to share and change it. By contrast, the GNU General Public License is intended to guarantee your freedom to share and change free software–to make sure the software is free for all its users. This General Public License applies to most of the Free Software Foundation's software and to any other program whose authors commit to using it. (Some other Free Software Foundation software is covered by the GNU Library General Public License instead.) You can apply it to your programs, too.

When we speak of free software, we are referring to freedom, not price. Our General Public Licenses are designed to make sure that you have the freedom to distribute copies of free software (and charge for this service if you wish), that you receive source code or can get it if you want it, that you can change the software or use pieces of it in new free programs; and that you know you can do these things.

To protect your rights, we need to make restrictions that forbid anyone to deny you these rights or to ask you to surrender the rights. These restrictions translate to certain responsibilities for you if you distribute copies of the software, or if you modify it.

For example, if you distribute copies of such a program, whether gratis or for a fee, you must give the recipients all the rights that you have. You must make sure that they, too, receive or can get the source code. And you must show them these terms so they know their rights.

We protect your rights with two steps: (1) copyright the software, and (2) offer you this license which gives you legal permission to copy, distribute and/or modify the software.

Also, for each author's protection and ours, we want to make certain that everyone understands that there is no warranty for this free software. If the software is modified by someone else and passed on, we want its recipients to know that what they have is not the original, so that any problems introduced by others will not reflect on the original authors' reputations.

Finally, any free program is threatened constantly by software patents. We wish to avoid the danger that redistributors of a free program will individually obtain patent licenses, in effect making the program proprietary. To prevent this, we have made it clear that any patent must be licensed for everyone's free use or not licensed at all.

The precise terms and conditions for copying, distribution and modification follow.

_

```
                    GNU GENERAL PUBLIC LICENSE
   TERMS AND CONDITIONS FOR COPYING, DISTRIBUTION AND MODIFICATION
```

0. This License applies to any program or other work which contains a notice placed by the copyright holder saying it may be distributed under the terms of this General Public License. The "Program", below, refers to any such program or work, and a "work based on the Program" means either the Program or any derivative work under copyright law: that is to say, a work containing the Program or a portion of it, either verbatim or with modifications and/or translated into another language. (Hereinafter, translation is included without limitation in the term "modification".) Each licensee is addressed as "you".

Activities other than copying, distribution and modification are not covered by this License; they are outside its scope. The act of running the Program is not restricted, and the output from the Program is covered only if its contents constitute a work based on the Program (independent of having been made by running the Program). Whether that is true depends on what the Program does.

1. You may copy and distribute verbatim copies of the Program's source code as you receive it, in any medium, provided that you conspicuously and appropriately publish on each copy an appropriate copyright notice and disclaimer of warranty; keep intact all the notices that refer to this License and to the absence of any warranty; and give any other recipients of the Program a copy of this License along with the Program.

You may charge a fee for the physical act of transferring a copy, and you may at your option offer warranty protection in exchange for a fee.

2. You may modify your copy or copies of the Program or any portion of it, thus forming a work based on the Program, and copy and distribute such modifications or work under the terms of Section 1 above, provided that you also meet all of these conditions:

```
    a) You must cause the modified files to carry prominent notices
    stating that you changed the files and the date of any change.

    b) You must cause any work that you distribute or publish, that in
    whole or in part contains or is derived from the Program or any
    part thereof, to be licensed as a whole at no charge to all third
    parties under the terms of this License.

    c) If the modified program normally reads commands interactively
    when run, you must cause it, when started running for such
    interactive use in the most ordinary way, to print or display an
    announcement including an appropriate copyright notice and a
    notice that there is no warranty (or else, saying that you provide
    a warranty) and that users may redistribute the program under
    these conditions, and telling the user how to view a copy of this
    License.  (Exception: if the Program itself is interactive but
    does not normally print such an announcement, your work based on
    the Program is not required to print an announcement.)
```

–

These requirements apply to the modified work as a whole. If identifiable sections of that work are not derived from the Program, and can be reasonably considered independent and separate works in themselves, then this License, and its terms, do not apply to those sections when you distribute them as separate works. But when you distribute the same sections as part of a whole which is a work based on the Program, the distribution of the whole must be on the terms of this License, whose permissions for other licensees extend to the entire whole, and thus to each and every part regardless of who wrote it.

Thus, it is not the intent of this section to claim rights or contest your rights to work written entirely by you; rather, the intent is to exercise the right to control the distribution of derivative or collective works based on the Program.

In addition, mere aggregation of another work not based on the Program with the Program (or with a work based on the Program) on a volume of a storage or distribution medium does not bring the other work under the scope of this License.

3. You may copy and distribute the Program (or a work based on it, under Section 2) in object code or executable form under the terms of Sections 1 and 2 above provided that you also do one of the following:

```
    a) Accompany it with the complete corresponding machine-readable
    source code, which must be distributed under the terms of Sections
    1 and 2 above on a medium customarily used for software interchange; or,

    b) Accompany it with a written offer, valid for at least three
    years, to give any third party, for a charge no more than your
    cost of physically performing source distribution, a complete
    machine-readable copy of the corresponding source code, to be
    distributed under the terms of Sections 1 and 2 above on a medium
    customarily used for software interchange; or,

    c) Accompany it with the information you received as to the offer
    to distribute corresponding source code.  (This alternative is
    allowed only for noncommercial distribution and only if you
    received the program in object code or executable form with such
    an offer, in accord with Subsection b above.)
```

The source code for a work means the preferred form of the work for making modifications to it. For an executable work, complete source code means all the source code for all modules it contains, plus any associated interface definition files, plus the scripts used to control compilation and installation of the executable. However, as a special exception, the source code distributed need not include anything that is normally distributed (in either source or binary form) with the major components (compiler, kernel, and so on) of the operating system on which the executable runs, unless that component itself accompanies the executable.

If distribution of executable or object code is made by offering access to copy from a designated place, then offering equivalent access to copy the source code from the same place counts as distribution of the source code, even though third parties are not compelled to copy the source along with the object code.

–

4. You may not copy, modify, sublicense, or distribute the Program except as expressly provided under this License. Any attempt otherwise to copy, modify, sublicense or distribute the Program is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.

5. You are not required to accept this License, since you have not signed it. However, nothing else grants you permission to modify or distribute the Program or its derivative works. These actions are prohibited by law if you do not accept this

License. Therefore, by modifying or distributing the Program (or any work based on the Program), you indicate your acceptance of this License to do so, and all its terms and conditions for copying, distributing or modifying the Program or works based on it.

6. Each time you redistribute the Program (or any work based on the Program), the recipient automatically receives a license from the original licensor to copy, distribute or modify the Program subject to these terms and conditions. You may not impose any further restrictions on the recipients' exercise of the rights granted herein. You are not responsible for enforcing compliance by third parties to this License.

7. If, as a consequence of a court judgment or allegation of patent infringement or for any other reason (not limited to patent issues), conditions are imposed on you (whether by court order, agreement or otherwise) that contradict the conditions of this License, they do not excuse you from the conditions of this License. If you cannot distribute so as to satisfy simultaneously your obligations under this License and any other pertinent obligations, then as a consequence you may not distribute the Program at all. For example, if a patent license would not permit royalty-free redistribution of the Program by all those who receive copies directly or indirectly through you, then the only way you could satisfy both it and this License would be to refrain entirely from distribution of the Program.

If any portion of this section is held invalid or unenforceable under any particular circumstance, the balance of the section is intended to apply and the section as a whole is intended to apply in other circumstances.

It is not the purpose of this section to induce you to infringe any patents or other property right claims or to contest validity of any such claims; this section has the sole purpose of protecting the integrity of the free software distribution system, which is implemented by public license practices. Many people have made generous contributions to the wide range of software distributed through that system in reliance on consistent application of that system; it is up to the author/donor to decide if he or she is willing to distribute software through any other system and a licensee cannot impose that choice.

This section is intended to make thoroughly clear what is believed to be a consequence of the rest of this License.

–

8. If the distribution and/or use of the Program is restricted in certain countries either by patents or by copyrighted interfaces, the original copyright holder who places the Program under this License may add an explicit geographical distribution limitation excluding those countries, so that distribution is permitted only in or among countries not thus excluded. In such case, this License incorporates the limitation as if written in the body of this License.

9. The Free Software Foundation may publish revised and/or new versions of the General Public License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns.

Each version is given a distinguishing version number. If the Program specifies a version number of this License which applies to it and "any later version", you have the option of following the terms and conditions either of that version or of any later version published by the Free Software Foundation. If the Program does not specify a version number of this License, you may choose any version ever published by the Free Software Foundation.

10. If you wish to incorporate parts of the Program into other free programs whose distribution conditions are different, write to the author to ask for permission. For software which is copyrighted by the Free Software Foundation, write to the Free Software Foundation; we sometimes make exceptions for this. Our decision will be guided by the two goals of preserving the free status of all derivatives of our free software and of promoting the sharing and reuse of software generally.

```
                                    NO WARRANTY
```

11. BECAUSE THE PROGRAM IS LICENSED FREE OF CHARGE, THERE IS NO WARRANTY FOR THE PROGRAM, TO THE EXTENT PERMITTED BY APPLICABLE LAW. EXCEPT WHEN OTHERWISE STATED IN WRITING THE COPYRIGHT HOLDERS AND/OR OTHER PARTIES PROVIDE THE PROGRAM "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE PROGRAM IS WITH YOU. SHOULD THE PROGRAM PROVE DEFECTIVE, YOU ASSUME THE COST OF ALL NECESSARY SERVICING, REPAIR OR CORRECTION.

12. IN NO EVENT UNLESS REQUIRED BY APPLICABLE LAW OR AGREED TO IN WRITING WILL ANY COPYRIGHT HOLDER, OR ANY OTHER PARTY WHO MAY MODIFY AND/OR REDISTRIBUTE THE

PROGRAM AS PERMITTED ABOVE, BE LIABLE TO YOU FOR DAMAGES, INCLUDING ANY GENERAL, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OR INABILITY TO USE THE PROGRAM (INCLUDING BUT NOT LIMITED TO LOSS OF DATA OR DATA BEING RENDERED INACCURATE OR LOSSES SUSTAINED BY YOU OR THIRD PARTIES OR A FAILURE OF THE PROGRAM TO OPERATE WITH ANY OTHER PROGRAMS), EVEN IF SUCH HOLDER OR OTHER PARTY HAS BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGES.

```
                     END OF TERMS AND CONDITIONS
```

_

```
        Appendix: How to Apply These Terms to Your New Programs
```

If you develop a new program, and you want it to be of the greatest possible use to the public, the best way to achieve this is to make it free software which everyone can redistribute and change under these terms.

To do so, attach the following notices to the program. It is safest to attach them to the start of each source file to most effectively convey the exclusion of warranty; and each file should have at least the "copyright" line and a pointer to where the full notice is found.

```
    <one line to give the program's name and a brief idea of what it does.>
    Copyright (C) 19yy  <name of author>

    This program is free software; you can redistribute it and/or modify
    it under the terms of the GNU General Public License as published by
    the Free Software Foundation; either version 2 of the License, or
    (at your option) any later version.

    This program is distributed in the hope that it will be useful,
    but WITHOUT ANY WARRANTY; without even the implied warranty of
    MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.  See the
    GNU General Public License for more details.

    You should have received a copy of the GNU General Public License
    along with this program; if not, write to the Free Software
    Foundation, Inc., 59 Temple Place - Suite 330, Boston, MA 02111-1307, USA.
```

Also add information on how to contact you by electronic and paper mail.

If the program is interactive, make it output a short notice like this when it starts in an interactive mode:

```
    Gnomovision version 69, Copyright (C) 19yy name of author
    Gnomovision comes with ABSOLUTELY NO WARRANTY; for details type 'show w'.
    This is free software, and you are welcome to redistribute it
    under certain conditions; type 'show c' for details.
```

The hypothetical commands 'show w' and 'show c' should show the appropriate parts of the General Public License. Of course, the commands you use may be called something other than 'show w' and 'show c'; they could even be mouse-clicks or menu items–whatever suits your program.

You should also get your employer (if you work as a programmer) or your school, if any, to sign a "copyright disclaimer" for the program, if necessary. Here is a sample; alter the names:

```
  Yoyodyne, Inc., hereby disclaims all copyright interest in the program
  'Gnomovision' (which makes passes at compilers) written by James Hacker.

  <signature of Ty Coon>, 1 April 1989
  Ty Coon, President of Vice
```

This General Public License does not permit incorporating your program into proprietary programs. If your program is a subroutine library, you may consider it more useful to permit linking proprietary applications with the library. If this is what you want to do, use the GNU Library General Public License instead of this License.

[End.]

Part VI

Platform-Specific

Chapter 97

README.aix

Perl version 5 on IBM Unix (AIX) systems

97.1 DESCRIPTION

This document describes various features of IBM's Unix operating system (AIX) that will affect how Perl version 5 (hereafter just Perl) is compiled and/or runs.

97.1.1 Compiling Perl 5 on AIX

When compiling Perl, you must use an ANSI C compiler. AIX does not ship an ANSI compliant C-compiler with AIX by default, but binary builds of gcc for AIX are widely available.

At the moment of writing, AIX supports two different native C compilers, for which you have to pay: **xlC** and **vac**. If you decide to use either of these two (which is quite a lot easier than using gcc), be sure to upgrade to the latest available patch level. Currently:

```
    xlC.C     3.1.4.10 or 3.6.6.0 or 4.0.2.2 or 5.0.2.9 or 6.0.0.3
    vac.C     4.4.0.3  or 5.0.2.6 or 6.0.0.1
```

note that xlC has the OS version in the name as of version 4.0.2.0, so you will find xlC.C for AIX-5.0 as package

```
    xlC.aix50.rte   5.0.2.0 or 6.0.0.3
```

subversions are not the same 'latest' on all OS versions. For example, the latest xlC-5 on aix41 is 5.0.2.9, while on aix43, it is 5.0.2.7.

Perl can be compiled with either IBM's ANSI C compiler or with gcc. The former is recommended, as not only can it compile Perl with no difficulty, but also can take advantage of features listed later that require the use of IBM compiler-specific command-line flags.

The IBM's compiler patch levels 5.0.0.0 and 5.0.1.0 have compiler optimization bugs that affect compiling perl.c and regcomp.c, respectively. If Perl's configuration detects those compiler patch levels, optimization is turned off for the said source code files. Upgrading to at least 5.0.2.0 is recommended.

If you decide to use gcc, make sure your installation is recent and complete, and be sure to read the Perl README file for more gcc-specific details. Please report any hoops you had to jump through to the development team.

97.1.2 OS level

Before installing the patches to the IBM C-compiler you need to know the level of patching for the Operating System. IBM's command 'oslevel' will show the base, but is not always complete (in this example oslevel shows 4.3.NULL, whereas the system might run most of 4.3.THREE):

```
# oslevel
4.3.0.0
# lslpp -l | grep 'bos.rte '
bos.rte           4.3.3.75  COMMITTED  Base Operating System Runtime
bos.rte            4.3.2.0  COMMITTED  Base Operating System Runtime
#
```

The same might happen to AIX 5.1 or other OS levels. As a side note, perl cannot be built without bos.adt.syscalls and bos.adt.libm installed

```
# lslpp -l | egrep "syscalls|libm"
bos.adt.libm      5.1.0.25  COMMITTED  Base Application Development
bos.adt.syscalls  5.1.0.36  COMMITTED  System Calls Application
#
```

97.1.3 Building Dynamic Extensions on AIX

AIX supports dynamically loadable objects as well as shared libraries. Shared libraries by convention end with the suffix .a, which is a bit misleading, as an archive can contain static as well as dynamic members. For perl dynamically loaded objects we use the .so suffix also used on many other platforms.

Note that starting from Perl 5.7.2 (and consequently 5.8.0) and AIX 4.3 or newer Perl uses the AIX native dynamic loading interface in the so called runtime linking mode instead of the emulated interface that was used in Perl releases 5.6.1 and earlier or, for AIX releases 4.2 and earlier. This change does break backward compatibility with compiled modules from earlier perl releases. The change was made to make Perl more compliant with other applications like Apache/mod_perl which are using the AIX native interface. This change also enables the use of C++ code with static constructors and destructors in perl extensions, which was not possible using the emulated interface.

97.1.4 The IBM ANSI C Compiler

All defaults for Configure can be used.

If you've chosen to use vac 4, be sure to run 4.4.0.3. Older versions will turn up nasty later on. For vac 5 be sure to run at least 5.0.1.0, but vac 5.0.2.6 or up is highly recommended. Note that since IBM has removed vac 5.0.2.1 through 5.0.2.5 from the software depot, these versions should be considered obsolete.

Here's a brief lead of how to upgrade the compiler to the latest level. Of course this is subject to changes. You can only upgrade versions from ftp-available updates if the first three digit groups are the same (in where you can skip intermediate unlike the patches in the developer snapshots of perl), or to one version up where the 'base' is available. In other words, the AIX compiler patches are cumulative.

```
vac.C.4.4.0.1 => vac.C.4.4.0.3  is OK     (vac.C.4.4.0.2 not needed)
xlC.C.3.1.3.3 => xlC.C.3.1.4.10 is NOT OK (xlC.C.3.1.4.0 is not available)

# ftp ftp.software.ibm.com

-rw-rw-rw-   1 merijn   system      29170 Nov  2 17:29 xlc.ll
```

On AIX 4.2 using xlC, we continue:

```
# lslpp -l | fgrep 'xlC.C '
  xlC.C                     3.1.4.9  COMMITTED  C for AIX Compiler
  xlC.C                     3.1.4.0  COMMITTED  C for AIX Compiler
# grep 'xlC.C.3.1.4.*.bff' xlc.ll
-rw-r--r--   1 45776101 1       6286336 Jul 22 1996  xlC.C.3.1.4.1.bff
-rw-rw-r--   1 45776101 1       6173696 Aug 24 1998  xlC.C.3.1.4.10.bff
-rw-r--r--   1 45776101 1       6319104 Aug 14 1996  xlC.C.3.1.4.2.bff
-rw-r--r--   1 45776101 1       6316032 Oct 21 1996  xlC.C.3.1.4.3.bff
-rw-r--r--   1 45776101 1       6315008 Dec 20 1996  xlC.C.3.1.4.4.bff
-rw-rw-r--   1 45776101 1       6178816 Mar 28 1997  xlC.C.3.1.4.5.bff
-rw-rw-r--   1 45776101 1       6188032 May 22 1997  xlC.C.3.1.4.6.bff
-rw-rw-r--   1 45776101 1       6191104 Sep  5 1997  xlC.C.3.1.4.7.bff
-rw-rw-r--   1 45776101 1       6185984 Jan 13 1998  xlC.C.3.1.4.8.bff
-rw-rw-r--   1 45776101 1       6169600 May 27 1998  xlC.C.3.1.4.9.bff
# wget ftp://ftp.software.ibm.com/aix/fixes/v4/xlc/xlC.C.3.1.4.10.bff
#
```

On AIX 4.3 using vac, we continue:

```
# lslpp -l | grep 'vac.C '
 vac.C                      5.0.2.2  COMMITTED  C for AIX Compiler
 vac.C                      5.0.2.0  COMMITTED  C for AIX Compiler
# grep 'vac.C.5.0.2.*.bff' other.ll
-rw-rw-r--   1 45776101 1       13592576 Apr 16 2001  vac.C.5.0.2.0.bff
-rw-rw-r--   1 45776101 1       14133248 Apr  9 2002  vac.C.5.0.2.3.bff
-rw-rw-r--   1 45776101 1       14173184 May 20 2002  vac.C.5.0.2.4.bff
-rw-rw-r--   1 45776101 1       14192640 Nov 22 2002  vac.C.5.0.2.6.bff
# wget ftp://ftp.software.ibm.com/aix/fixes/v4/other/vac.C.5.0.2.6.bff
#
```

Likewise on all other OS levels. Then execute the following command, and fill in its choices

```
# smit install_update
 -> Install and Update from LATEST Available Software
 * INPUT device / directory for software [ vac.C.5.0.2.6.bff    ]
 [ OK ]
 [ OK ]
```

Follow the messages ... and you're done.

If you like a more web-like approach, a good start point can be http://www14.software.ibm.com/webapp/download/downloadaz.jsp and click "C for AIX", and follow the instructions.

97.1.5 The usenm option

If linking miniperl

```
cc -o miniperl ... miniperlmain.o opmini.o perl.o ... -lm -lc ...
```

causes error like this

```
ld: 0711-317 ERROR: Undefined symbol: .aintl
ld: 0711-317 ERROR: Undefined symbol: .copysignl
ld: 0711-317 ERROR: Undefined symbol: .syscall
ld: 0711-317 ERROR: Undefined symbol: .eaccess
ld: 0711-317 ERROR: Undefined symbol: .setresuid
ld: 0711-317 ERROR: Undefined symbol: .setresgid
ld: 0711-317 ERROR: Undefined symbol: .setproctitle
ld: 0711-345 Use the -bloadmap or -bnoquiet option to obtain more information.
```

you could retry with

```
make realclean
rm config.sh
./Configure -Dusenm ...
```

which makes Configure to use the `nm` tool when scanning for library symbols, which usually is not done in AIX.

Related to this, you probably should not use the `-r` option of Configure in AIX, because that affects of how the `nm` tool is used.

97.1.6 Using GNU's gcc for building perl

Using gcc-3.x (tested with 3.0.4, 3.1, and 3.2) now works out of the box, as do recent gcc-2.9 builds available directly from IBM as part of their Linux compatibility packages, available here:

```
 http://www.ibm.com/servers/aix/products/aixos/linux/
```

97.1.7 Using Large Files with Perl

Should yield no problems.

97.1.8 Threaded Perl

Threads seem to work OK, though at the moment not all tests pass when threads are used in combination with 64-bit configurations.

You may get a warning when doing a threaded build:

```
 "pp_sys.c", line 4640.39: 1506-280 (W) Function argument assignment between types "unsigned char*" an
```

The exact line number may vary, but if the warning (W) comes from a line line this

```
 hent = PerlSock_gethostbyaddr(addr, (Netdb_hlen_t) addrlen, addrtype);
```

in the "pp_ghostent" function, you may ignore it safely. The warning is caused by the reentrant variant of gethostbyaddr() having a slightly different prototype than its non-reentrant variant, but the difference is not really significant here.

97.1.9 64-bit Perl

If your AIX is installed with 64-bit support, you can expect 64-bit configurations to work. In combination with threads some tests might still fail.

97.1.10 AIX 4.2 and extensions using C++ with statics

In AIX 4.2 Perl extensions that use C++ functions that use statics may have problems in that the statics are not getting initialized. In newer AIX releases this has been solved by linking Perl with the libC_r library, but unfortunately in AIX 4.2 the said library has an obscure bug where the various functions related to time (such as time() and gettimeofday()) return broken values, and therefore in AIX 4.2 Perl is not linked against the libC_r.

Chapter 98

perlamiga

Perl under Amiga OS

98.1 NOTE

Perl 5.8.0 cannot be built in AmigaOS. You can use either the maintenance release Perl 5.6.1 or the development release Perl 5.7.2 in AmigaOS. See §98.7 if you want to help fixing this problem.

98.2 SYNOPSIS

One can read this document in the following formats:

```
        man perlamiga
        multiview perlamiga.guide
```

to list some (not all may be available simultaneously), or it may be read *as is*: either as *README.amiga*, or *pod/perlamiga.pod*.

A recent version of perl for the Amiga can be found at the Geek Gadgets section of the Aminet:

```
      http://www.aminet.net/~aminet/dev/gg/index.html
```

98.3 DESCRIPTION

98.3.1 Prerequisites for Compiling Perl on AmigaOS

Unix emulation for AmigaOS: ixemul.library

You need the Unix emulation for AmigaOS, whose most important part is **ixemul.library**. For a minimum setup, get the latest versions of the following packages from the Aminet archives (http://www.aminet.net/˜aminet/):

```
        ixemul-bin
        ixemul-env-bin
        pdksh-bin
```

Note also that this is a minimum setup; you might want to add other packages of **ADE** (the *Amiga Developers Environment*).

Version of Amiga OS

You need at the very least AmigaOS version 2.0. Recommended is version 3.1.

98.3.2 Starting Perl programs under AmigaOS

Start your Perl program *foo* with arguments `arg1 arg2 arg3` the same way as on any other platform, by

```
perl foo arg1 arg2 arg3
```

If you want to specify perl options `-my_opts` to the perl itself (as opposed to your program), use

```
perl -my_opts foo arg1 arg2 arg3
```

Alternately, you can try to get a replacement for the system's **Execute** command that honors the #!/usr/bin/perl syntax in scripts and set the s-Bit of your scripts. Then you can invoke your scripts like under UNIX with

```
foo arg1 arg2 arg3
```

(Note that having *nixish full path to perl */usr/bin/perl* is not necessary, *perl* would be enough, but having full path would make it easier to use your script under *nix.)

98.3.3 Shortcomings of Perl under AmigaOS

Perl under AmigaOS lacks some features of perl under UNIX because of deficiencies in the UNIX-emulation, most notably:

- fork()
- some features of the UNIX filesystem regarding link count and file dates
- inplace operation (the -i switch) without backup file
- umask() works, but the correct permissions are only set when the file is finally close()d

98.4 INSTALLATION

Change to the installation directory (most probably ADE:), and extract the binary distribution:
lha -mraxe x perl-$VERSION-bin.lha
or
tar xvzpf perl-$VERSION-bin.tgz
(Of course you need lha or tar and gunzip for this.)
For installation of the Unix emulation, read the appropriate docs.

98.5 Accessing documentation

98.5.1 Manpages for Perl on AmigaOS

If you have `man` installed on your system, and you installed perl manpages, use something like this:

```
man perlfunc
man less
man ExtUtils.MakeMaker
```

to access documentation for different components of Perl. Start with

```
man perl
```

Note: You have to modify your man.conf file to search for manpages in the /ade/lib/perl5/man/man3 directory, or the man pages for the perl library will not be found.
Note that dot (.) is used as a package separator for documentation for packages, and as usual, sometimes you need to give the section - `3` above - to avoid shadowing by the *less(1) manpage*.

98.5.2 Perl HTML Documentation on AmigaOS

If you have some WWW browser available, you can build **HTML** docs. Cd to directory with *.pod* files, and do like this

```
        cd /ade/lib/perl5/pod
        pod2html
```

After this you can direct your browser the file *perl.html* in this directory, and go ahead with reading docs.
Alternatively you may be able to get these docs prebuilt from `CPAN`.

98.5.3 Perl GNU Info Files on AmigaOS

Users of `Emacs` would appreciate it very much, especially with `CPerl` mode loaded. You need to get latest `pod2info` from `CPAN`, or, alternately, prebuilt info pages.

98.5.4 Perl LaTeX Documentation on AmigaOS

Can be constructed using `pod2latex`.

98.6 BUILDING PERL ON AMIGAOS

Here we discuss how to build Perl under AmigaOS.

98.6.1 Build Prerequisites for Perl on AmigaOS

You need to have the latest **ixemul** (Unix emulation for Amiga) from Aminet.

98.6.2 Getting the Perl Source for AmigaOS

You can either get the latest perl-for-amiga source from Ninemoons and extract it with:

```
  tar xvzpf perl-$VERSION-src.tgz
```

or get the official source from CPAN:

```
  http://www.cpan.org/src/5.0
```

Extract it like this

```
  tar xvzpf perl-$VERSION.tar.gz
```

You will see a message about errors while extracting *Configure*. This is normal and expected. (There is a conflict with a similarly-named file *configure*, but it causes no harm.)

98.6.3 Making Perl on AmigaOS

Remember to use a hefty wad of stack (I use 2000000)

```
  sh configure.gnu --prefix=/gg
```

Now type

```
  make depend
```

Now!

```
  make
```

98.6.4 Testing Perl on AmigaOS

Now run

```
  make test
```

Some tests will be skipped because they need the fork() function:
io/pipe.t, op/fork.t, lib/filehand.t, lib/open2.t, lib/open3.t, lib/io_pipe.t, lib/io_sock.t

98.6.5 Installing the built Perl on AmigaOS

Run

```
  make install
```

98.7 PERL 5.8.0 BROKEN IN AMIGAOS

As told above, Perl 5.6.1 was still good in AmigaOS, as was 5.7.2. After Perl 5.7.2 (change #11423, see the Changes file, and the file pod/perlhack.pod for how to get the individual changes) Perl dropped its internal support for vfork(), and that was very probably the step that broke AmigaOS (since the ixemul library has only vfork). The build finally fails when the ext/DynaLoader is being built, and PERL ends up as "0" in the produced Makefile, trying to run "0" does not quite work. Also, executing miniperl in backticks seems to generate nothing: very probably related to the (v)fork problems. **Fixing the breakage requires someone quite familiar with the ixemul library, and how one is supposed to run external commands in AmigaOS without fork().**

README.beos

Perl version 5 on BeOS

100.1 DESCRIPTION

Notes for building Perl under BeOS.

100.1.1 General Issues with Perl on BeOS

To compile perl under BeOS R4 x86:

```
        ./Configure -d
```

and hit ˆC when it asks you if you want to make changes to config.sh; edit config.sh and do the following: change d_socket='define' to ='undef'; remove SDBM, Errno, and Socket from dynamic_ext= and nonxs_ext=; add '#define bool short' to x2p/a2p.h;

```
        ../Configure -S; make; make install

        cd ~/config/lib; ln -s 5.00502/BeOS-BePC/CORE/libperl.so .
```

(substitute 5.00502 with the appropriate filename)

100.1.2 BeOS Release-specific Notes

R4 x86

Dynamic loading finally works! Yay! This means you can compile your own modules into perl. However, Sockets and Errno still don't work. (Hopefully, sockets will at least work by R5, if not sooner.)

R4 PPC

I have not tested this. I rather severely doubt that dynamic loading will work. (My BeBox is in pieces right now, following a nasty disk crash.) You may have to disable dynamic loading to get the thing to compile at all. (use './Configure' without -d, and say 'no' to 'Build a shared libperl.so'.)

100.1.3 Contact Information

If you have comments, problem reports, or even patches or bugfixes (gasp!) please email me.

28 Jan 1999 Tom Spindler dogcow@isi.net

100.1.4 Update 2002-05-30

The following tests fail on 5.8.0 Perl in BeOS Personal 5.03:

```
t/op/lfs............................FAILED at test 17
t/op/magic..........................FAILED at test 24
ext/Fcntl/t/syslfs..................FAILED at test 17
ext/File/Glob/t/basic...............FAILED at test 3
ext/POSIX/t/sigaction...............FAILED at test 13
ext/POSIX/t/waitpid.................FAILED at test 1
```

The reasons for the failures are as follows:

- The t/op/lfs and ext/Fcntl/t/syslfs failures indicate that the LFS (large file support, files larger than 2 gigabytes) doesn't work from Perl (BeFS itself is well capable of supporting large files). What fails is that trying to position the file pointer past 2 gigabytes doesn't work right, the position gets truncated to its lower 32 bits.
- The op/magic failures look like something funny going on with $0 and $^X that I can't now figure out: none of the generated pathnames are wrong as such, they just seem to accumulate "./" prefixes and infixes in ways that define logic.
- The Glob/t/basic indicates a bug in the getpw*() functions: they do not always return the correct user db entries.
- The sigaction #13 means that signal mask doesn't get properly restored if sigaction returns early.
- The waitpid failure means that after there are no more child processes, waitpid is supposed to start returning -1 (and set errno to ECHILD). In BeOS, it doesn't seem to.

Disclaimer: I just installed BeOS Personal Edition 5.0 and the Developer Tools, that is the whole extent of my BeOS expertise, so please don't ask me for further help in BeOS Perl problems.

Chapter 101

README.BS2000

Building and installing Perl for BS2000.

101.1 SYNOPSIS

This document will help you Configure, build, test and install Perl on BS2000 in the POSIX subsystem.

101.2 DESCRIPTION

This is a ported perl for the POSIX subsystem in BS2000 VERSION OSD V3.1A or later. It may work on other versions, but we started porting and testing it with 3.1A and are currently using Version V4.0A.

You may need the following GNU programs in order to install perl:

101.2.1 gzip on BS2000

We used version 1.2.4, which could be installed out of the box with one failure during 'make check'.

101.2.2 bison on BS2000

The yacc coming with BS2000 POSIX didn't work for us. So we had to use bison. We had to make a few changes to perl in order to use the pure (reentrant) parser of bison. We used version 1.25, but we had to add a few changes due to EBCDIC. See below for more details concerning yacc.

101.2.3 Unpacking Perl Distribution on BS2000

To extract an ASCII tar archive on BS2000 POSIX you need an ASCII filesystem (we used the mountpoint /usr/local/ascii for this). Now you extract the archive in the ASCII filesystem without I/O-conversion:

cd /usr/local/ascii export IO_CONVERSION=NO gunzip < /usr/local/src/perl.tar.gz | pax -r

You may ignore the error message for the first element of the archive (this doesn't look like a tar archive / skipping to next file...), it's only the directory which will be created automatically anyway.

After extracting the archive you copy the whole directory tree to your EBCDIC filesystem. **This time you use I/O-conversion**:

cd /usr/local/src IO_CONVERSION=YES cp -r /usr/local/ascii/perl5.005_02 ./

101.2.4 Compiling Perl on BS2000

There is a "hints" file for BS2000 called hints.posix-bc (because posix-bc is the OS name given by ‘uname‘) that specifies the correct values for most things. The major problem is (of course) the EBCDIC character set. We have german EBCDIC version.

Because of our problems with the native yacc we used GNU bison to generate a pure (=reentrant) parser for perly.y. So our yacc is really the following script:

—–8<—–/usr/local/bin/yacc—–8<—– #! /usr/bin/sh

# Bison as a reentrant yacc:

# save parameters: params="" while [[$# -gt 1]]; do params="$params $1" shift done

# add flag %pure_parser:

tmpfile=/tmp/bison.$$.y echo %pure_parser > $tmpfile cat $1 >> $tmpfile

# call bison:

echo "/usr/local/bin/bison –yacc $params $1\t\t\t(Pure Parser)" /usr/local/bin/bison –yacc $params $tmpfile

# cleanup:

rm -f $tmpfile —–8<———–-8<—–

We still use the normal yacc for a2p.y though!!! We made a softlink called byacc to distinguish between the two versions:

ln -s /usr/bin/yacc /usr/local/bin/byacc

We build perl using GNU make. We tried the native make once and it worked too.

101.2.5 Testing Perl on BS2000

We still got a few errors during `make test`. Some of them are the result of using bison. Bison prints *parser error* instead of *syntax error*, so we may ignore them. The following list shows our errors, your results may differ:

op/numconvert.......FAILED tests 1409-1440 op/regexp...........FAILED tests 483, 496 op/regexp_noamp.....FAILED tests 483, 496 pragma/overload.....FAILED tests 152-153, 170-171 pragma/warnings.....FAILED tests 14, 82, 129, 155, 192, 205, 207 lib/bigfloat........FAILED tests 351-352, 355 lib/bigfltpm........FAILED tests 354-355, 358 lib/complex.........FAILED tests 267, 487 lib/dumper..........FAILED tests 43, 45 Failed 11/231 test scripts, 95.24% okay. 57/10595 subtests failed, 99.46% okay.

101.2.6 Installing Perl on BS2000

We have no nroff on BS2000 POSIX (yet), so we ignored any errors while installing the documentation.

101.2.7 Using Perl in the Posix-Shell of BS2000

BS2000 POSIX doesn’t support the shebang notation (`#!/usr/local/bin/perl`), so you have to use the following lines instead:

: # use perl eval ’exec /usr/local/bin/perl -S $0 ${1+"$@"}’ if $running_under_some_shell;

101.2.8 Using Perl in "native" BS2000

We don’t have much experience with this yet, but try the following:

Copy your Perl executable to a BS2000 LLM using bs2cp:

```
bs2cp /usr/local/bin/perl 'bs2:perl(perl,l)'
```

Now you can start it with the following (SDF) command:

```
/START-PROG FROM-FILE=*MODULE(PERL,PERL),PROG-MODE=*ANY,RUN-MODE=*ADV
```

First you get the BS2000 commandline prompt (’*’). Here you may enter your parameters, e.g. `-e 'print "Hello World!\\n";'` (note the double backslash!) or `-w` and the name of your Perl script. Filenames starting with `/` are searched in the Posix filesystem, others are searched in the BS2000 filesystem. You may even use wildcards if you put a `%` in front of your filename (e.g. `-w checkfiles.pl %*.c`). Read your C/C++ manual for additional possibilities of the commandline prompt (look for PARAMETER-PROMPTING).

101.2.9 Floating point anomalies on BS2000

There appears to be a bug in the floating point implementation on BS2000 POSIX systems such that calling int() on the product of a number and a small magnitude number is not the same as calling int() on the quotient of that number and a large magnitude number. For example, in the following Perl code:

```
    my $x = 100000.0;
    my $y = int($x * 1e-5) * 1e5; # '0'
    my $z = int($x / 1e+5) * 1e5;  # '100000'
    print "\$y is $y and \$z is $z\n"; # $y is 0 and $z is 100000
```

Although one would expect the quantities $y and $z to be the same and equal to 100000 they will differ and instead will be 0 and 100000 respectively.

101.2.10 Using PerlIO and different encodings on ASCII and EBCDIC partitions

Since version 5.8 Perl uses the new PerlIO on BS2000. This enables you using different encodings per IO channel. For example you may use

```
    use Encode;
    open($f, ">:encoding(ascii)", "test.ascii");
    print $f "Hello World!\n";
    open($f, ">:encoding(posix-bc)", "test.ebcdic");
    print $f "Hello World!\n";
    open($f, ">:encoding(latin1)", "test.latin1");
    print $f "Hello World!\n";
    open($f, ">:encoding(utf8)", "test.utf8");
    print $f "Hello World!\n";
```

to get two files containing "Hello World!\n" in ASCII, EBCDIC, ISO Latin-1 (in this example identical to ASCII) respective UTF-EBCDIC (in this example identical to normal EBCDIC). See the documentation of Encode::PerlIO for details.

As the PerlIO layer uses raw IO internally, all this totally ignores the type of your filesystem (ASCII or EBCDIC) and the IO_CONVERSION environment variable. If you want to get the old behavior, that the BS2000 IO functions determine conversion depending on the filesystem PerlIO still is your friend. You use IO_CONVERSION as usual and tell Perl, that it should use the native IO layer:

```
    export IO_CONVERSION=YES
    export PERLIO=stdio
```

Now your IO would be ASCII on ASCII partitions and EBCDIC on EBCDIC partitions. See the documentation of PerlIO (without `Encode::`!) for further posibilities.

101.5 HISTORY

This document was originally written by Thomas Dorner for the 5.005 release of Perl.

This document was podified for the 5.6 release of perl 11 July 2000.

Chapter 102

perlce

Perl for WinCE

102.1 DESCRIPTION

This file gives the instructions for building Perl5.8 and above for WinCE. Please read and understand the terms under which this software is distributed.

102.2 BUILD

This section describes the steps to be performed to build PerlCE. You may find additional and newer information about building perl for WinCE using following URL:

```
  http://perlce.sourceforge.net
```

There should also be pre-built binaries there.

Don't be confused by large size of downloaded distribution or constructed binaries: entire distribution could be large for WinCE ideology, but you may strip it at your wish and use only required parts.

102.2.1 Tools & SDK

For compiling, you need following:

- Microsoft Embedded Visual Tools
- Microsoft Visual C++
- Rainer Keuchel's celib-sources
- Rainer Keuchel's console-sources

Needed source files can be downloaded via: www.rainer-keuchel.de/wince/dirlist.html

102.2.2 Make

Please pay attention that starting from 5.8.0 miniperl *is* built and it facilitates in further building process. This means that in addition to compiler installation for mobile device you also need to have Microsoft Visual C++ installed as well.
On the bright side, you do not need to edit any files from ./win32 subdirectory. Normally you only need to edit ./wince/compile.bat to reflect your system and run it.
File ./wince/compile.bat is actually a wrapper to call nmake -f makefile.ce with appropriate parameters and it accepts extra parameters and forwards them to "nmake" command as additional arguments. You should pass target this way.
To prepare distribution you need to do following:

- go to ./wince subdirectory
- edit file compile.bat
- run compile.bat
- run compile.bat dist

makefile.ce has CROSS_NAME macro, and it is used further to refer to your cross-compilation scheme. You could assign a name to it, but this is not necessary, because by default it is assigned after your machine configuration name, such as "wince-sh3-hpc-wce211", and this is enough to distinguish different builds at the same time. This option could be handy for several different builds on same platform to perform, say, threaded build. In a following example we assume that all required environment variables are set properly for C cross-compiler (a special *.bat file could fit perfectly to this purpose) and your compile.bat has proper "MACHINE" parameter set, to, say, "wince-mips-pocket-wce300".

```
compile.bat
compile.bat dist
compile.bat CROSS_NAME=mips-wce300-thr "USE_ITHREADS=define" "USE_IMP_SYS=define" "USE_MULTI=define"
compile.bat CROSS_NAME=mips-wce300-thr "USE_ITHREADS=define" "USE_IMP_SYS=define" "USE_MULTI=define"
```

If all goes okay and no errors during a build, you'll get two independent distributions: "wince-mips-pocket-wce300" and "mips-wce300-thr".
Target 'dist' prepares distribution file set. Target 'zipdist' performs same as 'dist' but additionally compresses distribution files into zip archive.
NOTE: during a build there could be created a number (or one) of Config.pm for cross-compilation ("foreign" Config.pm) and those are hidden inside ../xlib/$(CROSS_NAME) with other auxilary files, but, and this is important to note, there should be *no* Config.pm for host miniperl. If you'll get an error that perl could not find Config.pm somewhere in building process this means something went wrong. Most probably you forgot to specify a cross-compilation when invoking miniperl.exe to Makefile.PL When building an extension for cross-compilation your command line should look like

```
..\miniperl.exe -I..\lib -MCross=mips-wce300-thr Makefile.PL
```

or just

```
..\miniperl.exe -I..\lib -MCross Makefile.PL
```

to refer a cross-compilation that was created last time.
If you decided to build with fcrypt.c file, please refer to README.win32 file, as long as all legal considerations and steps to do are exactly same in this case.
All questions related to building for WinCE devices could be asked in perlce-users@lists.sourceforge.net mailing list.

102.3 ACKNOWLEDGEMENTS

The port for Win32 was used as a reference.

102.4 AUTHORS

Chapter 103

README.cygwin

Perl for Cygwin

103.1 SYNOPSIS

This document will help you configure, make, test and install Perl on Cygwin. This document also describes features of Cygwin that will affect how Perl behaves at runtime.

NOTE: There are pre-built Perl packages available for Cygwin and a version of Perl is provided in the normal Cygwin install. If you do not need to customize the configuration, consider using one of those packages.

103.2 PREREQUISITES FOR COMPILING PERL ON CYGWIN

103.2.1 Cygwin = GNU+Cygnus+Windows (Don't leave UNIX without it)

The Cygwin tools are ports of the popular GNU development tools for Win32 platforms. They run thanks to the Cygwin library which provides the UNIX system calls and environment these programs expect. More information about this project can be found at:

```
  http://www.cygwin.com/
```

A recent net or commercial release of Cygwin is required.

At the time this document was last updated, Cygwin 1.5.2 was current.

103.2.2 Cygwin Configuration

While building Perl some changes may be necessary to your Cygwin setup so that Perl builds cleanly. These changes are **not** required for normal Perl usage.

NOTE: The binaries that are built will run on all Win32 versions. They do not depend on your host system (Win9x/WinME, WinNT/Win2K) or your Cygwin configuration (*ntea*, *ntsec*, binary/text mounts). The only dependencies come from hard-coded pathnames like `/usr/local`. However, your host system and Cygwin configuration will affect Perl's runtime behavior (see §**??**).

- `PATH`

  Set the `PATH` environment variable so that Configure finds the Cygwin versions of programs. Any Windows directories should be removed or moved to the end of your `PATH`.

- *nroff*

  If you do not have *nroff* (which is part of the *groff* package), Configure will **not** prompt you to install *man* pages.

- Permissions

  On WinNT with either the *ntea* or *ntsec* `CYGWIN` settings, directory and file permissions may not be set correctly. Since the build process creates directories and files, to be safe you may want to run a '`chmod -R +w *`' on the entire Perl source tree.

  Also, it is a well known WinNT "feature" that files created by a login that is a member of the *Administrators* group will be owned by the *Administrators* group. Depending on your umask, you may find that you can not write to files that you just created (because you are no longer the owner). When using the *ntsec* `CYGWIN` setting, this is not an issue because it "corrects" the ownership to what you would expect on a UNIX system.

103.3 CONFIGURE PERL ON CYGWIN

The default options gathered by Configure with the assistance of *hints/cygwin.sh* will build a Perl that supports dynamic loading (which requires a shared *libperl.dll*).

This will run Configure and keep a record:

```
./Configure 2>&1 | tee log.configure
```

If you are willing to accept all the defaults run Configure with **-de**. However, several useful customizations are available.

103.3.1 Stripping Perl Binaries on Cygwin

It is possible to strip the EXEs and DLLs created by the build process. The resulting binaries will be significantly smaller. If you want the binaries to be stripped, you can either add a **-s** option when Configure prompts you,

```
Any additional ld flags (NOT including libraries)? [none] -s
Any special flags to pass to gcc to use dynamic linking? [none] -s
Any special flags to pass to ld2 to create a dynamically loaded library?
[none] -s
```

or you can edit *hints/cygwin.sh* and uncomment the relevant variables near the end of the file.

103.3.2 Optional Libraries for Perl on Cygwin

Several Perl functions and modules depend on the existence of some optional libraries. Configure will find them if they are installed in one of the directories listed as being used for library searches. Pre-built packages for most of these are available from the Cygwin installer.

- `-lcrypt`

  The crypt package distributed with Cygwin is a Linux compatible 56-bit DES crypt port by Corinna Vinschen.

  Alternatively, the crypt libraries in GNU libc have been ported to Cygwin.

  The DES based Ultra Fast Crypt port was done by Alexey Truhan:

  ```
  ftp://ftp.uni-erlangen.de/pub/pc/gnuwin32/cygwin/porters/Okhapkin_Sergey/cw32crypt-dist-0.tgz
  ```

  NOTE: There are various export restrictions on DES implementations, see the glibc README for more details.

  The MD5 port was done by Andy Piper:

  ```
  ftp://ftp.uni-erlangen.de/pub/pc/gnuwin32/cygwin/porters/Okhapkin_Sergey/libcrypt.tgz
  ```

- `-lgdbm` (`use GDBM_File`)

  GDBM is available for Cygwin.

  NOTE: The GDBM library only works on NTFS partitions.

- `-ldb` (`use DB_File`)

  BerkeleyDB is available for Cygwin.

  NOTE: The BerkeleyDB library only completely works on NTFS partitions.

- `-lcygipc` (`use IPC::SysV`)

  A port of SysV IPC is available for Cygwin.

  NOTE: This has **not** been extensively tested. In particular, `d_semctl_semun` is undefined because it fails a Configure test and on Win9x the *shm*()* functions seem to hang. It also creates a compile time dependency because *perl.h* includes <*sys/ipc.h*> and <*sys/sem.h*> (which will be required in the future when compiling CPAN modules). CURRENTLY NOT SUPPORTED!

- `-lutil`

  Included with the standard Cygwin netrelease is the inetutils package which includes libutil.a.

103.3.3 Configure-time Options for Perl on Cygwin

The *INSTALL* document describes several Configure-time options. Some of these will work with Cygwin, others are not yet possible. Also, some of these are experimental. You can either select an option when Configure prompts you or you can define (undefine) symbols on the command line.

- `-Uusedl`

  Undefining this symbol forces Perl to be compiled statically.

- `-Uusemymalloc`

  By default Perl uses the `malloc()` included with the Perl source. If you want to force Perl to build with the system `malloc()` undefine this symbol.

- `-Uuseperlio`

  Undefining this symbol disables the PerlIO abstraction. PerlIO is now the default; it is not recommended to disable PerlIO.

- `-Dusemultiplicity`

  Multiplicity is required when embedding Perl in a C program and using more than one interpreter instance. This works with the Cygwin port.

- `-Duse64bitint`

  By default Perl uses 32 bit integers. If you want to use larger 64 bit integers, define this symbol.

- `-Duselongdouble`

  gcc supports long doubles (12 bytes). However, several additional long double math functions are necessary to use them within Perl (*{atan2, cos, exp, floor, fmod, frexp, isnan, log, modf, pow, sin, sqrt}l, strtold*). These are **not** yet available with Cygwin.

- `-Dusethreads`

  POSIX threads are implemented in Cygwin, define this symbol if you want a threaded perl.

- `-Duselargefiles`

  Cygwin uses 64-bit integers for internal size and position calculations, this will be correctly detected and defined by Configure.

- `-Dmksymlinks`

  Use this to build perl outside of the source tree. This works with Cygwin. Details can be found in the *INSTALL* document. This is the recommended way to build perl from sources.

103.3.4 Suspicious Warnings on Cygwin

You may see some messages during Configure that seem suspicious.

- *dlsym()*

  ld2 is needed to build dynamic libraries, but it does not exist when `dlsym()` checking occurs (it is not created until '`make`' runs). You will see the following message:

  ```
  Checking whether your C<dlsym()> needs a leading underscore ...
  ld2: not found
  I can't compile and run the test program.
  I'm guessing that dlsym doesn't need a leading underscore.
  ```

  Since the guess is correct, this is not a problem.

- Win9x and `d_eofnblk`

  Win9x does not correctly report `EOF` with a non-blocking read on a closed pipe. You will see the following messages:

  ```
  But it also returns -1 to signal EOF, so be careful!
  WARNING: you can't distinguish between EOF and no data!

  *** WHOA THERE!!! ***
      The recommended value for $d_eofnblk on this machine was "define"!
      Keep the recommended value? [y]
  ```

  At least for consistency with WinNT, you should keep the recommended value.

- Compiler/Preprocessor defines

  The following error occurs because of the Cygwin `#define` of `_LONG_DOUBLE`:

  ```
  Guessing which symbols your C compiler and preprocessor define...
  try.c:<line#>: missing binary operator
  ```

  This failure does not seem to cause any problems. With older gcc versions, "parse error" is reported instead of "missing binary operator".

103.4 MAKE ON CYGWIN

Simply run *make* and wait:

```
make 2>&1 | tee log.make
```

103.4.1 Errors on Cygwin

Errors like these are normal:

```
...
make: [extra.pods] Error 1 (ignored)
...
make: [extras.make] Error 1 (ignored)
```

103.4.2 ld2 on Cygwin

During '`make`', *ld2* will be created and installed in your $installbin directory (where you said to put public executables). It does not wait until the '`make install`' process to install the *ld2* script, this is because the remainder of the '`make`' refers to *ld2* without fully specifying its path and does this from multiple subdirectories. The assumption is that $installbin is in your current `PATH`. If this is not the case '`make`' will fail at some point. If this happens, just manually copy *ld2* from the source directory to somewhere in your `PATH`.

103.5 TEST ON CYGWIN

There are two steps to running the test suite:

```
make test 2>&1 | tee log.make-test
```

```
cd t;./perl harness 2>&1 | tee ../log.harness
```

The same tests are run both times, but more information is provided when running as '`./perl harness`'.

Test results vary depending on your host system and your Cygwin configuration. If a test can pass in some Cygwin setup, it is always attempted and explainable test failures are documented. It is possible for Perl to pass all the tests, but it is more likely that some tests will fail for one of the reasons listed below.

103.5.1 File Permissions on Cygwin

UNIX file permissions are based on sets of mode bits for {read,write,execute} for each {user,group,other}. By default Cygwin only tracks the Win32 read-only attribute represented as the UNIX file user write bit (files are always readable, files are executable if they have a *.{com,bat,exe}* extension or begin with `#!`, directories are always readable and executable). On WinNT with the *ntea* `CYGWIN` setting, the additional mode bits are stored as extended file attributes. On WinNT with the *ntsec* `CYGWIN` setting, permissions use the standard WinNT security descriptors and access control lists. Without one of these options, these tests will fail (listing not updated yet):

```
Failed Test           List of failed
------------------------------------
io/fs.t               5, 7, 9-10
lib/anydbm.t          2
lib/db-btree.t        20
lib/db-hash.t         16
lib/db-recno.t        18
lib/gdbm.t            2
lib/ndbm.t            2
lib/odbm.t            2
lib/sdbm.t            2
op/stat.t             9, 20 (.tmp not an executable extension)
```

103.5.2 NDBM_File and ODBM_File do not work on FAT filesystems

Do not use NDBM_File or ODBM_File on FAT filesystem. They can be built on a FAT filesystem, but many tests will fail:

```
../ext/NDBM_File/ndbm.t       13  3328    71   59  83.10%  1-2 4 16-71
../ext/ODBM_File/odbm.t      255 65280    ??   ??       %  ??
../lib/AnyDBM_File.t           2   512    12    2  16.67%  1 4
../lib/Memoize/t/errors.t      0   139    11    5  45.45%  7-11
../lib/Memoize/t/tie_ndbm.t   13  3328     4    4 100.00%  1-4
run/fresh_perl.t                          97    1   1.03%  91
```

If you intend to run only on FAT (or if using AnyDBM_File on FAT), run Configure with the -Ui_ndbm and -Ui_dbm options to prevent NDBM_File and ODBM_File being built.

With NTFS (and CYGWIN=ntsec), there should be no problems even if perl was built on FAT.

103.5.3 `fork()` failures in io_* tests

A `fork()` failure may result in the following tests failing:

```
ext/IO/lib/IO/t/io_multihomed.t
ext/IO/lib/IO/t/io_sock.t
ext/IO/lib/IO/t/io_unix.t
```

See comment on fork in *Miscellaneous* below.

103.5.4 Script Portability on Cygwin

Cygwin does an outstanding job of providing UNIX-like semantics on top of Win32 systems. However, in addition to the items noted above, there are some differences that you should know about. This is a very brief guide to portability, more information can be found in the Cygwin documentation.

- Pathnames

  Cygwin pathnames can be separated by forward (*/*) or backward (\\) slashes. They may also begin with drive letters (*C:*) or Universal Naming Codes (*//UNC*). DOS device names (*aux*, *con*, *prn*, *com**, *lpt?*, *nul*) are invalid as base filenames. However, they can be used in extensions (e.g., *hello.aux*). Names may contain all printable characters except these:

  ```
  : * ? " < > |
  ```

  File names are case insensitive, but case preserving. A pathname that contains a backslash or drive letter is a Win32 pathname (and not subject to the translations applied to POSIX style pathnames).

- Text/Binary

  When a file is opened it is in either text or binary mode. In text mode a file is subject to CR/LF/Ctrl-Z translations. With Cygwin, the default mode for an `open()` is determined by the mode of the mount that underlies the file. Perl provides a `binmode()` function to set binary mode on files that otherwise would be treated as text. `sysopen()` with the `O_TEXT` flag sets text mode on files that otherwise would be treated as binary:

  ```
      sysopen(FOO, "bar", O_WRONLY|O_CREAT|O_TEXT)
  ```

  `lseek()`, `tell()` and `sysseek()` only work with files opened in binary mode.

  The text/binary issue is covered at length in the Cygwin documentation.

- PerlIO

  PerlIO overrides the default Cygwin Text/Binary behaviour. A file will always treated as binary, regardless which mode of the mount it lives on, just like it is in UNIX. So CR/LF translation needs to be requested in either the `open()` call like this:

  ```
  open(FH, ">:crlf", "out.txt");
  ```

  which will do conversion from LF to CR/LF on the output, or in the environment settings (add this to your .bashrc):

  ```
  export PERLIO=crlf
  ```

  which will pull in the crlf PerlIO layer which does LF -> CRLF conversion on every output generated by perl.

- *.exe*

  The Cygwin `stat()`, `lstat()` and `readlink()` functions make the *.exe* extension transparent by looking for *foo.exe* when you ask for *foo* (unless a *foo* also exists). Cygwin does not require a *.exe* extension, but *gcc* adds it automatically when building a program. However, when accessing an executable as a normal file (e.g., *cp* in a makefile) the *.exe* is not transparent. The *install* included with Cygwin automatically appends a *.exe* when necessary.

- `chown()`

  On WinNT `chown()` can change a file's user and group IDs. On Win9x `chown()` is a no-op, although this is appropriate since there is no security model.

- Miscellaneous

  File locking using the `F_GETLK` command to `fcntl()` is a stub that returns `ENOSYS`.

  Win9x can not `rename()` an open file (although WinNT can).

  The Cygwin `chroot()` implementation has holes (it can not restrict file access by native Win32 programs).

  Inplace editing `perl -i` of files doesn't work without doing a backup of the file being edited `perl -i.bak` because of windowish restrictions, therefore Perl adds the suffix `.bak` automatically if you use `perl -i` without specifying a backup extension.

  Using `fork()` after loading multiple dlls may fail with an internal cygwin error like the following:

```
C:\CYGWIN\BIN\PERL.EXE: *** couldn't allocate memory 0x10000(4128768) for 'C:\CYGWIN\LIB\PERL5\5

  200 [main] perl 377147 sync_with_child: child -395691(0xB8) died before initialization with st
 1370 [main] perl 377147 sync_with_child: *** child state child loading dlls
```

  Use the rebase utility to resolve the conflicting dll addresses. The rebase package is included in the Cygwin netrelease. Use setup.exe from *http://www.cygwin.com/setup.exe* to install it and run rebaseall.

103.6 INSTALL PERL ON CYGWIN

This will install Perl, including *man* pages.

```
make install 2>&1 | tee log.make-install
```

NOTE: If `STDERR` is redirected '`make install`' will **not** prompt you to install *perl* into */usr/bin*.

You may need to be *Administrator* to run '`make install`'. If you are not, you must have write access to the directories in question.

Information on installing the Perl documentation in HTML format can be found in the *INSTALL* document.

103.7 MANIFEST ON CYGWIN

These are the files in the Perl release that contain references to Cygwin. These very brief notes attempt to explain the reason for all conditional code. Hopefully, keeping this up to date will allow the Cygwin port to be kept as clean as possible (listing not updated yet).

perl.c                - os_extras
perl.h                - binmode
doio.c                - win9x can not rename a file when it is open
pp_sys.c              - do not define h_errno, pp_system with spawn
util.c                - use setenv
```

Compiled Module Source

```
ext/POSIX/POSIX.xs    - tzname defined externally
ext/SDBM_File/sdbm/pair.c
                      - EXTCONST needs to be redefined from EXTERN.h
ext/SDBM_File/sdbm/sdbm.c
                      - binary open
```

Perl Modules/Scripts

```
lib/Cwd.pm            - hook to internal Cwd::cwd
lib/ExtUtils/MakeMaker.pm
                      - require MM_Cygwin.pm
lib/ExtUtils/MM_Cygwin.pm
                      - canonpath, cflags, manifypods, perl_archive
lib/File/Find.pm      - on remote drives stat() always sets st_nlink to 1
lib/File/Spec/Unix.pm - preserve //unc
lib/File/Temp.pm      - no directory sticky bit
lib/perl5db.pl        - use stdin not /dev/tty
utils/perldoc.PL      - version comment
```

103.8 BUGS ON CYGWIN

Support for swapping real and effective user and group IDs is incomplete. On WinNT Cygwin provides `setuid()`, `seteuid()`, `setgid()` and `setegid()`. However, additional Cygwin calls for manipulating WinNT access tokens and security contexts are required.

103.10 HISTORY

Last updated: 2003-08-12

Chapter 104

perldgux

Perl under DG/UX.

104.1 SYNOPSIS

One can read this document in the following formats:

```
        man perldgux
        view perl perldgux
        explorer perldgux.html
        info perldgux
```

to list some (not all may be available simultaneously), or it may be read *as is*: as *README.dgux*.

104.2 DESCRIPTION

Perl 5.7/8.x for DG/UX ix86 R4.20MU0x

104.3 BUILDING PERL ON DG/UX

104.3.1 Non-threaded Perl on DG/UX

Just run ./Configure script from the top directory. Then give "make" to compile.

104.3.2 Threaded Perl on DG/UX

If you are using as compiler GCC-2.95.x rev(DG/UX) an easy solution for configuring perl in your DG/UX machine is to run the command:
./Configure -Dusethreads -Duseithreads -Dusedevel -des
This will automatically accept all the defaults and in particular /usr/local/ as installation directory. Note that GCC-2.95.x rev(DG/UX) knows the switch -pthread which allows it to link correctly DG/UX's -lthread library.
If you want to change the installation directory or have a standard DG/UX with C compiler GCC-2.7.2.x then you have no choice than to do an interactive build by issuing the command:
./Configure -Dusethreads -Duseithreads
In particular with GCC-2.7.2.x accept all the defaults and *watch* out for the message:

```
    Any additional ld flags (NOT including libraries)? [ -pthread]
```

Instead of -pthread put here -lthread. CGCC-2.7.2.x that comes with the DG/UX OS does NOT know the -pthread switch. So your build will fail if you choose the defaults. After configuration is done correctly give "make" to compile.

104.3.3 Testing Perl on DG/UX

Issuing a "make test" will run all the tests. If the test lib/ftmp-security gives you as a result something like

```
    lib/ftmp-security....File::Temp::_gettemp:
    Parent directory (/tmp/) is not safe (sticky bit not set
    when world writable?) at lib/ftmp-security.t line 100
```

don't panic and just set the sticky bit in your /tmp directory by doing the following as root:

cd / chmod +t /tmp (=set the sticky bit to /tmp).

Then rerun the tests. This time all must be OK.

104.3.4 Installing the built perl on DG/UX

Run the command "make install"

Chapter 105

perldos

Perl under DOS, W31, W95.

105.1 SYNOPSIS

These are instructions for building Perl under DOS (or w??), using DJGPP v2.03 or later. Under w95 long filenames are supported.

105.2 DESCRIPTION

Before you start, you should glance through the README file found in the top-level directory where the Perl distribution was extracted. Make sure you read and understand the terms under which this software is being distributed.

This port currently supports MakeMaker (the set of modules that is used to build extensions to perl). Therefore, you should be able to build and install most extensions found in the CPAN sites.

Detailed instructions on how to build and install perl extension modules, including XS-type modules, is included. See 'BUILDING AND INSTALLING MODULES'.

105.2.1 Prerequisites for Compiling Perl on DOS

DJGPP

DJGPP is a port of GNU C/C++ compiler and development tools to 32-bit, protected-mode environment on Intel 32-bit CPUs running MS-DOS and compatible operating systems, by DJ Delorie <dj@delorie.com> and friends.

For more details (FAQ), check out the home of DJGPP at:

```
    http://www.delorie.com/djgpp/
```

If you have questions about DJGPP, try posting to the DJGPP newsgroup: comp.os.msdos.djgpp, or use the email gateway djgpp@delorie.com.

You can find the full DJGPP distribution on any SimTel.Net mirror all over the world. Like:

```
    ftp://ftp.simtel.net/pub/simtelnet/gnu/djgpp/v2*
```

You need the following files to build perl (or add new modules):

```
    v2/djdev203.zip
    v2gnu/bnu2112b.zip
    v2gnu/gcc2953b.zip
    v2gnu/bsh204b.zip
    v2gnu/mak3791b.zip
    v2gnu/fil40b.zip
    v2gnu/sed3028b.zip
    v2gnu/txt20b.zip
    v2gnu/dif272b.zip
    v2gnu/grep24b.zip
    v2gnu/shl20jb.zip
    v2gnu/gwk306b.zip
    v2misc/csdpmi5b.zip
```

or possibly any newer version.

Pthreads

Thread support is not tested in this version of the djgpp perl.

105.2.2 Shortcomings of Perl under DOS

Perl under DOS lacks some features of perl under UNIX because of deficiencies in the UNIX-emulation, most notably:

- fork() and pipe()
- some features of the UNIX filesystem regarding link count and file dates
- in-place operation is a little bit broken with short filenames
- sockets

105.2.3 Building Perl on DOS

- Unpack the source package *perl5.8*.tar.gz* with djtarx. If you want to use long file names under w95 and also to get Perl to pass all its tests, don't forget to use

  ```
  set LFN=y
  set FNCASE=y
  ```

  before unpacking the archive.

- Create a "symlink" or copy your bash.exe to sh.exe in your `($DJDIR)/bin` directory.

  ```
  ln -s bash.exe sh.exe
  ```

  [If you have the recommended version of bash for DJGPP, this is already done for you.]

  And make the `SHELL` environment variable point to this *sh.exe*:

  ```
  set SHELL=c:/djgpp/bin/sh.exe (use full path name!)
  ```

  You can do this in *djgpp.env* too. Add this line BEFORE any section definition:

  ```
  +SHELL=%DJDIR%/bin/sh.exe
  ```

- If you have *split.exe* and *gsplit.exe* in your path, then rename *split.exe* to *djsplit.exe*, and *gsplit.exe* to *split.exe*. Copy or link *gecho.exe* to *echo.exe* if you don't have *echo.exe*. Copy or link *gawk.exe* to *awk.exe* if you don't have *awk.exe*.

  [If you have the recommended versions of djdev, shell utilities and gawk, all these are already done for you, and you will not need to do anything.]

- Chdir to the djgpp subdirectory of perl toplevel and type the following commands:

  ```
  set FNCASE=y
  configure.bat
  ```

  This will do some preprocessing then run the Configure script for you. The Configure script is interactive, but in most cases you just need to press ENTER. The "set" command ensures that DJGPP preserves the letter case of file names when reading directories. If you already issued this set command when unpacking the archive, and you are in the same DOS session as when you unpacked the archive, you don't have to issue the set command again. This command is necessary *before* you start to (re)configure or (re)build perl in order to ensure both that perl builds correctly and that building XS-type modules can succeed. See the DJGPP info entry for "_preserve_fncase" for more information:

  ```
  info libc alphabetical _preserve_fncase
  ```

  If the script says that your package is incomplete, and asks whether to continue, just answer with Y (this can only happen if you don't use long filenames or forget to issue "set FNCASE=y" first).

  When Configure asks about the extensions, I suggest IO and Fcntl, and if you want database handling then SDBM_File or GDBM_File (you need to install gdbm for this one). If you want to use the POSIX extension (this is the default), make sure that the stack size of your *cc1.exe* is at least 512kbyte (you can check this with: `stubedit cc1.exe`).

  You can use the Configure script in non-interactive mode too. When I built my *perl.exe*, I used something like this:

  ```
  configure.bat -des
  ```

  You can find more info about Configure's command line switches in the *INSTALL* file.

  When the script ends, and you want to change some values in the generated *config.sh* file, then run

  ```
  sh Configure -S
  ```

  after you made your modifications.

  IMPORTANT: if you use this `-S` switch, be sure to delete the CONFIG environment variable before running the script:

  ```
  set CONFIG=
  ```

- Now you can compile Perl. Type:

  ```
  make
  ```

105.2.4 Testing Perl on DOS

Type:

```
make test
```

If you're lucky you should see "All tests successful". But there can be a few failed subtests (less than 5 hopefully) depending on some external conditions (e.g. some subtests fail under linux/dosemu or plain dos with short filenames only).

105.2.5 Installation of Perl on DOS

Type:

```
        make install
```

This will copy the newly compiled perl and libraries into your DJGPP directory structure. Perl.exe and the utilities go into `($DJDIR)/bin`, and the library goes under `($DJDIR)/lib/perl5`. The pod documentation goes under `($DJDIR)/lib/perl5/pod`.

105.3 BUILDING AND INSTALLING MODULES ON DOS

105.3.1 Building Prerequisites for Perl on DOS

For building and installing non-XS modules, all you need is a working perl under DJGPP. Non-XS modules do not require re-linking the perl binary, and so are simpler to build and install.

XS-type modules do require re-linking the perl binary, because part of an XS module is written in "C", and has to be linked together with the perl binary to be executed. This is required because perl under DJGPP is built with the "static link" option, due to the lack of "dynamic linking" in the DJGPP environment.

Because XS modules require re-linking of the perl binary, you need both the perl binary distribution and the perl source distribution to build an XS extension module. In addition, you will have to have built your perl binary from the source distribution so that all of the components of the perl binary are available for the required link step.

105.3.2 Unpacking CPAN Modules on DOS

First, download the module package from CPAN (e.g., the "Comma Separated Value" text package, Text-CSV-0.01.tar.gz). Then expand the contents of the package into some location on your disk. Most CPAN modules are built with an internal directory structure, so it is usually safe to expand it in the root of your DJGPP installation. Some people prefer to locate source trees under /usr/src (i.e., `($DJDIR)/usr/src`), but you may put it wherever seems most logical to you, *EXCEPT* under the same directory as your perl source code. There are special rules that apply to modules which live in the perl source tree that do not apply to most of the modules in CPAN.

Unlike other DJGPP packages, which are normal "zip" files, most CPAN module packages are "gzipped tarballs". Recent versions of WinZip will safely unpack and expand them, *UNLESS* they have zero-length files. It is a known WinZip bug (as of v7.0) that it will not extract zero-length files.

From the command line, you can use the djtar utility provided with DJGPP to unpack and expand these files. For example:

```
        C:\djgpp>djtarx -v Text-CSV-0.01.tar.gz
```

This will create the new directory `($DJDIR)/Text-CSV-0.01`, filling it with the source for this module.

105.3.3 Building Non-XS Modules on DOS

To build a non-XS module, you can use the standard module-building instructions distributed with perl modules.

```
    perl Makefile.PL
    make
    make test
    make install
```

This is sufficient because non-XS modules install only ".pm" files and (sometimes) pod and/or man documentation. No re-linking of the perl binary is needed to build, install or use non-XS modules.

105.3.4 Building XS Modules on DOS

To build an XS module, you must use the standard module-building instructions distributed with perl modules *PLUS* three extra instructions specific to the DJGPP "static link" build environment.

```
    set FNCASE=y
    perl Makefile.PL
    make
    make perl
    make test
    make -f Makefile.aperl inst_perl MAP_TARGET=perl.exe
    make install
```

The first extra instruction sets DJGPP's FNCASE environment variable so that the new perl binary which you must build for an XS-type module will build correctly. The second extra instruction re-builds the perl binary in your module directory before you run "make test", so that you are testing with the new module code you built with "make". The third extra instruction installs the perl binary from your module directory into the standard DJGPP binary directory, `($DJDIR)/bin`, replacing your previous perl binary.

Note that the MAP_TARGET value *must* have the ".exe" extension or you will not create a "perl.exe" to replace the one in `($DJDIR)/bin`.

When you are done, the XS-module install process will have added information to your "perllocal" information telling that the perl binary has been replaced, and what module was installed. You can view this information at any time by using the command:

```
        perl -S perldoc perllocal
```

Chapter 106

README.epoc

Perl for EPOC

106.1 SYNOPSIS

Perl 5 README file for the EPOC Release 5 operating system.

106.2 INTRODUCTION

EPOC is an OS for palmtops and mobile phones. For more informations look at: http://www.symbian.com/

This is a port of perl to the epocemx SDK by Eberhard Mattes, which itself uses the SDK by symbian. Essentially epocemx it is a POSIX look alike environment for the EPOC OS. For more information look at: http://epocemx.sourceforge.net/

perl and epocemx runs on Epoc Release 5 machines: Psion 5mx, 5mx Pro, Psion Revo, Psion Netbook and on the Ericson M128. It may run on Epoc Release 3 Hardware (Series 5 classic), too. For more information about this hardware please refer to http://www.psion.com/

Vendors which like to have support for their devices are free to send me a sample.

106.3 INSTALLING PERL ON EPOC

You can download a ready-to-install version from http://www.oflebbe.de/oflebbe/perl/

You will need at least ˜6MB free space in order to install and run perl.

Please install the emxusr.sis package from http://epocemx.sourceforge.net/ first.

Install perl.sis on the EPOC machine. If you do not know how to do that, consult your PsiWin documentation.

Perl itself and its standard library is using 4 MB disk space. Unicode support and some other modules are left out. (For details, please look into epoc/createpkg.pl). If you like to use these modules, you are free to copy them from a current perl release.

106.4 STARTING PERL ON EPOC

Please use the epocemx shell to start perl. perl integrates with the conventions of epocemx.

106.4.1 Editors on Epoc

A suitable text editor can be downloaded from symbian http://www.symbian.com/developer/downloads/files/editor.zip

106.4.2 Features of Perl on Epoc

The built-in function EPOC::getcwd returns the current directory.

106.4.3 Restrictions of Perl on Epoc

Features are left out, because of restrictions of the POSIX support in EPOC:

- socket IO is only implemented poorly. You can only use sysread and syswrite on them. The commands read, write, print, <> do not work for sockets. This may change iff epocemx supports sockets.
- kill, alarm and signals. Do not try to use them. This may be impossible to implement on EPOC.
- select is missing.
- binmode does not exist. (No CR LF to LF translation for text files)
- EPOC does not handle the notion of current drive and current directory very well (i.e. not at all, but it tries hard to emulate one). See PATH.
- Heap is limited to 4MB.
- Dynamic loading is not implemented.

106.4.4 Compiling Perl 5 on the EPOC cross compiling environment

Sorry, this is far too short.

- You will need the epocemx SDK from Eberhard Mattes.
- Get the Perl sources from your nearest CPAN site.
- Unpack the sources.
- Build a native perl from this sources... Make sure to save the miniperl executable as miniperl.native.
  Start again from scratch

```
cp epoc/* .
./Configure -S
make
cp miniperl.native miniperl
touch miniperl.exe
make
perl createpkg.pl

emxsis perl.pkg perl.sis
```

106.5 SUPPORT STATUS OF PERL ON EPOC

I’m offering this port "as is". You can ask me questions, but I can’t guarantee I’ll be able to answer them. Since the port to epocemx is quite new, please check the web for updates first.
Very special thanks to Eberhard Mattes for epocemx.

106.6 AUTHOR

Olaf Flebbe <olaf@oflebbe.de> http://www.oflebbe.de/oflebbe/perl/

106.7 LAST UPDATE

2003-01-18

Chapter 107

README.freebsd

Perl version 5 on FreeBSD systems

107.1 DESCRIPTION

This document describes various features of FreeBSD that will affect how Perl version 5 (hereafter just Perl) is compiled and/or runs.

107.1.1 FreeBSD core dumps from readdir_r with ithreads

When perl is configured to use ithreads, it will use re-entrant library calls in preference to non-re-entrant versions. There is a bug in FreeBSD's `readdir_r` function in versions 4.5 and earlier that can cause a SEGV when reading large directories. A patch for FreeBSD libc is available (see http://www.freebsd.org/cgi/query-pr.cgi?pr=misc/30631) which has been integrated into FreeBSD 4.6.

107.1.2 $ ^X doesn't always contain a full path in FreeBSD

perl 5.8.0 sets `$^X` where possible to a full path by asking the operating system. On FreeBSD the full path of the perl interpreter is found by reading the symlink */proc/curproc/file*. There is a bug on FreeBSD, where the result of reading this symlink is can be wrong in certain circumstances (see http://www.freebsd.org/cgi/query-pr.cgi?pr=35703). In these cases perl will fall back to the old behaviour of using C's argv[0] value for `$^X`.

107.1.3 Perl will no longer be part of "base FreeBSD"

Not as bad as it sounds–what this means is that Perl will no longer be part of the **kernel build system** of FreeBSD. Perl will still very probably be part of the "default install", and in any case the latest version will be in the ports system. The first FreeBSD version this change will affect is 5.0, all 4.n versions will keep the status quo.

Please report any errors, updates, or suggestions to *perlbug@perl.org*.

Chapter 108

README.hpux

Perl version 5 on Hewlett-Packard Unix (HP-UX) systems

108.1 DESCRIPTION

This document describes various features of HP's Unix operating system (HP-UX) that will affect how Perl version 5 (hereafter just Perl) is compiled and/or runs.

108.1.1 Using perl as shipped with HP-UX

As of application release September 2001, HP-UX 11.00 is shipped with perl-5.6.1 in /opt/perl. The first occurrence is on CD 5012-7954 and can be installed using

```
    swinstall -s /cdrom perl
```

assuming you have mounted that CD on /cdrom. In this version the following modules are installed:

```
    ActivePerl::DocTools-0.04   HTML::Parser-3.19   XML::DOM-1.25
    Archive::Tar-0.072          HTML::Tagset-3.03   XML::Parser-2.27
    Compress::Zlib-1.08         MIME::Base64-2.11   XML::Simple-1.05
    Convert::ASN1-0.10          Net-1.07            XML::XPath-1.09
    Digest::MD5-2.11            PPM-2.1.5           XML::XSLT-0.32
    File::CounterFile-0.12      SOAP::Lite-0.46     libwww-perl-5.51
    Font::AFM-1.18              Storable-1.011      libxml-perl-0.07
    HTML-Tree-3.11              URI-1.11            perl-ldap-0.23
```

The build is a portable hppa-1.1 multithread build that supports large files compiled with gcc-2.9-hppa-991112

If you perform a new installation, then Perl will be installed automatically.

108.1.2 Using perl from HP's porting centre

HP porting centre tries very hard to keep up with customer demand and release updates from the Open Source community. Having precompiled Perl binaries available is obvious.

The HP porting centres are limited in what systems they are allowed to port to and they usually choose the two most recent OS versions available. This means that at the moment of writing, there are only HPUX-11.00 and 11-20/22 (IA64) ports available on the porting centres.

HP has asked the porting centre to move Open Source binaries from /opt to /usr/local, so binaries produced since the start of July 2002 are located in /usr/local.

One of HP porting centres URL's is http://hpux.connect.org.uk/ The port currently available is built with GNU gcc.

108.1.3 Compiling Perl 5 on HP-UX

When compiling Perl, you must use an ANSI C compiler. The C compiler that ships with all HP-UX systems is a K&R compiler that should only be used to build new kernels.

Perl can be compiled with either HP's ANSI C compiler or with gcc. The former is recommended, as not only can it compile Perl with no difficulty, but also can take advantage of features listed later that require the use of HP compiler-specific command-line flags.

If you decide to use gcc, make sure your installation is recent and complete, and be sure to read the Perl INSTALL file for more gcc-specific details.

108.1.4 PA-RISC

HP's current Unix systems run on its own Precision Architecture (PA-RISC) chip. HP-UX used to run on the Motorola MC68000 family of chips, but any machine with this chip in it is quite obsolete and this document will not attempt to address issues for compiling Perl on the Motorola chipset.

The most recent version of PA-RISC at the time of this document's last update is 2.0.

A complete list of models at the time the OS was built is in the file /usr/sam/lib/mo/sched.models. The first column corresponds to the last part of the output of the "model" command. The second column is the PA-RISC version and the third column is the exact chip type used. (Start browsing at the bottom to prevent confusion ;-)

```
    # model
    9000/800/L1000-44
    # grep L1000-44 /usr/sam/lib/mo/sched.models
    L1000-44        2.0     PA8500
```

108.1.5 PA-RISC 1.0

The original version of PA-RISC, HP no longer sells any system with this chip.

The following systems contained PA-RISC 1.0 chips:

```
    600, 635, 645, 808, 815, 822, 825, 832, 834, 835, 840, 842, 845, 850,
    852, 855, 860, 865, 870, 890
```

108.1.6 PA-RISC 1.1

An upgrade to the PA-RISC design, it shipped for many years in many different system.

The following systems contain with PA-RISC 1.1 chips:

```
    705, 710, 712, 715, 720, 722, 725, 728, 730, 735, 742, 743, 744, 745,
    747, 750, 755, 770, 777, 778, 779, 800, 801, 803, 806, 807, 809, 811,
    813, 816, 817, 819, 821, 826, 827, 829, 831, 837, 839, 841, 847, 849,
    851, 856, 857, 859, 867, 869, 877, 887, 891, 892, 897, A180, A180C,
    B115, B120, B132L, B132L+, B160L, B180L, C100, C110, C115, C120,
    C160L, D200, D210, D220, D230, D250, D260, D310, D320, D330, D350,
    D360, D410, DX0, DX5, DXO, E25, E35, E45, E55, F10, F20, F30, G30,
    G40, G50, G60, G70, H20, H30, H40, H50, H60, H70, I30, I40, I50, I60,
    I70, J200, J210, J210XC, K100, K200, K210, K220, K230, K400, K410,
    K420, S700i, S715, S744, S760, T500, T520
```

108.1.7 PA-RISC 2.0

The most recent upgrade to the PA-RISC design, it added support for 64-bit integer data.

As of the date of this document's last update, the following systems contain PA-RISC 2.0 chips:

```
700, 780, 781, 782, 783, 785, 802, 804, 810, 820, 861, 871, 879, 889,
893, 895, 896, 898, 899, A400, A500, B1000, B2000, C130, C140, C160,
C180, C180+, C180-XP, C200+, C400+, C3000, C360, C3600, CB260, D270,
D280, D370, D380, D390, D650, J220, J2240, J280, J282, J400, J410,
J5000, J5500XM, J5600, J7000, J7600, K250, K260, K260-EG, K270, K360,
K370, K380, K450, K460, K460-EG, K460-XP, K470, K570, K580, L1000,
L2000, L3000, N4000, R380, R390, SD16000, SD32000, SD64000, T540,
T600, V2000, V2200, V2250, V2500, V2600
```

Just before HP took over Compaq, some systems were renamed. the link that contained the explanation is dead, so here's a short summary:

```
HP 9000 A-Class servers, now renamed HP Server rp2400 series.
HP 9000 L-Class servers, now renamed HP Server rp5400 series.
HP 9000 N-Class servers, now renamed HP Server rp7400.

rp2400, rp2405, rp2430, rp2450, rp2470, rp3410, rp3440, rp5400,
rp5405, rp5430, rp5450, rp5470, rp7400, rp7405, rp7410, rp7420,
rp8400, rp8420, Superdome
```

The current naming convention is:

```
aadddd
||||`+- 00 - 99 relative capacity & newness (upgrades, etc.)
|||`--- unique number for each architecture to ensure different
|||     systems do not have the same numbering across
|||     architectures
||`---- 1 - 9 identifies family and/or relative positioning
||
|`----- c = ia32 (cisc)
|       p = pa-risc
|       x = ia-64 (Itanium & Itanium 2)
|       h = housing
`------ t = tower
        r = rack optimized
        s = super scalable
        b = blade
        sa = appliance
```

108.1.8 Itanium & Itanium 2

HP also ships servers with the 128-bit Itanium processor(s). As of the date of this document's last update, the following systems contain Itanium or Itanium 2 chips (this is very likely to be out of date):

```
rx1600, rx2600, rx2600hptc, rx4610, rx4640, rx5670, rx7620, rx8620,
rx9610
```

To see all about your machine, type

```
# model
ia64 hp server rx2600
# /usr/contrib/bin/machinfo
```

108.1.9 Portability Between PA-RISC Versions

An executable compiled on a PA-RISC 2.0 platform will not execute on a PA-RISC 1.1 platform, even if they are running the same version of HP-UX. If you are building Perl on a PA-RISC 2.0 platform and want that Perl to also run on a PA-RISC 1.1, the compiler flags +DAportable and +DS32 should be used.

It is no longer possible to compile PA-RISC 1.0 executables on either the PA-RISC 1.1 or 2.0 platforms. The command-line flags are accepted, but the resulting executable will not run when transferred to a PA-RISC 1.0 system.

108.1.10 Itanium Processor Family and HP-UX

HP-UX also runs on the new Itanium processor. This requires the use of a different version of HP-UX (currently 11.23 or 11i v1.6), and with the exception of a few differences detailed below and in later sections, Perl should compile with no problems.

Although PA-RISC binaries can run on Itanium systems, you should not attempt to use a PA-RISC version of Perl on an Itanium system. This is because shared libraries created on an Itanium system cannot be loaded while running a PA-RISC executable.

108.1.11 Building Dynamic Extensions on HP-UX

HP-UX supports dynamically loadable libraries (shared libraries). Shared libraries end with the suffix .sl. On Itanium systems, they end with the suffix .so.

Shared libraries created on a platform using a particular PA-RISC version are not usable on platforms using an earlier PA-RISC version by default. However, this backwards compatibility may be enabled using the same +DAportable compiler flag (with the same PA-RISC 1.0 caveat mentioned above).

Shared libraries created on an Itanium platform cannot be loaded on a PA-RISC platform. Shared libraries created on a PA-RISC platform can only be loaded on an Itanium platform if it is a PA-RISC executable that is attempting to load the PA-RISC library. A PA-RISC shared library cannot be loaded into an Itanium executable nor vice-versa.

To create a shared library, the following steps must be performed:

```
    1. Compile source modules with +z or +Z flag to create a .o module
       which contains Position-Independent Code (PIC).  The linker will
       tell you in the next step if +Z was needed.
       (For gcc, the appropriate flag is -fpic or -fPIC.)

    2. Link the shared library using the -b flag.  If the code calls
       any functions in other system libraries (e.g., libm), it must
       be included on this line.
```

(Note that these steps are usually handled automatically by the extension’s Makefile).

If these dependent libraries are not listed at shared library creation time, you will get fatal "Unresolved symbol" errors at run time when the library is loaded.

You may create a shared library that refers to another library, which may be either an archive library or a shared library. If this second library is a shared library, this is called a "dependent library". The dependent library’s name is recorded in the main shared library, but it is not linked into the shared library. Instead, it is loaded when the main shared library is loaded. This can cause problems if you build an extension on one system and move it to another system where the libraries may not be located in the same place as on the first system.

If the referred library is an archive library, then it is treated as a simple collection of .o modules (all of which must contain PIC). These modules are then linked into the shared library.

Note that it is okay to create a library which contains a dependent library that is already linked into perl.

Some extensions, like DB_File and Compress::Zlib use/require prebuilt libraries for the perl extensions/modules to work. If these libraries are built using the default configuration, it might happen that you run into an error like "invalid loader fixup" during load phase. HP is aware of this problem. Search the HP-UX cxx-dev forums for discussions about the subject. The short answer is that **everything** (all libraries, everything) must be compiled with `+z` or `+Z` to be PIC (position independent code). (For gcc, that would be `-fpic` or `-fPIC`). In HP-UX 11.00 or newer the linker error message should tell the name of the offending object file.

A more general approach is to intervene manually, as with an example for the DB_File module, which requires SleepyCat's libdb.sl:

```
# cd .../db-3.2.9/build_unix
# vi Makefile
... add +Z to all cflags to create shared objects
CFLAGS=         -c $(CPPFLAGS) +Z -Ae +O2 +Onolimit \
                -I/usr/local/include -I/usr/include/X11R6
CXXFLAGS=       -c $(CPPFLAGS) +Z -Ae +O2 +Onolimit \
                -I/usr/local/include -I/usr/include/X11R6

# make clean
# make
# mkdir tmp
# cd tmp
# ar x ../libdb.a
# ld -b -o libdb-3.2.sl *.o
# mv libdb-3.2.sl /usr/local/lib
# rm *.o
# cd /usr/local/lib
# rm -f libdb.sl
# ln -s libdb-3.2.sl libdb.sl

# cd .../DB_File-1.76
# make distclean
# perl Makefile.PL
# make
# make test
# make install
```

It is no longer possible to link PA-RISC 1.0 shared libraries (even though the command-line flags are still present).

PA-RISC and Itanium object files are not interchangeable. Although you may be able to use ar to create an archive library of PA-RISC object files on an Itanium system, you cannot link against it using an Itanium link editor.

108.1.12 The HP ANSI C Compiler

When using this compiler to build Perl, you should make sure that the flag -Aa is added to the cpprun and cppstdin variables in the config.sh file (though see the section on 64-bit perl below). If you are using a recent version of the Perl distribution, these flags are set automatically.

108.1.13 The GNU C Compiler

When you are going to use the GNU C compiler (gcc), and you don't have gcc yet, you can either build it yourself from the sources (available from e.g. http://www.gnu.ai.mit.edu/software/gcc/releases.html) or fetch a prebuilt binary from the HP porting center. There are two places where gcc prebuilds can be fetched; the first and best (for HP-UX 11 only) is http://h21007.www2.hp.com/dspp/tech/tech_TechSoftwareDetailPage_IDX/1,1703,547,00.html the second is http://hpux.cs.utah.edu/hppd/hpux/Gnu/ where you can also find the GNU binutils package. (Browse through the list, because there are often multiple versions of the same package available).

Above mentioned distributions are depots. H.Merijn Brand has made prebuilt gcc binaries available on http://mirrors.develooper.com/hpux/ and/or http://www.cmve.net/˜merijn/ for HP-UX 10.20, HP-UX 11.00, and HP-UX

11.11 (HP-UX 11i) in both 32- and 64-bit versions. These are bzipped tar archives that also include recent GNU binutils and GNU gdb. Read the instructions on that page to rebuild gcc using itself.

On PA-RISC you need a different compiler for 32-bit applications and for 64-bit applications. On PA-RISC, 32-bit objects and 64-bit objects do not mix. period. There is no different behaviour for HP C-ANSI-C or GNU gcc. So if you require your perl binary to use 64-bit libraries, like Oracle-64bit, you MUST build a 64-bit perl.

Building a 64-bit capable gcc on PA-RISC from source is possible only when you have the HP C-ANSI C compiler or an already working 64-bit binary of gcc available. Best performance for perl is achieved with HP's native compiler.

108.1.14 Using Large Files with Perl on HP-UX

Beginning with HP-UX version 10.20, files larger than 2GB (2ˆ31 bytes) may be created and manipulated. Three separate methods of doing this are available. Of these methods, the best method for Perl is to compile using the -Duselargefiles flag to Configure. This causes Perl to be compiled using structures and functions in which these are 64 bits wide, rather than 32 bits wide. (Note that this will only work with HP's ANSI C compiler. If you want to compile Perl using gcc, you will have to get a version of the compiler that supports 64-bit operations. See above for where to find it.)

There are some drawbacks to this approach. One is that any extension which calls any file-manipulating C function will need to be recompiled (just follow the usual "perl Makefile.PL; make; make test; make install" procedure).

The list of functions that will need to recompiled is: creat, fgetpos, fopen, freopen, fsetpos, fstat, fstatvfs, fstatvfsdev, ftruncate, ftw, lockf, lseek, lstat, mmap, nftw, open, prealloc, stat, statvfs, statvfsdev, tmpfile, truncate, getrlimit, setrlimit

Another drawback is only valid for Perl versions before 5.6.0. This drawback is that the seek and tell functions (both the builtin version and POSIX module version) will not perform correctly.

It is strongly recommended that you use this flag when you run Configure. If you do not do this, but later answer the question about large files when Configure asks you, you may get a configuration that cannot be compiled, or that does not function as expected.

108.1.15 Threaded Perl on HP-UX

It is possible to compile a version of threaded Perl on any version of HP-UX before 10.30, but it is strongly suggested that you be running on HP-UX 11.00 at least.

To compile Perl with threads, add -Dusethreads to the arguments of Configure. Verify that the -D_POSIX_C_SOURCE=199506L compiler flag is automatically added to the list of flags. Also make sure that -lpthread is listed before -lc in the list of libraries to link Perl with. The hints provided for HP-UX during Configure will try very hard to get this right for you.

HP-UX versions before 10.30 require a separate installation of a POSIX threads library package. Two examples are the HP DCE package, available on "HP-UX Hardware Extensions 3.0, Install and Core OS, Release 10.20, April 1999 (B3920-13941)" or the Freely available PTH package, available though worldwide HP-UX mirrors of precompiled packages (e.g. http://hpux.tn.tudelft.nl/hppd/hpux/)

If you are going to use the HP DCE package, the library used for threading is /usr/lib/libcma.sl, but there have been multiple updates of that library over time. Perl will build with the first version, but it will not pass the test suite. Older Oracle versions might be a compelling reason not to update that library, otherwise please find a newer version in one of the following patches: PHSS_19739, PHSS_20608, or PHSS_23672

reformatted output:

```
d3:/usr/lib 106 > what libcma-*.1
libcma-00000.1:
   HP DCE/9000 1.5               Module: libcma.sl (Export)
                                 Date: Apr 29 1996 22:11:24
libcma-19739.1:
   HP DCE/9000 1.5 PHSS_19739-40 Module: libcma.sl (Export)
                                 Date: Sep  4 1999 01:59:07
libcma-20608.1:
   HP DCE/9000 1.5 PHSS_20608    Module: libcma.1 (Export)
                                 Date: Dec  8 1999 18:41:23
libcma-23672.1:
   HP DCE/9000 1.5 PHSS_23672    Module: libcma.1 (Export)
                                 Date: Apr  9 2001 10:01:06
d3:/usr/lib 107 >
```

108.1.16 64-bit Perl on HP-UX

Beginning with HP-UX 11.00, programs compiled under HP-UX can take advantage of the LP64 programming environment (LP64 means Longs and Pointers are 64 bits wide).

Work is being performed on Perl to make it 64-bit compliant on all versions of Unix. Once this is complete, scalar variables will be able to hold numbers larger than 2^32 with complete precision.

As of the date of this document, Perl is fully 64-bit compliant on HP-UX 11.00 and up for both cc- and gcc builds. If you are about to build a 64-bit perl with GNU gcc, please read the gcc section carefully.

Should a user wish to experiment with compiling Perl in the LP64 environment, use the -Duse64bitall flag to Configure. This will force Perl to be compiled in a pure LP64 environment (with the +DD64 flag for HP C-ANSI-C, with no additional options for GNU gcc 64-bit on PA-RISC, and with -mlp64 for GNU gcc on Itanium). If you want to compile Perl using gcc, you will have to get a version of the compiler that supports 64-bit operations.)

You can also use the -Duse64bitint flag to Configure. Although there are some minor differences between compiling Perl with this flag versus the -Duse64bitall flag, they should not be noticeable from a Perl user's perspective.

In both cases, it is strongly recommended that you use these flags when you run Configure. If you do not use do this, but later answer the questions about 64-bit numbers when Configure asks you, you may get a configuration that cannot be compiled, or that does not function as expected.

108.1.17 Oracle on HP-UX

Using perl to connect to Oracle databases through DBI and DBD::Oracle has caused a lot of people many headaches. Read README.hpux in the DBD::Oracle for much more information. The reason to mention it here is that Oracle requires a perl built with libcl and libpthread, the latter even when perl is build without threads. Building perl using all defaults, but still enabling to build DBD::Oracle later on can be achieved using

```
  Configure -A prepend:libswanted='cl pthread ' ...
```

Do not forget the space before the trailing quote.

Also note that this does not (yet) work with all configurations, it is known to fail with 64-bit versions of GCC.

108.1.18 GDBM and Threads on HP-UX

If you attempt to compile Perl with threads on an 11.X system and also link in the GDBM library, then Perl will immediately core dump when it starts up. The only workaround at this point is to relink the GDBM library under 11.X, then relink it into Perl.

108.1.19 NFS filesystems and utime(2) on HP-UX

If you are compiling Perl on a remotely-mounted NFS filesystem, the test io/fs.t may fail on test #18. This appears to be a bug in HP-UX and no fix is currently available.

108.1.20 perl -P and // and HP-UX

If HP-UX Perl is compiled with flags that will cause problems if the -P flag of Perl (preprocess Perl code with the C preprocessor before perl sees it) is used. The problem is that `//`, being a C++-style until-end-of-line comment, will disappear along with the remainder of the line. This means that common Perl constructs like

```
    s/foo//;
```

will turn into illegal code

```
    s/foo
```

The workaround is to use some other quoting separator than `"/"`, like for example `"!"`:

```
    s!foo!!;
```

108.1.21 HP-UX Kernel Parameters (maxdsiz) for Compiling Perl

By default, HP-UX comes configured with a maximum data segment size of 64MB. This is too small to correctly compile Perl with the maximum optimization levels. You can increase the size of the maxdsiz kernel parameter through the use of SAM.
When using the GUI version of SAM, click on the Kernel Configuration icon, then the Configurable Parameters icon. Scroll down and select the maxdsiz line. From the Actions menu, select the Modify Configurable Parameter item. Insert the new formula into the Formula/Value box. Then follow the instructions to rebuild your kernel and reboot your system.
In general, a value of 256MB (or "256*1024*1024") is sufficient for Perl to compile at maximum optimization.

108.2 nss_delete core dump from op/pwent or op/grent

You may get a bus error core dump from the op/pwent or op/grent tests. If compiled with -g you will see a stack trace much like the following:

```
  #0  0xc004216c in  () from /usr/lib/libc.2
  #1  0xc00d7550 in __nss_src_state_destr () from /usr/lib/libc.2
  #2  0xc00d7768 in __nss_src_state_destr () from /usr/lib/libc.2
  #3  0xc00d78a8 in nss_delete () from /usr/lib/libc.2
  #4  0xc01126d8 in endpwent () from /usr/lib/libc.2
  #5  0xd1950 in Perl_pp_epwent () from ./perl
  #6  0x94d3c in Perl_runops_standard () from ./perl
  #7  0x23728 in S_run_body () from ./perl
  #8  0x23428 in perl_run () from ./perl
  #9  0x2005c in main () from ./perl
```

The key here is the `nss_delete` call. One workaround for this bug seems to be to create add to the file */etc/nsswitch.conf* (at least) the following lines

```
  group: files
  passwd: files
```

Whether you are using NIS does not matter. Amazingly enough, the same bug also affects Solaris.

Chapter 109

README.hurd

Perl version 5 on Hurd

109.1 DESCRIPTION

If you want to use Perl on the Hurd, I recommend using the Debian GNU/Hurd distribution (see http://www.debian.org/), even if an official, stable release has not yet been made. The old 'gnu-0.2' binary distribution will most certainly have additional problems.

109.1.1 Known Problems with Perl on Hurd

The Perl test suite may still report some errors on the Hurd. The 'lib/anydbm' and 'pragma/warnings' tests will almost certainly fail. Both failures are not really specific to the Hurd, as indicated by the test suite output.

The socket tests may fail if the network is not configured. You have to make '/hurd/pfinet' the translator for '/servers/socket/2', giving it the right arguments. Try '/hurd/pfinet –help' for more information.

Here are the statistics for Perl 5.005_62 on my system:

```
Failed Test  Status Wstat Total Fail  Failed  List of failed
-------------------------------------------------------------------------
lib/anydbm.t                 12    1   8.33%  12
pragma/warnings             333    1   0.30%  215

8 tests and 24 subtests skipped.
Failed 2/229 test scripts, 99.13% okay. 2/10850 subtests failed, 99.98% okay.
```

There are quite a few systems out there that do worse!

However, since I am running a very recent Hurd snapshot, in which a lot of bugs that were exposed by the Perl test suite have been fixed, you may encounter more failures. Likely candidates are: 'op/stat', 'lib/io_pipe', 'lib/io_sock', 'lib/io_udp' and 'lib/time'.

In any way, if you're seeing failures beyond those mentioned in this document, please consider upgrading to the latest Hurd before reporting the failure as a bug.

Chapter 110

README.irix

Perl version 5 on Irix systems

110.1 DESCRIPTION

This document describes various features of Irix that will affect how Perl version 5 (hereafter just Perl) is compiled and/or runs.

110.1.1 Building 32-bit Perl in Irix

Use

```
        sh Configure -Dcc='cc -n32'
```

to compile Perl 32-bit. Don't bother with -n32 unless you have 7.1 or later compilers (use cc -version to check).
(Building 'cc -n32' is the default.)

110.1.2 Building 64-bit Perl in Irix

Use

```
        sh Configure -Dcc='cc -64' -Duse64bitint
```

This requires require a 64-bit MIPS CPU (R8000, R10000, ...)
You can also use

```
        sh Configure -Dcc='cc -64' -Duse64bitall
```

but that makes no difference compared with the -Duse64bitint because of the `cc -64`.
You can also do

```
        sh Configure -Dcc='cc -n32' -Duse64bitint
```

to use long longs for the 64-bit integer type, in case you don't have a 64-bit CPU.
If you are using gcc, just

```
        sh Configure -Dcc=gcc -Duse64bitint
```

should be enough, the Configure should automatically probe for the correct 64-bit settings.

110.1.3 About Compiler Versions of Irix

Some Irix cc versions, e.g. 7.3.1.1m (try cc -version) have been known to have issues (coredumps) when compiling perl.c. If you've used -OPT:fast_io=ON and this happens, try removing it. If that fails, or you didn't use that, then try adjusting other optimization options (-LNO, -INLINE, -O3 to -O2, etcetera). The compiler bug has been reported to SGI. (Allen Smith <easmith@beatrice.rutgers.edu>)

110.1.4 Linker Problems in Irix

If you get complaints about so_locations then search in the file hints/irix_6.sh for "lddflags" and do the suggested adjustments. (David Billinghurst <David.Billinghurst@riotinto.com.au>)

110.1.5 Malloc in Irix

Do not try to use Perl's malloc, this will lead into very mysterious errors (especially with -Duse64bitall).

110.1.6 Building with threads in Irix

Run Configure with -Duseithreads which will configure Perl with the new Perl 5.8.0 "interpreter threads", see *threads*.

The old Perl 5.005 threads is obsolete, unmaintained, and its use is discouraged. If you really want it, run Configure with the -Dusethreads -Duse5005threads options as described in INSTALL.

For either thread model and for Irix 6.2, you have to have the following patches installed:

```
        1404 Irix 6.2 Posix 1003.1b man pages
        1645 Irix 6.2 & 6.3 POSIX header file updates
        2000 Irix 6.2 Posix 1003.1b support modules
        2254 Pthread library fixes
        2401 6.2 all platform kernel rollup
```

IMPORTANT: Without patch 2401, a kernel bug in Irix 6.2 will cause your machine to panic and crash when running threaded perl. Irix 6.3 and later are okay.

```
    Thanks to Hannu Napari <Hannu.Napari@hut.fi> for the IRIX
    pthreads patches information.
```

110.1.7 Irix 5.3

While running Configure and when building, you are likely to get quite a few of these warnings:

```
  ld:
  The shared object /usr/lib/libm.so did not resolve any symbols.
        You may want to remove it from your link line.
```

Ignore them: in IRIX 5.3 there is no way to quieten ld about this.

During compilation you will see this warning from toke.c:

```
  uopt: Warning: Perl_yylex: this procedure not optimized because it
        exceeds size threshold; to optimize this procedure, use -Olimit option
        with value >= 4252.
```

Ignore the warning.

In IRIX 5.3 and with Perl 5.8.1 (Perl 5.8.0 didn't compile in IRIX 5.3) the following failures are known.

```
Failed Test                  Stat Wstat Total Fail  Failed  List of Failed
--------------------------------------------------------------------------
../ext/List/Util/t/shuffle.t    0   139    ??   ??       %  ??
../lib/Math/Trig.t            255 65280    29   12  41.38%  24-29
../lib/sort.t                   0   138   119   72  60.50%  48-119
56 tests and 474 subtests skipped.
Failed 3/811 test scripts, 99.63% okay. 78/75813 subtests failed, 99.90% okay.
```

They are suspected to be compiler errors (at least the shuffle.t failure is known from some IRIX 6 setups) and math library errors (the Trig.t failure), but since IRIX 5 is long since end-of-lifed, further fixes for the IRIX are unlikely. If you can get gcc for 5.3, you could try that, too, since gcc in IRIX 6 is a known workaround for at least the shuffle.t and sort.t failures.

110.2 AUTHOR

Jarkko Hietaniemi <jhi@iki.fi>

Please report any errors, updates, or suggestions to *perlbug@perl.org*.

Chapter 111

README.machten

Perl version 5 on Power MachTen systems

111.1 DESCRIPTION

This document describes how to build Perl 5 on Power MachTen systems, and discusses a few wrinkles in the implementation.

111.1.1 Perl version 5.8.x and greater not supported

Power MachTen is not supported by versions of Perl later than 5.6.x. If you wish to build a version from the 5.6 track, please obtain a source distribution from the archive at http://cpan.org/src/5.0/ and follow the instructions in its README.machten file.

MachTen is no longer supported by its developers, Tenon Intersystems. A UNIX environment hosted on Mac OS Classic, MachTen has been superseded by Mac OS X and by BSD and Linux implementations for Macintosh hardware. The final version of Power MachTen, 4.1.4, lacks many features found in modern implementations of UNIX, and has a number of bugs. These shortcomings prevent recent versions of Perl from being able to use extensions on MachTen, and cause numerous test suite failures in the perl core.

In September 2003, a discussion on the MachTen mailing list determined that there was no interest in making a later version of Perl build successfully on MachTen. Consequently, support for building Perl under MachTen has been suppressed in Perl distributions published after February 2004. The hints file, *hints/machten.sh*, remains a part of the distributions for reference purposes.

111.1.2 Compiling Perl 5.6.x on MachTen

To compile perl 5.6.x under MachTen 4.1.4 (and probably earlier versions):

```
  ./Configure -de
  make
  make test
  make install
```

This builds and installs a statically-linked perl; MachTen's dynamic linking facilities are not adequate to support Perl's use of dynamically linked libraries. (See *hints/machten.sh* for more information.)

You should have at least 32 megabytes of free memory on your system before running the `make` command.

For much more information on building perl – for example, on how to change the default installation directory – see *INSTALL*.

111.1.3 Failures during `make test` on MachTen

op/lexassign.t

This test may fail when first run after building perl. It does not fail subsequently. The cause is unknown.

pragma/warnings.t

Test 257 fails due to a failure to warn about attempts to read from a filehandle which is a duplicate of stdout when stdout is attached to a pipe. The output of the test contains a block comment which discusses a different failure, not applicable to MachTen.

The root of the problem is that Machten does not assign a file type to either end of a pipe (see *stat*), resulting, among other things in Perl's `-p` test failing on file descriptors belonging to pipes. As a result, perl becomes confused, and the test for reading from a write-only file fails. I am reluctant to patch perl to get around this, as it's clearly an OS bug (about which Tenon has been informed), and limited in its effect on practical Perl programs.

111.1.4 Building external modules on MachTen

To add an external module to perl, build in the normal way, which is documented in *ExtUtils::MakeMaker*, or which can be driven automatically by the CPAN module (see *CPAN*), which is part of the standard distribution. If you want to install a module which contains XS code (C or C++ source which compiles to object code for linking with perl), you will have to replace your perl binary with a new version containing the new statically-linked object module. The build process tells you how to do this.

There is a gotcha, however, which users usually encounter immediately they respond to CPAN's invitation to `install Bundle::CPAN`. When installing a *bundle* – a group of modules which together achieve some particular purpose, the installation process for later modules in the bundle tends to assume that earlier modules have been fully installed and are available for use. This is not true on a statically-linked system for earlier modules which contain XS code. As a result the installation of the bundle fails. The work-around is not to install the bundle as a one-shot operation, but instead to see what modules it contains, and install these one-at-a-time by hand in the order given.

Version 1.1.0 2004-02-13

Chapter 112

README.macos

Perl under Mac OS (Classic)

112.1 SYNOPSIS

This document briefly describes perl under Mac OS (Classic). If you are running perl under Mac OS X, you don't want to be here (unless you are in the Classic environment under Mac OS X).

When we say "Mac OS" below, we mean Mac OS 7, 8, and 9, and *not* Mac OS X.

112.2 DESCRIPTION

The latest perl source itself builds on Mac OS, with some additional pieces. Support for Mac OS is now in the perl core, and MacPerl is kept in close sync with regular perl releases.

To build perl for Mac OS (as an MPW tool), you will need the addition of the *macos* subdirectory, distributed separately. It includes extra source files, config files, and make files. It also includes extra Mac-specific modules.

To build the MacPerl application, you will also need the *macperl* directory, which includes the source files for creating the application itself.

All of this is available from the development site, via HTTP (in the MacPerl Installer, which includes all the source and binaries) and anonymous CVS.

```
    http://dev.macperl.org/
```

The source is also in the main perl repository in the macperl branch (the 5.6 source is in the maint-5.6/macperl branch).

You will also need compilers and libraries, all of them freely available. These are linked to from the SourceForge site. Go that site for all things having to do with MacPerl development.

MacPerl 5.6.1 and later are supported on Mac OS 8.1 and later, for 68040 and PowerPC architectures. The MPW tool may be used on Mac OS 7.5.5 and 68030 computers.

MacPerl 5.2.0r4 is also available, on the CPAN and on SourceForge. It is based on perl 5.004, and works with Mac OS 7.5.5 and 68030 computers.

112.3 AUTHOR

perl was ported to Mac OS by Matthias Neeracher <neeracher@mac.com>. It is currently maintained by Chris Nandor <pudge@pobox.com>.

Chapter 113

README.macosx

Perl under Mac OS X

113.1 SYNOPSIS

This document briefly describes perl under Mac OS X.

113.2 DESCRIPTION

The latest Perl (5.8.1-RC3 as of this writing) builds without changes under Mac OS X. Under the 10.3 "Panther" release, all self-tests pass, and all standard features are supported.

Earlier Mac OS X releases did not include a completely thread-safe libc, so threading is not fully supported. Also, earlier releases included a somewhat buggy libdb, so some of the DB_File tests are known to fail on those releases.

113.2.1 Installation Prefix

The default installation location for this release uses the traditional UNIX directory layout under /usr/local. This is the recommended location for most users, and will leave the Apple-supplied Perl and its modules undisturbed.

Using an installation prefix of '/usr' will result in a directory layout that mirrors that of Apple's default Perl, with core modules stored in '/System/Library/Perl/${version}', CPAN modules stored in '/Library/Perl/${version}', and the addition of '/Network/Library/Perl/${version}' to @INC for modules that are stored on a file server and used by many Macs.

113.2.2 libperl and Prebinding

Mac OS X ships with a dynamically-loaded libperl, but the default for this release is to compile a static libperl. The reason for this is pre-binding. Dynamic libraries can be pre-bound to a specific address in memory in order to decrease load time. To do this, one needs to be aware of the location and size of all previously-loaded libraries. Apple collects this information as part of their overall OS build process, and thus has easy access to it when building Perl, but ordinary users would need to go to a great deal of effort to obtain the information needed for pre-binding.

You can override the default and build a shared libperl if you wish (Configure ... -Duseshrlib), but the load time will be significantly greater than either the static library, or Apple's pre-bound dynamic library.

113.2.3 Updating Panther

As of this writing, the latest Perl release that has been tested and approved for inclusion in the 10.3 "Panther" release of Mac OS X is 5.8.1 RC3. It is currently unknown whether the final 5.8.1 release will be made in time to be tested and included with Panther.

If the final release of Perl 5.8.1 is not made in time to be included with Panther, it is recommended that you wait for an official Apple update to the OS, rather than attempting to update it yourself. In most cases, if you need a newer Perl, it is preferable to install it in some other location, such as /usr/local or /opt, rather than overwriting the system Perl. The default location (no -Dprefix=... specified when running Configure) is /usr/local.

If you find that you do need to update the system Perl, there is one potential issue. If you upgrade using the default static libperl, you will find that the dynamic libperl supplied by Apple will not be deleted. If both libraries are present when an application that links against libperl is built, ld will link against the dynamic library by default. So, if you need to replace Apple's dynamic libperl with a static libperl, you need to be sure to delete the older dynamic library after you've installed the update.

Note that this is only an issue when updating from an older build of the same Perl version. If you're updating from (for example) 5.8.1 to 5.8.2, this issue won't affect you.

113.2.4 Known problems

If you have installed extra libraries such as GDBM through Fink (in other words, you have libraries under */sw/lib*), or libdlcompat to */usr/local/lib*, you may need to be extra careful when running Configure to not to confuse Configure and Perl about which libraries to use. Being confused will show up for example as "dyld" errors about symbol problems, for example during "make test". The safest bet is to run Configure as

```
    Configure ... -Uloclibpth -Dlibpth=/usr/lib
```

to make Configure look only into the system libraries. If you have some extra library directories that you really want to use (such as newer Berkeley DB libraries in pre-Panther systems), add those to the libpth:

```
    Configure ... -Uloclibpth -Dlibpth='/usr/lib /opt/lib'
```

The default of building Perl statically may cause problems with complex applications like Tk: in that case consider building shared Perl

```
    Configure ... -Duseshrplib
```

but remember that there's a startup cost to pay in that case (see above "libperl and Prebinding").

113.2.5 MacPerl

Quite a bit has been written about MacPerl, the Perl distribution for "Classic MacOS" - that is, versions 9 and earlier of MacOS. Because it runs in environment that's very different from that of UNIX, many things are done differently in MacPerl. Modules are installed using a different procedure, Perl itself is built differently, path names are different, etc.

From the perspective of a Perl programmer, Mac OS X is more like a traditional UNIX than Classic MacOS. If you find documentation that refers to a special procedure that's needed for MacOS that's drastically different from the instructions provided for UNIX, the MacOS instructions are quite often intended for MacPerl on Classic MacOS. In that case, the correct procedure on Mac OS X is usually to follow the UNIX instructions, rather than the MacPerl instructions.

113.2.6 Carbon

MacPerl ships with a number of modules that are used to access the classic MacOS toolbox. Many of these modules have been updated to use Mac OS X's newer "Carbon" toolbox, and are available from CPAN in the "Mac::Carbon" module.

113.2.7 Cocoa

There are two ways to use Cocoa from Perl. Apple's PerlObjCBridge module, included with Mac OS X, can be used by standalone scripts to access Foundation (i.e. non-GUI) classes and objects.

An alternative is CamelBones, a framework that allows access to both Foundation and AppKit classes and objects, so that full GUI applications can be built in Perl. CamelBones can be found on SourceForge, at http://www.sourceforge.net/projects/camelbones/.

113.3 Starting From Scratch

Unfortunately it is not that difficult somehow manage to break one's Mac OS X Perl rather severely. If all else fails and you want to really, **REALLY**, start from scratch and remove even your Apple Perl installation (which has become corrupted somehow), the following instructions should do it. **Please think twice before following these instructions: they are much like conducting brain surgery to yourself. Without anesthesia.** We will **not** come to fix your system if you do this.

First, get rid of the libperl.dylib:

```
    # cd /System/Library/Perl/darwin/CORE
    # rm libperl.dylib
```

Then delete every .bundle file found anywhere in the folders:

```
    /System/Library/Perl
    /Library/Perl
```

You can find them for example by

```
    # find /System/Library/Perl /Library/Perl -name '*.bundle' -print
```

After this you can either copy Perl from your operating system CDs (you will need at least the /System/Library/Perl and /usr/bin/perl), or rebuild Perl from the source code with `Configure -Dprefix=/usr -Dusershrplib` NOTE: the `-Dprefix=/usr` to replace the system Perl works much better with Perl 5.8.1 and later, in Perl 5.8.0 the settings were not quite right.

113.4 AUTHOR

This README was written by Sherm Pendley <sherm@dot-app.org>. The "Starting From Scratch" recipe was contributed by John Montbriand <montbriand@apple.com>.

113.5 DATE

Last modified 2003-09-08.

Chapter 114

README.mint

Perl version 5 on Atari MiNT

114.1 DESCRIPTION

There is a binary version of perl available from the FreeMiNT project http://freemint.de/ You may wish to use this instead of trying to compile yourself.

The following advice is from perl 5.004_02 and is probably rather out of date.

If you want to build perl yourself on MiNT (or maybe on an Atari without MiNT) you may want to accept some advice from somebody who already did it...

There was a perl port for Atari ST done by ++jrb bammi@cadence.com. This port tried very hard to build on non-MiNT-systems. For the sake of efficiency I've left this way. Yet, I haven't removed bammi's patches but left them intact. Unfortunately some of the files that bammi contributed to the perl distribution seem to have vanished?

So, how can you distinguish my patches from bammi's patches? All of bammi's stuff is embedded in "#ifdef atarist" preprocessor macros. My MiNT port uses "#ifdef __MINT__" instead (and unconditionally undefines "atarist". If you want to continue on bammi's port, all you have to do is to swap the "-D" and "-U" switches for "__MINT__" and "atarist" in the variable ccflags.

However, I think that my version will still run on non-MiNT-systems provided that the user has a Eunuchs-like environment (i.e. the standard envariables like $PATH, $HOME, ... are set, there is a POSIX compliant shell in /bin/sh, and...)

114.2 Known problems with Perl on MiNT

The problems you may encounter when building perl on your machine are most probably due to deficiencies in MiNT resp. the Atari platform in general.

First of all, if you have less than 8 MB of RAM you shouldn't even try to build Perl yourself. Better grab a binary pre-compiled version somewhere. Even if you have more memory you should take some care. Try to run in a fresh environment (without memory fragmented too much) with as few daemons, accessories, xcontrol modules etc. as possible. If you run some AES you should consider to start a console based environment instead.

A problem has been reported with sed. Sed is used to create some configuration files based on the answers you have given to the Configure script. Unfortunately the Perl Configure script shows sed on MiNT its limits. I have sed 2.05 with a stacksize of 64k and I have encountered no problems. If sed crashes during your configuration process you should first try to augment sed's stacksize:

```
        fixstk 64k /usr/bin/sed
```

(or similar). If it still doesn't help you may have a look which other versions of sed are installed on your system. If you have a KGMD 1.0 installation you will find three in /usr/bin. Have a look there.

Perl has some "mammut" C files. If gcc reports "internal compiler error: program cc1 got fatal signal 10" this is very likely due to a stack overflow in program cc1. Find cc1 and fix its stack. I have made good experiences with

```
        fixstk 2 cc1
```

This doesn't establish a stack of 2 Bytes only as you might think. It really reserves one half of the available memory for cc1's stack. A setting of 1 would reserve the entire memory for cc1, 3 would reserve three fourths. You will have to find out the value that suits to your system yourself.

To find out the location of the program 'cc1' simply type 'gcc –print-prog-name cc1' at your shell prompt.

Now run make (maybe "make -k"). If you get a fatal signal 10 increase cc1's stacksize, if you run out of memory you should either decrease the stacksize or follow some more hints:

Perl's building process is very handy on machines with a lot of virtual memory but may result in a disaster if you are short of memory. If gcc fails to compile many source files you should reduce the optimization. Grep for "optimize" in the file config.sh and change the flags.

If only several huge files cause problems (actually it is not a matter of the file size resp. the amount of code but depends on the size of the individual functions) it is useful to bypass the make program and compile these files directly from the command line. For example if you got something like the following from make:

```
        CCCMD = gcc -DPERL_CORE ....
        ...
        ...: virtual memory exhausted
```

you should hack into the shell:

```
        gcc -DPERL_CORE ... toke.c
```

Please note that you have to add the name of the source file (here toke.c) at the end.

If none of this helps, you're helpless. Wait for a binary release. If you have succeeded you may encounter another problem at the linking process. If gcc complains that it can't find some libraries within the perl distribution you probably have an old linker. If it complains for example about "file not found for xxx.olb" you should cd into the directory in question and

```
        ln -s libxxx.a xxx.olb
```

This will fix the problem.

This version (5.00402) of perl has passed most of the tests on my system:

```
 Failed Test  Status Wstat Total Fail  Failed  List of failed
 ------------------------------------------------------------------------------
 io/pipe.t                   10    2  20.00%  7, 9
 io/tell.t                   13    1   7.69%  12
 lib/complex.t              762   13   1.71%  84-85, 248-251, 257, 272-273,
                                              371, 380, 419-420
 lib/io_pipe.t               10    1  10.00%  9
 lib/io_tell.t               13    1   7.69%  12
 op/magic.t                  30    2   6.67%  29-30
 Failed 6/152 test scripts, 96.05% okay. 20/4359 subtests failed, 99.54% okay.
```

Pipes always cause problems with MiNT, it's actually a surprise that most of the tests did work. I've got no idea why the "tell" test failed, this shouldn't mean too big a problem however.

Most of the failures of lib/complex seem to be harmless, actually errors far right to the decimal point... Two failures seem to be serious: The sign of the results is reversed. I would say that this is due to minor bugs in the portable math lib that I compiled perl with.

I haven't bothered very much to find the reason for the failures with op/magic.t and op/stat.t. Maybe you'll find it out.

###

Another possible problem may arise from the implementation of the "pwd" command. It happened to add a carriage return and newline to its output no matter what the setting of $UNIXMODE is. This is quite annoying since many library modules for perl take the output of pwd, chop off the trailing newline character and then expect to see a valid path in that. But the carriage return (last but second character!) isn't chopped off. You can either try to patch all library modules (at the price of performance for the extra transformation) or you can use my version of pwd that doesn't suffer from this deficiency.

The fixed implementation is in the mint subdirectory. Running "Configure" will attempt to build and install it if necessary (hints/mint.sh will do this work) but you can build and install it explicitly by:

```
    cd mint
    make install
```

This is the fastest solution.

Just in case you want to go the hard way: perl won't even build with a broken pwd! You will have to fix the library modules (ext/POSIX/POSIX.pm, lib/Cwd.pm, lib/pwd.pl) at last after building miniperl.

A major nuisance of current MiNTLib versions is the implementation of system() which is far from being POSIX compliant. A real system() should fork and then exec /bin/sh with its argument as a command line to the shell. The MiNTLib system() however doesn't expect that every user has a POSIX shell in /bin/sh. It tries to work around the problem by forking and exec'ing the first token in its argument string. To get a little bit of compliance to POSIX system() it tries to handle at least redirection ("<" or ">") on its own behalf.

This isn't a good idea since many programs expect that they can pass a command line to system() that exploits all features of a POSIX shell. If you use the MiNTLib version of system() with perl the Perl function system() will suffer from the same deficiencies.

You will find a fixed version of system() in the mint subdirectory. You can easily insert this version into your system libc:

```
    cd mint
    make system.o
    ar r /usr/lib/libc.a
    ranlib /usr/lib/libc.a
```

If you are suspicious you should either back up your libc before or extract the original system.o from your libc with "ar x /usr/lib/libc.a system.o". You can then backup the system.o module somewhere before you succeed.

Anything missing? Yep, I've almost forgotten... No file in this distribution without a fine saying. Take this one:

```
    "From a thief you should learn: (1) to work at night;
    (2) if one cannot gain what one wants in one night to
    try again the next night; (3) to love one's coworkers
    just as thieves love each other; (4) to be willing to
    risk one's life even for a little thing; (5) not to
    attach too much value to things even though one has
    risked one's life for them - just as a thief will resell
    a stolen article for a fraction of its real value;
    (6) to withstand all kinds of beatings and tortures
    but to remain what you are; and (7) to believe your
    work is worthwhile and not be willing to change it."

                    -- Rabbi Dov Baer, Maggid of Mezeritch
```

OK, this was my motto while working on Perl for MiNT, especially rule (1)...

Have fun with Perl!

Chapter 115

README.mpeix

Perl/iX for HP e3000 MPE

115.1 SYNOPSIS

```
http://www.bixby.org/mark/perlix.html
http://jazz.external.hp.com/src/hp_freeware/perl/
Perl language for MPE
Last updated July 29, 2003 @ 2100 UTC
```

115.2 NOTE

This is a podified version of the above-mentioned web page, podified by Jarkko Hietaniemi 2001-Jan-01.

115.3 Binary distribution from HP

The simplest way to obtain Perl for the MPE/iX is to go either of these URLs and follow the instructions within.

http://jazz.external.hp.com/src/hp_freeware/perl/ http://www.bixby.org/mark/perlix.html

Use which ever one is more recent.

115.4 What's New in Perl for MPE/iX

June 1, 2000

- Rebuilt to be compatible with mod_perl. If you plan on using mod_perl, you MUST download and install this version of Perl/iX!
- uselargefiles="undef": not available in MPE for POSIX files yet.
- Now bundled with various add-on packages:
  - libnet (as seen on CPAN)
  - libwww-perl (LWP) which lets Perl programs behave like web browsers:

```
1. #!/PERL/PUB/perl
2. use LWP::Simple;
3. $doc = get('http://www.bixby.org/mark/perlix.html');  # reads the
   web page into variable $doc
```

(http://www.bixby.org/mark/perlix.html)

- mod_perl (just the perl portion; the actual DSO will be released soon with Apache/iX 1.3.12 from bixby.org). This module allows you to write high performance persistent Perl CGI scripts and all sorts of cool things. (http://perl.apache.org/)

  and much much more hiding under /PERL/PUB/.cpan/
- The CPAN module now works for automatic downloading and installing of add-on packages:

```
1. export FTP_PASSIVE=1
2. perl -MCPAN -e shell
3. Ignore any terminal I/O related complaints!
```

  (http://theoryx5.uwinnipeg.ca/CPAN/data/perl/CPAN.html)

May 20, 2000

- Updated to version 5.6.0. Builds straight out of the box on MPE/iX.
- Perl's getpwnam() function which had regressed to being unimplemented on MPE is now implemented once again.

September 17, 1999

- Migrated from cccd.edu to bixby.org.

115.5 Welcome to Perl/iX

This is the official home page for the HP e3000 MPE/iX (http://www.hp.com/go/e3000) port of the Perl scripting language (http://www.perl.com/) which gives you all of the power of C, awk, sed, and sh in a single language. Check here for the latest news, implemented functionality, known bugs, to-do list, etc. Status reports about major milestones will also be posted to the HP3000-L mailing list (http://www.lsoft.com/scripts/wl.exe?SL1=HP3000-L&H=RAVEN.UTC.EDU) and its associated gatewayed newsgroup comp.sys.hp.mpe.

I'm doing this port because I can't live without Perl on the Unix machines that I administer, and I want to have the same power available to me on MPE.

Please send your comments, questions, and bug reports directly to me, Mark Bixby (http://www.bixby.org/mark/). Or just post them to HP3000-L.

The platform I'm using to do this port is an HP 3000 957RX running MPE/iX 6.0 and using the GNU gcc C compiler (http://jazz.external.hp.com/src/gnu/gnuframe.html).

The combined porting wisdom from all of my ports can be found in my MPE/iX Porting Guide (http://www.bixby.org/mark/porting.html).

IMPORTANT NOTICE: Yes, I do work for the HP CSY R&D lab, but ALL of the software you download from bixby.org is my personal freeware that is NOT supported by HP.

115.6 System Requirements for Perl/iX

- MPE/iX 5.5 or later. This version of Perl/iX does NOT run on MPE/iX 5.0 or earlier, nor does it run on "classic" MPE/V machines.
- If you wish to recompile Perl, you must install both GNUCORE and GNUGCC from jazz (http://jazz.external.hp.com/src/gnu/gnuframe.html).
- Perl/iX will be happier on MPE/iX 5.5 if you install the MPEKX40B extended POSIX filename characters patch, but this is optional.
- Patch LBCJXT6A is required on MPE/iX 5.5 machines in order to prevent Perl/iX from dying with an unresolved external reference to _getenv_libc.
- If you will be compiling Perl/iX yourself, you will also need Syslog/iX (http://www.bixby.org/mark/syslogix.html) and the /BIND/PUB/include and /BIND/PUB/lib portions of BIND/iX (http://www.bixby.org/mark/bindix.html).

115.7 How to Obtain Perl/iX

1. Download Perl using either FTP.ARPA.SYS or some other client
2. Extract the installation script
3. Edit the installation script
4. Run the installation script
5. Convert your *.a system archive libraries to *.sl shared libraries

Download Perl using FTP.ARPA.SYS from your HP 3000 (the preferred method).....

```
:HELLO MANAGER.SYS
:XEQ FTP.ARPA.SYS
open ftp.bixby.org
anonymous
your@email.address
bytestream
cd /pub/mpe
get perl-5.6.0-mpe.tar.Z /tmp/perl.tar.Z;disc=2147483647
exit
```

.....Or download using some other generic web or ftp client (the alternate method)
Download the following files (make sure that you use "binary mode" or whatever client feature that is 8-bit clean):

- Perl from

  ```
  http://www.bixby.org/ftp/pub/mpe/perl-5.6.0-mpe.tar.Z
  ```

  or

  ```
  ftp://ftp.bixby.org/pub/mpe/perl-5.6.0-mpe.tar.Z
  ```

- Upload those files to your HP 3000 in an 8-bit clean bytestream manner to:

  ```
  /tmp/perl.tar.Z
  ```

- Then extract the installation script (after both download methods)

  ```
  :CHDIR /tmp
  :XEQ TAR.HPBIN.SYS 'xvfopz /tmp/perl.tar.Z INSTALL'
  ```

- Edit the installation script

  Examine the accounting structure creation commands and modify if necessary (adding additional capabilities, choosing a non-system volume set, etc).

  ```
  :XEQ VI.HPBIN.SYS /tmp/INSTALL
  ```

- Run the installation script.

  The accounting structure will be created and then all files will be extracted from the archive.

  ```
  :XEQ SH.HPBIN.SYS /tmp/INSTALL
  ```

- Convert your *.a system archive libraries to *.sl shared libraries

  You only have to do this ONCE on your MPE/iX 5.5 machine in order to convert /lib/lib*.a and /usr/lib/lib*.a libraries to their *.sl equivalents. This step should not be necessary on MPE/iX 6.0 or later machines because the 6.0 or later update process does it for you.

  ```
  :XEQ SH.HPBIN.SYS /PERL/PUB/LIBSHP3K
  ```

115.8 Perl/iX Distribution Contents Highlights

README

The file you're reading now.

INSTALL

Perl/iX Installation script.

LIBSHP3K

Script to convert *.a system archive libraries to *.sl shared libraries.

PERL

Perl NMPRG executable. A version-numbered backup copy also exists. You might wish to "ln -s /PERL/PUB/PERL /usr/local/bin/perl".

.cpan/

Much add-on source code downloaded with the CPAN module.

lib/

Perl libraries, both core and add-on.

man/

Perl man page documentation.

public_html/feedback.cgi

Sample feedback CGI form written in Perl.

src/perl-5.6.0-mpe

Source code.

115.9 How to Compile Perl/iX

1. cd src/perl-5.6.0-mpe
2. Read the INSTALL file for the official instructions
3. ./Configure -d
4. make
5. ./mpeix/relink
6. make test (expect approximately 15 out of 11306 subtests to fail, mostly due to MPE not supporting hard links, UDP socket problems, and handling exit() return codes improperly)
7. make install
8. Optionally create symbolic links that point to the Perl executable, i.e. ln -s /PERL/PUB/PERL /usr/local/bin/perl

The summary test results from "cd t; ./perl -I../lib harness":

```
Failed Test  Status Wstat Total Fail  Failed  List of failed
-------------------------------------------------------------------------
io/fs.t                     29    8  27.59%  2-5, 7-9, 11
io/openpid.t                10    1  10.00%  7
lib/io_sock.t               14    1   7.14%  13
lib/io_udp.t                 7    2  28.57%  3, 5
```

```
  lib/posix.t                  27    1   3.70%  12
  op/lex_assign.t             187    1   0.53%  13
  op/stat.t                    58    1   1.72%  3
  15 tests and 94 subtests skipped.
  Failed 7/236 test scripts, 97.03% okay. 15/11306 subtests failed, 99.87% okay.
```

115.10 Getting Started with Perl/iX

Create your Perl script files with "#!/PERL/PUB/perl" (or an equivalent symbolic link) as the first line. Use the chmod command to make sure that your script has execute permission. Run your script!

Be sure to take a look at the CPAN module list (http://www.cpan.org/CPAN.html). A wide variety of free Perl software is available. You can automatically download these packages by using the CPAN module (http://theoryx5.uwinnipeg.ca/CPAN/data/perl/CPAN.html).

115.11 MPE/iX Implementation Considerations

There some minor functionality issues to be aware of when comparing Perl for Unix (Perl/UX) to Perl/iX:

- MPE gcc/ld doesn't properly support linking NMPRG executables against NMXL dynamic libraries, so you must manually run mpeix/relink after each re-build of Perl.
- Perl/iX File::Copy will use MPE's /bin/cp command to copy files by name in order to preserve file attributes like file code.
- MPE (and thus Perl/iX) lacks support for setgrent(), endgrent(), setpwent(), endpwent().
- MPE (and thus Perl/iX) lacks support for hard links.
- MPE requires GETPRIVMODE() in order to bind() to ports less than 1024. Perl/iX will call GETPRIVMODE() automatically on your behalf if you attempt to bind() to these low-numbered ports. Note that the Perl/iX executable and the PERL account do not normally have CAP=PM, so if you will be bind()-ing to these privileged ports, you will manually need to add PM capability as appropriate.
- MPE requires that you bind() to an IP address of zero. Perl/iX automatically replaces the IP address that you pass to bind() with a zero.
- MPE requires GETPRIVMODE() in order to setuid(). There are too many calls to setuid() within Perl/iX, so I have not attempted an automatic GETPRIVMODE() solution similar to bind().

115.12 Known Perl/iX Bugs Under Investigation

None.

115.13 Perl/iX To-Do List

- Make setuid()/setgid() support work.
- Make sure that fcntl() against a socket descriptor is redirected to sfcntl().
- Add support for Berkeley DB once I've finished porting Berkeley DB.
- Write an MPE XS extension library containing miscellaneous important MPE functions like GETPRIVMODE(), GETUSERMODE(), and sfcntl().

115.14 Perl/iX Change History

May 6, 1999

- Patch LBCJXT6A is required on MPE/iX 5.5 machines in order to prevent Perl/iX from dying with an unresolved external reference to _getenv_libc.

April 7, 1999

- Updated to version 5.005_03.
- The official source distribution once again compiles "straight out of the box" for MPE.
- The current incarnation of the 5.5 POSIX filename extended characters patch is now MPEKX40B.
- The LIBSHP3K *.a -> *.sl library conversion script is now included as /PERL/PUB/LIBSHP3K.

November 20, 1998

- Updated to version 5.005_02.
- Fixed a DynaLoader bug that was unable to load symbols from relative path name libraries.
- Fixed a .xs compilation bug where the mpeixish.sh include file wasn't being installed into the proper directory.
- All bugfixes will be submitted back to the official Perl developers.
- The current incarnation of the POSIX filename extended characters patch is now MPEKXJ3A.

August 14, 1998

- The previous POSIX filename extended characters patch MPEKX44C has been superseded by MPEKXB5A.

August 7, 1998

- The previous POSIX filename extended characters patch MPEKX76A has been superseded by MPEKX44C.

July 28, 1998

- Updated to version 5.005_01.

July 23, 1998

- Updated to version 5.005 (production release). The public freeware sources are now 100% MPE-ready "straight out of the box".

July 17, 1998

- Updated to version 5.005b1 (public beta release). The public freeware sources are now 99.9% MPE-ready. By installing and testing this beta on your own HP3000, you will be helping to insure that the final release of 5.005 will be 100% MPE-ready and 100% bug free.
- My MPE binary release is now extracted using my standard INSTALL script.

July 15, 1998

- Changed startperl to #!/PERL/PUB/perl so that Perl will recognize scripts more easily and efficiently.

July 8, 1998

- Updated to version 5.004_70 (internal developer release) which is now MPE-ready. The next public freeware release of Perl should compile "straight out of the box" on MPE. Note that this version of Perl/iX was strictly internal to me and never publicly released. Note that [21]BIND/iX is now required (well, the include files and libbind.a) if you wish to compile Perl/iX.

November 6, 1997

- Updated to version 5.004_04. No changes in MPE-specific functionality.

October 16, 1997

- Added Demos section to the Perl/iX home page so you can see some sample Perl applications running on my 3000.

October 3, 1997

- Added System Requirements section to the Perl/iX home page just so the prerequisites stand out more. Various other home page tweaks.

October 2, 1997

- Initial public release.

September 1997

- Porting begins.

Mark Bixby, http://www.bixby.org/mark/

Chapter 116

perlnetware

Perl for NetWare

116.1 DESCRIPTION

This file gives instructions for building Perl 5.7 and above, and also Perl modules for NetWare. Before you start, you may want to read the README file found in the top level directory into which the Perl source code distribution was extracted. Make sure you read and understand the terms under which the software is being distributed.

116.2 BUILD

This section describes the steps to be performed to build a Perl NLM and other associated NLMs.

116.2.1 Tools & SDK

The build requires CodeWarrior compiler and linker. In addition, the "NetWare SDK", "NLM & NetWare Libraries for C" and "NetWare Server Protocol Libraries for C", all available at http://developer.novell.com/ndk/, are also required. Microsoft Visual C++ version 4.2 or later is also required.

116.2.2 Setup

The build process is dependent on the location of the NetWare SDK. Once the Tools & SDK are installed, the build environment has to be setup. The following batch files setup the environment.

SetNWBld.bat

The Execution of this file takes 2 parameters as input. The first being the NetWare SDK path, second being the path for CodeWarrior Compiler & tools. Execution of this file sets these paths and also sets the build type to Release by default.

Buildtype.bat

This is used to set the build type to debug or release. Change the build type only after executing SetNWBld.bat

*****

Example: 1. Typing "buildtype d on" at the command prompt causes the buildtype to be set to Debug type with D2 flag set. 2. Typing "buildtype d off" or "buildtype d" at the command prompt causes the buildtype to be set to Debug type with D1 flag set. 2. Typing "buildtype r" at the command prompt sets it to Release Build type.

116.2.3 Make

The make process runs only under WinNT shell. The NetWare makefile is located under the NetWare folder. This makes use of miniperl.exe to run some of the Perl scripts. To create miniperl.exe, first set the required paths for Visual c++ compilier (specify vcvars32 location) at the command prompt. Then run nmake from win32 folder through WinNT command prompt. The build process can be stopped after miniperl.exe is created. Then run nmake from NetWare folder through WinNT command prompt.

Currently the following two build types are tested on NetWare:

- USE_MULTI, USE_ITHREADS & USE_IMP_SYS defined
- USE_MULTI & USE_IMP_SYS defined and USE_ITHREADS not defined

116.2.4 Interpreter

Once miniperl.exe creation is over, run nmake from the NetWare folder. This will build the Perl interpreter for NetWare as *perl.nlm*. This is copied under the *Release* folder if you are doing a release build, else will be copied under *Debug* folder for debug builds.

116.2.5 Extensions

The make process also creates the Perl extensions as <*Extension*.nlm>

116.3 INSTALL

To install NetWare Perl onto a NetWare server, first map the Sys volume of a NetWare server to *i:*. This is because the makefile by default sets the drive letter to *i:*. Type *nmake nwinstall* from NetWare folder on a WinNT command prompt. This will copy the binaries and module files onto the NetWare server under *sys:\Perl* folder. The Perl interpreter, *perl.nlm*, is copied under *sys:\perl\system* folder. Copy this to *sys:\system* folder.

Example: At the command prompt Type "nmake nwinstall". This will install NetWare Perl on the NetWare Server. Similiarly if you type "nmake install", This will cause the binaries to be installed on the local machine. (Typically under the c:\perl folder)

116.4 BUILD NEW EXTENSIONS

To build extensions other than standard extensions, NetWare Perl has to be installed on Windows along with Windows Perl. The Perl for Windows can be either downloaded from the CPAN site and built using the sources, or the binaries can be directly downloaded from the ActiveState site. Installation can be done by invoking *nmake install* from the NetWare folder on a WinNT command prompt after building NetWare Perl by following steps given above. This will copy all the *.pm files and other required files. Documentation files are not copied. Thus one must first install Windows Perl, Then install NetWare Perl.

Once this is done, do the following to build any extension:

- Change to the extension directory where its source files are present.
- Run the following command at the command prompt:

  ```
  perl -II<path to NetWare lib dir> -II<path to lib> Makefile.pl
  ```

  Example:

  ```
  perl -Ic:/perl/5.6.1/lib/NetWare-x86-multi-thread -Ic:\perl\5.6.1\lib MakeFile.pl
  ```

or

```
perl -Ic:/perl/5.8.0/lib/NetWare-x86-multi-thread -Ic:\perl\5.8.0\lib MakeFile.pl
```

- nmake
- nmake install

  Install will copy the files into the Windows machine where NetWare Perl is installed and these files may have to be copied to the NetWare server manually. Alternatively, pass *INSTALLSITELIB=i:\perl\lib* as an input to makefile.pl above. Here *i:* is the mapped drive to the sys: volume of the server where Perl on NetWare is installed. Now typing *nmake install*, will copy the files onto the NetWare server.

  Example: You can execute the following on the command prompt.

```
perl -Ic:/perl/5.6.1/lib/NetWare-x86-multi-thread -Ic:\perl\5.6.1\lib MakeFile.pl
INSTALLSITELIB=i:\perl\lib
```

or

```
perl -Ic:/perl/5.8.0/lib/NetWare-x86-multi-thread -Ic:\perl\5.8.0\lib MakeFile.pl
INSTALLSITELIB=i:\perl\lib
```

- Note: Some modules downloaded from CPAN may require NetWare related API in order to build on NetWare. Other modules may however build smoothly with or without minor changes depending on the type of module.

116.5 ACKNOWLEDGEMENTS

The makefile for Win32 is used as a reference to create the makefile for NetWare. Also, the make process for NetWare port uses miniperl.exe to run scripts during the make and installation process.

Chapter 117

perlos2

Perl under OS/2, DOS, Win0.3*, Win0.95 and WinNT.

117.1 SYNOPSIS

One can read this document in the following formats:

```
        man perlos2
        view perl perlos2
        explorer perlos2.html
        info perlos2
```

to list some (not all may be available simultaneously), or it may be read *as is*: either as *README.os2*, or *pod/perlos2.pod*.

To read the *.INF* version of documentation (**very** recommended) outside of OS/2, one needs an IBM's reader (may be available on IBM ftp sites (?) (URL anyone?)) or shipped with PC DOS 7.0 and IBM's Visual Age C++ 3.5.

A copy of a Win* viewer is contained in the "Just add OS/2 Warp" package

```
  ftp://ftp.software.ibm.com/ps/products/os2/tools/jaow/jaow.zip
```

in *?:\JUST_ADD\view.exe*. This gives one an access to EMX's *.INF* docs as well (text form is available in */emx/doc* in EMX's distribution). There is also a different viewer named xview.

Note that if you have *lynx.exe* or *netscape.exe* installed, you can follow WWW links from this document in *.INF* format. If you have EMX docs installed correctly, you can follow library links (you need to have `view emxbook` working by setting `EMXBOOK` environment variable as it is described in EMX docs).

117.2 DESCRIPTION

117.2.1 Target

The target is to make OS/2 one of the best supported platform for using/building/developing Perl and *Perl applications*, as well as make Perl the best language to use under OS/2. The secondary target is to try to make this work under DOS and Win* as well (but not **too** hard).

The current state is quite close to this target. Known limitations:

- Some *nix programs use fork() a lot; with the mostly useful flavors of perl for OS/2 (there are several built simultaneously) this is supported; but some flavors do not support this (e.g., when Perl is called from inside REXX). Using fork() after *use*ing dynamically loading extensions would not work with *very* old versions of EMX.

- You need a separate perl executable *perl__.exe* (see perl__.exe) if you want to use PM code in your application (as Perl/Tk or OpenGL Perl modules do) without having a text-mode window present.

  While using the standard *perl.exe* from a text-mode window is possible too, I have seen cases when this causes degradation of the system stability. Using *perl__.exe* avoids such a degradation.

- There is no simple way to access WPS objects. The only way I know is via `OS2::REXX` and `SOM` extensions (see *OS2::REXX*, *Som*). However, we do not have access to convenience methods of Object-REXX. (Is it possible at all? I know of no Object-REXX API.) The `SOM` extension (currently in alpha-text) may eventually remove this shortcoming; however, due to the fact that DII is not supported by the `SOM` module, using `SOM` is not as convenient as one would like it.

Please keep this list up-to-date by informing me about other items.

117.2.2 Other OSes

Since OS/2 port of perl uses a remarkable EMX environment, it can run (and build extensions, and - possibly - be built itself) under any environment which can run EMX. The current list is DOS, DOS-inside-OS/2, Win0.3*, Win0.95 and WinNT. Out of many perl flavors, only one works, see §117.11.4.

Note that not all features of Perl are available under these environments. This depends on the features the *extender* - most probably RSX - decided to implement.

Cf. *Prerequisites*.

117.2.3 Prerequisites

EMX

EMX runtime is required (may be substituted by RSX). Note that it is possible to make *perl_.exe* to run under DOS without any external support by binding *emx.exe*/*rsx.exe* to it, see *emxbind*. Note that under DOS for best results one should use RSX runtime, which has much more functions working (like `fork`, `popen` and so on). In fact RSX is required if there is no VCPI present. Note the RSX requires DPMI. Many implementations of DPMI are known to be very buggy, beware!

Only the latest runtime is supported, currently `0.9d fix 03`. Perl may run under earlier versions of EMX, but this is not tested.

One can get different parts of EMX from, say

```
http://www.leo.org/pub/comp/os/os2/leo/gnu/emx+gcc/
http://powerusersbbs.com/pub/os2/dev/   [EMX+GCC Development]
http://hobbes.nmsu.edu/pub/os2/dev/emx/v0.9d/
```

The runtime component should have the name *emxrt.zip*.

NOTE. When using *emx.exe*/*rsx.exe*, it is enough to have them on your path. One does not need to specify them explicitly (though this

```
emx perl_.exe -de 0
```

will work as well.)

RSX

To run Perl on DPMI platforms one needs RSX runtime. This is needed under DOS-inside-OS/2, Win0.3*, Win0.95 and WinNT (see §117.2.2). RSX would not work with VCPI only, as EMX would, it requires DMPI.

Having RSX and the latest *sh.exe* one gets a fully functional ***nix**-ish environment under DOS, say, `fork`, “ and pipe-`open` work. In fact, MakeMaker works (for static build), so one can have Perl development environment under DOS.

One can get RSX from, say

```
ftp://ftp.cdrom.com/pub/os2/emx09c/contrib
ftp://ftp.uni-bielefeld.de/pub/systems/msdos/misc
ftp://ftp.leo.org/pub/comp/os/os2/leo/devtools/emx+gcc/contrib
```

Contact the author on `rainer@mathematik.uni-bielefeld.de`.

The latest *sh.exe* with DOS hooks is available in

```
http://www.ilyaz.org/software/os2/
```

as *sh_dos.zip* or under similar names starting with `sh`, `pdksh` etc.

HPFS

Perl does not care about file systems, but the perl library contains many files with long names, so to install it intact one needs a file system which supports long file names.

Note that if you do not plan to build the perl itself, it may be possible to fool EMX to truncate file names. This is not supported, read EMX docs to see how to do it.

pdksh

To start external programs with complicated command lines (like with pipes in between, and/or quoting of arguments), Perl uses an external shell. With EMX port such shell should be named *sh.exe*, and located either in the wired-in-during-compile locations (usually *F:/bin*), or in configurable location (see §117.12.4).

For best results use EMX pdksh. The standard binary (5.2.14 or later) runs under DOS (with *RSX*) as well, see

```
http://www.ilyaz.org/software/os2/
```

117.2.4 Starting Perl programs under OS/2 (and DOS and...)

Start your Perl program *foo.pl* with arguments `arg1 arg2 arg3` the same way as on any other platform, by

```
perl foo.pl arg1 arg2 arg3
```

If you want to specify perl options `-my_opts` to the perl itself (as opposed to your program), use

```
perl -my_opts foo.pl arg1 arg2 arg3
```

Alternately, if you use OS/2-ish shell, like CMD or 4os2, put the following at the start of your perl script:

```
extproc perl -S -my_opts
```

rename your program to *foo.cmd*, and start it by typing

```
foo arg1 arg2 arg3
```

Note that because of stupid OS/2 limitations the full path of the perl script is not available when you use `extproc`, thus you are forced to use `-S` perl switch, and your script should be on the `PATH`. As a plus side, if you know a full path to your script, you may still start it with

```
perl ../../blah/foo.cmd arg1 arg2 arg3
```

(note that the argument `-my_opts` is taken care of by the `extproc` line in your script, see `extproc` on the first line).
To understand what the above *magic* does, read perl docs about `-S` switch - see *perlrun*, and cmdref about `extproc`:

```
view perl perlrun
man perlrun
view cmdref extproc
help extproc
```

or whatever method you prefer.
There are also endless possibilities to use *executable extensions* of 4os2, *associations* of WPS and so on... However, if you use *nixish shell (like *sh.exe* supplied in the binary distribution), you need to follow the syntax specified in Switches in *perlrun*.
Note that **-S** switch supports scripts with additional extensions *.cmd*, *.btm*, *.bat*, *.pl* as well.

117.2.5 Starting OS/2 (and DOS) programs under Perl

This is what system() (see system in *perlfunc*), " (see I/O Operators in *perlop*), and *open pipe* (see open in *perlfunc*) are for. (Avoid exec() (see exec in *perlfunc*) unless you know what you do).

Note however that to use some of these operators you need to have a sh-syntax shell installed (see §**??**, §117.3), and perl should be able to find it (see §117.12.4).

The cases when the shell is used are:

1. One-argument system() (see system in *perlfunc*), exec() (see exec in *perlfunc*) with redirection or shell meta-characters;
2. Pipe-open (see open in *perlfunc*) with the command which contains redirection or shell meta-characters;
3. Backticks " (see I/O Operators in *perlop*) with the command which contains redirection or shell meta-characters;
4. If the executable called by system()/exec()/pipe-open()/" is a script with the "magic" `#!` line or `extproc` line which specifies shell;
5. If the executable called by system()/exec()/pipe-open()/" is a script without "magic" line, and `$ENV{EXECSHELL}` is set to shell;
6. If the executable called by system()/exec()/pipe-open()/" is not found (is not this remark obsolete?);
7. For globbing (see glob in *perlfunc*, I/O Operators in *perlop*) (obsolete? Perl uses builtin globbing nowadays...).

For the sake of speed for a common case, in the above algorithms backslashes in the command name are not considered as shell metacharacters.

Perl starts scripts which begin with cookies `extproc` or `#!` directly, without an intervention of shell. Perl uses the same algorithm to find the executable as *pdksh*: if the path on `#!` line does not work, and contains `/`, then the directory part of the executable is ignored, and the executable is searched in . and on `PATH`. To find arguments for these scripts Perl uses a different algorithm than *pdksh*: up to 3 arguments are recognized, and trailing whitespace is stripped.

If a script does not contain such a cooky, then to avoid calling *sh.exe*, Perl uses the same algorithm as *pdksh*: if `$ENV{EXECSHELL}` is set, the script is given as the first argument to this command, if not set, then `$ENV{COMSPEC} /c` is used (or a hardwired guess if `$ENV{COMSPEC}` is not set).

When starting scripts directly, Perl uses exactly the same algorithm as for the search of script given by **-S** command-line option: it will look in the current directory, then on components of `$ENV{PATH}` using the following order of appended extensions: no extension, *.cmd*, *.btm*, *.bat*, *.pl*.

Note that Perl will start to look for scripts only if OS/2 cannot start the specified application, thus `system 'blah'` will not look for a script if there is an executable file *blah.exe anywhere* on `PATH`. In other words, `PATH` is essentially searched twice: once by the OS for an executable, then by Perl for scripts.

Note also that executable files on OS/2 can have an arbitrary extension, but *.exe* will be automatically appended if no dot is present in the name. The workaround is as simple as that: since *blah.* and *blah* denote the same file (at list on FAT and HPFS file systems), to start an executable residing in file *n:/bin/blah* (no extension) give an argument `n:/bin/blah.` (dot appended) to system().

Perl will start PM programs from VIO (=text-mode) Perl process in a separate PM session; the opposite is not true: when you start a non-PM program from a PM Perl process, Perl would not run it in a separate session. If a separate session is desired, either ensure that shell will be used, as in `system 'cmd /c myprog'`, or start it using optional arguments to system() documented in `OS2::Process` module. This is considered to be a feature.

117.3 Frequently asked questions

117.3.1 "It does not work"

Perl binary distributions come with a *testperl.cmd* script which tries to detect common problems with misconfigured installations. There is a pretty large chance it will discover which step of the installation you managed to goof. `;-)`

117.3.2 I cannot run external programs

- Did you run your programs with `-w` switch? See Starting OS/2 (and DOS) programs under Perl.
- Do you try to run *internal* shell commands, like `` `copy a b` `` (internal for *cmd.exe*), or `` `glob a*b` `` (internal for ksh)? You need to specify your shell explicitly, like `` `cmd /c copy a b` ``, since Perl cannot deduce which commands are internal to your shell.

117.3.3 I cannot embed perl into my program, or use *perl.dll* from my program.

Is your program EMX-compiled with `-Zmt -Zcrtdll`?

Well, nowadays Perl DLL should be usable from a differently compiled program too... If you can run Perl code from REXX scripts (see *OS2::REXX*), then there are some other aspect of interaction which are overlooked by the current hackish code to support differently-compiled principal programs.

If everything else fails, you need to build a stand-alone DLL for perl. Contact me, I did it once. Sockets would not work, as a lot of other stuff.

Did you use *ExtUtils::Embed*?

Some time ago I had reports it does not work. Nowadays it is checked in the Perl test suite, so grep *./t* subdirectory of the build tree (as well as **.t* files in the *./lib* subdirectory) to find how it should be done "correctly".

117.3.4 ‘ and pipe-open do not work under DOS.

This may a variant of just §117.3.2, or a deeper problem. Basically: you *need* RSX (see §117.6.2) for these commands to work, and you may need a port of *sh.exe* which understands command arguments. One of such ports is listed in §117.6.2 under RSX. Do not forget to set variable §`117.12.4` as well.

DPMI is required for RSX.

117.3.5 Cannot start `find.exe "pattern" file`

The whole idea of the "standard C API to start applications" is that the forms `foo` and `"foo"` of program arguments are completely interchangable. *find* breaks this paradigm;

```
find "pattern" file
find pattern file
```

are not equivalent; *find* cannot be started directly using the above API. One needs a way to surround the doublequotes in some other quoting construction, necessarily having an extra non-Unixish shell in between.

Use one of

```
system 'cmd', '/c', 'find "pattern" file';
`cmd /c 'find "pattern" file'`
```

This would start *find.exe* via *cmd.exe* via `sh.exe` via `perl.exe`, but this is a price to pay if you want to use non-conforming program.

117.4 INSTALLATION

117.4.1 Automatic binary installation

The most convenient way of installing a binary distribution of perl is via perl installer *install.exe*. Just follow the instructions, and 99% of the installation blues would go away.

Note however, that you need to have *unzip.exe* on your path, and EMX environment *running*. The latter means that if you just installed EMX, and made all the needed changes to *Config.sys*, you may need to reboot in between. Check EMX runtime by running

```
        emxrev
```

Binary installer also creates a folder on your desktop with some useful objects. If you need to change some aspects of the work of the binary installer, feel free to edit the file *Perl.pkg*. This may be useful e.g., if you need to run the installer many times and do not want to make many interactive changes in the GUI.

Things not taken care of by automatic binary installation:

`PERL_BADLANG`

may be needed if you change your codepage *after* perl installation, and the new value is not supported by EMX. See §117.12.2.

`PERL_BADFREE`

see §117.12.3.

Config.pm

This file resides somewhere deep in the location you installed your perl library, find it out by

```
  perl -MConfig -le "print $INC{'Config.pm'}"
```

While most important values in this file *are* updated by the binary installer, some of them may need to be hand-edited. I know no such data, please keep me informed if you find one. Moreover, manual changes to the installed version may need to be accompanied by an edit of this file.

NOTE. Because of a typo the binary installer of 5.00305 would install a variable `PERL_SHPATH` into *Config.sys*. Please remove this variable and put PERL_SH_DIR instead.

117.4.2 Manual binary installation

As of version 5.00305, OS/2 perl binary distribution comes split into 11 components. Unfortunately, to enable configurable binary installation, the file paths in the zip files are not absolute, but relative to some directory.

Note that the extraction with the stored paths is still necessary (default with unzip, specify `-d` to pkunzip). However, you need to know where to extract the files. You need also to manually change entries in *Config.sys* to reflect where did you put the files. Note that if you have some primitive unzipper (like `pkunzip`), you may get a lot of warnings/errors during unzipping. Upgrade to `(w)unzip`.

Below is the sample of what to do to reproduce the configuration on my machine. In *VIEW.EXE* you can press `Ctrl-Insert` now, and cut-and-paste from the resulting file - created in the directory you started *VIEW.EXE* from.

For each component, we mention environment variables related to each installation directory. Either choose directories to match your values of the variables, or create/append-to variables to take into account the directories.

Perl VIO and PM executables (dynamically linked)

```
  unzip perl_exc.zip *.exe *.ico -d f:/emx.add/bin
  unzip perl_exc.zip *.dll -d f:/emx.add/dll
```

(have the directories with `*.exe` on PATH, and `*.dll` on LIBPATH);

Perl_ VIO executable (statically linked)

```
unzip perl_aou.zip -d f:/emx.add/bin
```

(have the directory on PATH);

Executables for Perl utilities

```
unzip perl_utl.zip -d f:/emx.add/bin
```

(have the directory on PATH);

Main Perl library

```
unzip perl_mlb.zip -d f:/perllib/lib
```

If this directory is exactly the same as the prefix which was compiled into *perl.exe*, you do not need to change anything. However, for perl to find the library if you use a different path, you need to `set PERLLIB_PREFIX` in *Config.sys*, see §117.12.1.

Additional Perl modules

```
unzip perl_ste.zip -d f:/perllib/lib/site_perl/5.8.5/
```

Same remark as above applies. Additionally, if this directory is not one of directories on @INC (and @INC is influenced by `PERLLIB_PREFIX`), you need to put this directory and subdirectory *./os2* in `PERLLIB` or `PERL5LIB` variable. Do not use `PERL5LIB` unless you have it set already. See ENVIRONMENT in *perl*.

[Check whether this extraction directory is still applicable with the new directory structure layout!]

Tools to compile Perl modules

```
unzip perl_blb.zip -d f:/perllib/lib
```

Same remark as for *perl_ste.zip*.

Manpages for Perl and utilities

```
unzip perl_man.zip -d f:/perllib/man
```

This directory should better be on `MANPATH`. You need to have a working *man* to access these files.

Manpages for Perl modules

```
unzip perl_mam.zip -d f:/perllib/man
```

This directory should better be on `MANPATH`. You need to have a working man to access these files.

Source for Perl documentation

```
unzip perl_pod.zip -d f:/perllib/lib
```

This is used by the `perldoc` program (see *perldoc*), and may be used to generate HTML documentation usable by WWW browsers, and documentation in zillions of other formats: `info`, `LaTeX`, `Acrobat`, `FrameMaker` and so on. [Use programs such as *pod2latex* etc.]

Perl manual in *.INF* format

```
unzip perl_inf.zip -d d:/os2/book
```

This directory should better be on BOOKSHELF.

Pdksh

```
unzip perl_sh.zip -d f:/bin
```

This is used by perl to run external commands which explicitly require shell, like the commands using *redirection* and *shell metacharacters*. It is also used instead of explicit */bin/sh*.

Set PERL_SH_DIR (see §117.12.4) if you move *sh.exe* from the above location.

Note. It may be possible to use some other sh-compatible shell (untested).

After you installed the components you needed and updated the *Config.sys* correspondingly, you need to hand-edit *Config.pm*. This file resides somewhere deep in the location you installed your perl library, find it out by

```
perl -MConfig -le "print $INC{'Config.pm'}"
```

You need to correct all the entries which look like file paths (they currently start with f:/).

117.4.3 Warning

The automatic and manual perl installation leave precompiled paths inside perl executables. While these paths are overwriteable (see §117.12.1, §117.12.4), some people may prefer binary editing of paths inside the executables/DLLs.

117.5 Accessing documentation

Depending on how you built/installed perl you may have (otherwise identical) Perl documentation in the following formats:

117.5.1 OS/2 .*INF* file

Most probably the most convenient form. Under OS/2 view it as

```
view perl
view perl perlfunc
view perl less
view perl ExtUtils::MakeMaker
```

(currently the last two may hit a wrong location, but this may improve soon). Under Win* see §117.1.

If you want to build the docs yourself, and have *OS/2 toolkit*, run

```
pod2ipf > perl.ipf
```

in */perllib/lib/pod* directory, then

```
ipfc /inf perl.ipf
```

(Expect a lot of errors during the both steps.) Now move it on your BOOKSHELF path.

117.5.2 Plain text

If you have perl documentation in the source form, perl utilities installed, and GNU groff installed, you may use

```
        perldoc perlfunc
        perldoc less
        perldoc ExtUtils::MakeMaker
```

to access the perl documentation in the text form (note that you may get better results using perl manpages).
Alternately, try running pod2text on *.pod* files.

117.5.3 Manpages

If you have *man* installed on your system, and you installed perl manpages, use something like this:

```
        man perlfunc
        man 3 less
        man ExtUtils.MakeMaker
```

to access documentation for different components of Perl. Start with

```
        man perl
```

Note that dot (.) is used as a package separator for documentation for packages, and as usual, sometimes you need to give the section - `3` above - to avoid shadowing by the *less(1) manpage*.
Make sure that the directory **above** the directory with manpages is on our `MANPATH`, like this

```
  set MANPATH=c:/man;f:/perllib/man
```

for Perl manpages in `f:/perllib/man/man1/` etc.

117.5.4 HTML

If you have some WWW browser available, installed the Perl documentation in the source form, and Perl utilities, you can build HTML docs. Cd to directory with *.pod* files, and do like this

```
        cd f:/perllib/lib/pod
        pod2html
```

After this you can direct your browser the file *perl.html* in this directory, and go ahead with reading docs, like this:

```
        explore file:///f:/perllib/lib/pod/perl.html
```

Alternatively you may be able to get these docs prebuilt from CPAN.

117.5.5 GNU `info` files

Users of Emacs would appreciate it very much, especially with `CPerl` mode loaded. You need to get latest `pod2texi` from `CPAN`, or, alternately, the prebuilt info pages.

117.5.6 *PDF* files

for `Acrobat` are available on CPAN (may be for slightly older version of perl).

117.5.7 LaTeX docs

can be constructed using `pod2latex`.

117.6 BUILD

Here we discuss how to build Perl under OS/2. There is an alternative (but maybe older) view on http://www.shadow.net/˜troc/os2perl.html.

117.6.1 The short story

Assume that you are a seasoned porter, so are sure that all the necessary tools are already present on your system, and you know how to get the Perl source distribution. Untar it, change to the extract directory, and

```
  gnupatch -p0 < os2\diff.configure
  sh Configure -des -D prefix=f:/perllib
  make
  make test
  make install
  make aout_test
  make aout_install
```

This puts the executables in f:/perllib/bin. Manually move them to the `PATH`, manually move the built *perl*.dll* to `LIBPATH` (here for Perl DLL * is a not-very-meaningful hex checksum), and run

```
  make installcmd INSTALLCMDDIR=d:/ir/on/path
```

Assuming that the `man`-files were put on an appropriate location, this completes the installation of minimal Perl system. (The binary distribution contains also a lot of additional modules, and the documentation in INF format.)

What follows is a detailed guide through these steps.

117.6.2 Prerequisites

You need to have the latest EMX development environment, the full GNU tool suite (gawk renamed to awk, and GNU *find.exe* earlier on path than the OS/2 *find.exe*, same with *sort.exe*, to check use

```
  find --version
  sort --version
```

). You need the latest version of *pdksh* installed as *sh.exe*.

Check that you have **BSD** libraries and headers installed, and - optionally - Berkeley DB headers and libraries, and crypt.

Possible locations to get the files:

```
  ftp://hobbes.nmsu.edu/os2/unix/
  ftp://ftp.cdrom.com/pub/os2/unix/
  ftp://ftp.cdrom.com/pub/os2/dev32/
  ftp://ftp.cdrom.com/pub/os2/emx09c/
```

It is reported that the following archives contain enough utils to build perl: *gnufutil.zip*, *gnusutil.zip*, *gnututil.zip*, *gnused.zip*, *gnupatch.zip*, *gnuawk.zip*, *gnumake.zip*, *gnugrep.zip*, *bsddev.zip* and *ksh527rt.zip* (or a later version). Note that all these utilities are known to be available from LEO:

```
  ftp://ftp.leo.org/pub/comp/os/os2/leo/gnu
```

Note also that the *db.lib* and *db.a* from the EMX distribution are not suitable for multi-threaded compile (even single-threaded flavor of Perl uses multi-threaded C RTL, for compatibility with XFree86-OS/2). Get a corrected one from

```
http://www.ilyaz.org/software/os2/db_mt.zip
```

If you have *exactly the same version of Perl* installed already, make sure that no copies or perl are currently running. Later steps of the build may fail since an older version of *perl.dll* loaded into memory may be found. Running `make test` becomes meaningless, since the test are checking a previous build of perl (this situation is detected and reported by *lib/os2_base.t* test). Do not forget to unset `PERL_EMXLOAD_SEC` in environment.

Also make sure that you have */tmp* directory on the current drive, and . directory in your `LIBPATH`. One may try to correct the latter condition by

```
set BEGINLIBPATH .\.
```

if you use something like *CMD.EXE* or latest versions of *4os2.exe*. (Setting BEGINLIBPATH to just `.` is ignored by the OS/2 kernel.)

Make sure your gcc is good for `-Zomf` linking: run `omflibs` script in */emx/lib* directory.

Check that you have link386 installed. It comes standard with OS/2, but may be not installed due to customization. If typing

```
link386
```

shows you do not have it, do *Selective install*, and choose `Link object modules` in *Optional system utilities/More*. If you get into link386 prompts, press `Ctrl-C` to exit.

117.6.3 Getting perl source

You need to fetch the latest perl source (including developers releases). With some probability it is located in

```
http://www.cpan.org/src/5.0
http://www.cpan.org/src/5.0/unsupported
```

If not, you may need to dig in the indices to find it in the directory of the current maintainer.

Quick cycle of developers release may break the OS/2 build time to time, looking into

```
http://www.cpan.org/ports/os2/
```

may indicate the latest release which was publicly released by the maintainer. Note that the release may include some additional patches to apply to the current source of perl.

Extract it like this

```
tar vzxf perl5.00409.tar.gz
```

You may see a message about errors while extracting *Configure*. This is because there is a conflict with a similarly-named file *configure*.

Change to the directory of extraction.

117.6.4 Application of the patches

You need to apply the patches in *./os2/diff.** like this:

```
  gnupatch -p0 < os2\diff.configure
```

You may also need to apply the patches supplied with the binary distribution of perl. It also makes sense to look on the perl5-porters mailing list for the latest OS/2-related patches (see http://www.xray.mpe.mpg.de/mailing-lists/perl5-porters/). Such patches usually contain strings `/os2/` and `patch`, so it makes sense looking for these strings.

117.6.5 Hand-editing

You may look into the file *./hints/os2.sh* and correct anything wrong you find there. I do not expect it is needed anywhere.

117.6.6 Making

```
  sh Configure -des -D prefix=f:/perllib
```

`prefix` means: where to install the resulting perl library. Giving correct prefix you may avoid the need to specify `PERLLIB_PREFIX`, see §117.12.1.

Ignore the message about missing `ln`, and about `-c` option to tr. The latter is most probably already fixed, if you see it and can trace where the latter spurious warning comes from, please inform me.

Now

```
  make
```

At some moment the built may die, reporting a *version mismatch* or *unable to run* perl. This means that you do not have . in your LIBPATH, so *perl.exe* cannot find the needed *perl67B2.dll* (treat these hex digits as line noise). After this is fixed the build should finish without a lot of fuss.

117.6.7 Testing

Now run

```
  make test
```

All tests should succeed (with some of them skipped). If you have the same version of Perl installed, it is crucial that you have `.` early in your LIBPATH (or in BEGINLIBPATH), otherwise your tests will most probably test the wrong version of Perl.

Some tests may generate extra messages similar to

A lot of bad `free`

in database tests related to Berkeley DB. *This should be fixed already.* If it persists, you may disable this warnings, see §117.12.3.

Process terminated by SIGTERM/SIGINT

This is a standard message issued by OS/2 applications. *nix applications die in silence. It is considered to be a feature. One can easily disable this by appropriate sighandlers.

However the test engine bleeds these message to screen in unexpected moments. Two messages of this kind *should* be present during testing.

To get finer test reports, call

```
  perl t/harness
```

The report with *io/pipe.t* failing may look like this:

```
  Failed Test  Status Wstat Total Fail  Failed  List of failed
  ------------------------------------------------------------
  io/pipe.t                    12    1   8.33%  9
  7 tests skipped, plus 56 subtests skipped.
  Failed 1/195 test scripts, 99.49% okay. 1/6542 subtests failed, 99.98% okay.
```

The reasons for most important skipped tests are:

op/fs.t

1. Checks `atime` and `mtime` of `stat()` - unfortunately, HPFS provides only 2sec time granularity (for compatibility with FAT?).
2. Checks `truncate()` on a filehandle just opened for write - I do not know why this should or should not work.

op/stat.t

Checks `stat()`. Tests:

1. Checks `atime` and `mtime` of `stat()` - unfortunately, HPFS provides only 2sec time granularity (for compatibility with FAT?).

117.6.8 Installing the built perl

If you haven't yet moved `perl*.dll` onto LIBPATH, do it now.
Run

```
  make install
```

It would put the generated files into needed locations. Manually put *perl.exe*, *perl__.exe* and *perl___.exe* to a location on your PATH, *perl.dll* to a location on your LIBPATH.
Run

```
  make installcmd INSTALLCMDDIR=d:/ir/on/path
```

to convert perl utilities to *.cmd* files and put them on PATH. You need to put *.EXE*-utilities on path manually. They are installed in `$prefix/bin`, here `$prefix` is what you gave to *Configure*, see *Making*.
If you use `man`, either move the installed **/man/* directories to your `MANPATH`, or modify `MANPATH` to match the location. (One could have avoided this by providing a correct `manpath` option to *./Configure*, or editing *./config.sh* between configuring and making steps.)

117.6.9 `a.out`-style build

Proceed as above, but make *perl_.exe* (see §117.11.4) by

```
  make perl_
```

test and install by

```
  make aout_test
  make aout_install
```

Manually put *perl_.exe* to a location on your PATH.
Note. The build process for `perl_` *does not know* about all the dependencies, so you should make sure that anything is up-to-date, say, by doing

```
  make perl_dll
```

first.

117.7 Building a binary distribution

[This section provides a short overview only...]

Building should proceed differently depending on whether the version of perl you install is already present and used on your system, or is a new version not yet used. The description below assumes that the version is new, so installing its DLLs and *.pm* files will not disrupt the operation of your system even if some intermediate steps are not yet fully working.

The other cases require a little bit more convoluted procedures. Below I suppose that the current version of Perl is `5.8.2`, so the executables are named accordingly.

1. Fully build and test the Perl distribution. Make sure that no tests are failing with `test` and `aout_test` targets; fix the bugs in Perl and the Perl test suite detected by these tests. Make sure that `all_test` make target runs as clean as possible. Check that `os2/perlrexx.cmd` runs fine.

2. Fully install Perl, including `installcmd` target. Copy the generated DLLs to `LIBPATH`; copy the numbered Perl executables (as in *perl5.8.2.exe*) to `PATH`; copy `perl_.exe` to `PATH` as `perl_5.8.2.exe`. Think whether you need backward-compatibility DLLs. In most cases you do not need to install them yet; but sometime this may simplify the following steps.

3. Make sure that `CPAN.pm` can download files from CPAN. If not, you may need to manually install `Net::FTP`.

4. Install the bundle `Bundle::OS2_default`

   ```
   perl5.8.2 -MCPAN -e "install Bundle::OS2_default" < nul |& tee 00cpan_i_1
   ```

   This may take a couple of hours on 1GHz processor (when run the first time). And this should not be necessarily a smooth procedure. Some modules may not specify required dependencies, so one may need to repeat this procedure several times until the results stabilize.

   ```
   perl5.8.2 -MCPAN -e "install Bundle::OS2_default" < nul |& tee 00cpan_i_2
   perl5.8.2 -MCPAN -e "install Bundle::OS2_default" < nul |& tee 00cpan_i_3
   ```

   Even after they stabilize, some tests may fail.

   Fix as many discovered bugs as possible. Document all the bugs which are not fixed, and all the failures with unknown reasons. Inspect the produced logs *00cpan_i_1* to find suspiciously skipped tests, and other fishy events.

   Keep in mind that *installation* of some modules may fail too: for example, the DLLs to update may be already loaded by *CPAN.pm*. Inspect the `install` logs (in the example above *00cpan_i_1* etc) for errors, and install things manually, as in

   ```
   cd $CPANHOME/.cpan/build/Digest-MD5-2.31
   make install
   ```

   Some distributions may fail some tests, but you may want to install them anyway (as above, or via `force install` command of `CPAN.pm` shell-mode).

   Since this procedure may take quite a long time to complete, it makes sense to "freeze" your CPAN configuration by disabling periodic updates of the local copy of CPAN index: set `index_expire` to some big value (I use 365), then save the settings

   ```
   CPAN> o conf index_expire 365
   CPAN> o conf commit
   ```

   Reset back to the default value `1` when you are finished.

5. When satisfied with the results, rerun the `installcmd` target. Now you can copy `perl5.8.2.exe` to `perl.exe`, and install the other OMF-build executables: `perl__.exe` etc. They are ready to be used.

6. Change to the `./pod` directory of the build tree, download the Perl logo *CamelGrayBig.BMP*, and run

   ```
   ( perl2ipf > perl.ipf ) |& tee 00ipf
   ipfc /INF perl.ipf |& tee 00inf
   ```

   This produces the Perl docs online book `perl.INF`. Install in on `BOOKSHELF` path.

7. Now is the time to build statically linked executable *perl_.exe* which includes newly-installed via `Bundle::OS2_default` modules. Doing testing via `CPAN.pm` is going to be painfully slow, since it statically links a new executable per XS extension.

   Here is a possible workaround: create a toplevel *Makefile.PL* in *$ CPANHOME/.cpan/build/* with contents being (compare with Making executables with a custom collection of statically loaded extensions)

   ```
   use ExtUtils::MakeMaker;
   WriteMakefile NAME => 'dummy';
   ```

   execute this as

   ```
   perl_5.8.2.exe Makefile.PL <nul |& tee 00aout_c1
   make -k all test <nul |& 00aout_t1
   ```

   Again, this procedure should not be absolutely smooth. Some `Makefile.PL`'s in subdirectories may be buggy, and would not run as "child" scripts. The interdependency of modules can strike you; however, since non-XS modules are already installed, the prerequisites of most modules have a very good chance to be present.

   If you discover some glitches, move directories of problematic modules to a different location; if these modules are non-XS modules, you may just ignore them - they are already installed; the remaining, XS, modules you need to install manually one by one.

   After each such removal you need to rerun the `Makefile.PL`/`make` process; usually this procedure converges soon. (But be sure to convert all the necessary external C libraries from *.lib* format to *.a* format: run one of

   ```
   emxaout foo.lib
   emximp -o foo.a foo.lib
   ```

   whichever is appropriate.) Also, make sure that the DLLs for external libraries are usable with with executables compiled without `-Zmtd` options.

   When you are sure that only a few subdirectories lead to failures, you may want to add `-j4` option to `make` to speed up skipping subdirectories with already finished build.

   When you are satisfied with the results of tests, install the build C libraries for extensions:

   ```
   make install |& tee 00aout_i
   ```

   Now you can rename the file *./perl.exe* generated during the last phase to *perl_5.8.2.exe*; place it on `PATH`; if there is an inter-dependency between some XS modules, you may need to repeat the `test`/`install` loop with this new executable and some excluded modules - until the procedure converges.

   Now you have all the necessary *.a* libraries for these Perl modules in the places where Perl builder can find it. Use the perl builder: change to an empty directory, create a "dummy" *Makefile.PL* again, and run

   ```
   perl_5.8.2.exe Makefile.PL |& tee 00c
   make perl                  |& tee 00p
   ```

   This should create an executable *./perl.exe* with all the statically loaded extensions built in. Compare the generated *perlmain.c* files to make sure that during the iterations the number of loaded extensions only increases. Rename *./perl.exe* to *perl_5.8.2.exe* on `PATH`.

   When it converges, you got a functional variant of *perl_5.8.2.exe*; copy it to `perl_.exe`. You are done with generation of the local Perl installation.

8. Make sure that the installed modules are actually installed in the location of the new Perl, and are not inherited from entries of @INC given for inheritance from the older versions of Perl: set `PERLLIB_582_PREFIX` to redirect the new version of Perl to a new location, and copy the installed files to this new location. Redo the tests to make sure that the versions of modules inherited from older versions of Perl are not needed.

   Actually, the log output of *pod2ipf* during the step 6 gives a very detailed info about which modules are loaded from which place; so you may use it as an additional verification tool.

   Check that some temporary files did not make into the perl install tree. Run something like this

   ```
   pfind . -f "!(/\.(pm|pl|ix|al|h|a|lib|txt|pod|imp|bs|dll|ld|bs|inc|xbm|yml|cgi|uu|e2x|skip|packl
   ```

   in the install tree (both top one and *sitelib* one).

   Compress all the DLLs with *lxlite*. The tiny *.exe* can be compressed with `/c:max` (the bug only appears when there is a fixup in the last 6 bytes of a page (?); since the tiny executables are much smaller than a page, the bug will not hit). Do not compress `perl_.exe` - it would not work under DOS.

9. Now you can generate the binary distribution. This is done by running the test of the CPAN distribution `OS2::SoftInstaller`. Tune up the file *test.pl* to suit the layout of current version of Perl first. Do not forget to pack the necessary external DLLs accordingly. Include the description of the bugs and test suite failures you could not fix. Include the small-stack versions of Perl executables from Perl build directory.

   Include *perl5.def* so that people can relink the perl DLL preserving the binary compatibility, or can create compatibility DLLs. Include the diff files (`diff -pu old new`) of fixes you did so that people can rebuild your version. Include *perl5.map* so that one can use remote debugging.

10. Share what you did with the other people. Relax. Enjoy fruits of your work.

11. Brace yourself for thanks, bug reports, hate mail and spam coming as result of the previous step. No good deed should remain unpunished!

117.8 Building custom *.EXE* files

The Perl executables can be easily rebuilt at any moment. Moreover, one can use the *embedding* interface (see *perlembed*) to make very customized executables.

117.8.1 Making executables with a custom collection of statically loaded extensions

It is a little bit easier to do so while *decreasing* the list of statically loaded extensions. We discuss this case only here.

1. Change to an empty directory, and create a placeholder <Makefile.PL>:

   ```
   use ExtUtils::MakeMaker;
   WriteMakefile NAME => 'dummy';
   ```

2. Run it with the flavor of Perl (*perl.exe* or *perl_.exe*) you want to rebuild.

   ```
   perl_ Makefile.PL
   ```

3. Ask it to create new Perl executable:

   ```
   make perl
   ```

   (you may need to manually add `PERLTYPE=-DPERL_CORE` to this commandline on some versions of Perl; the symptom is that the command-line globbing does not work from OS/2 shells with the newly-compiled executable; check with

```
    .\perl.exe -wle "print for @ARGV" *
```

).

4. The previous step created *perlmain.c* which contains a list of newXS() calls near the end. Removing unnecessary calls, and rerunning

   ```
   make perl
   ```

   will produce a customized executable.

117.8.2 Making executables with a custom search-paths

The default perl executable is flexible enough to support most usages. However, one may want something yet more flexible; for example, one may want to find Perl DLL relatively to the location of the EXE file; or one may want to ignore the environment when setting the Perl-library search patch, etc.

If you fill comfortable with *embedding* interface (see *perlembed*), such things are easy to do repeating the steps outlined in Making executables with a custom collection of statically loaded extensions, and doing more comprehensive edits to main() of *perlmain.c*. The people with little desire to understand Perl can just rename main(), and do necessary modification in a custom main() which calls the renamed function in appropriate time.

However, there is a third way: perl DLL exports the main() function and several callbacks to customize the search path. Below is a complete example of a "Perl loader" which

1. Looks for Perl DLL in the directory `$exedir/../dll`;
2. Prepends the above directory to `BEGINLIBPATH`;
3. Fails if the Perl DLL found via `BEGINLIBPATH` is different from what was loaded on step 1; e.g., another process could have loaded it from `LIBPATH` or from a different value of `BEGINLIBPATH`. In these cases one needs to modify the setting of the system so that this other process either does not run, or loads the DLL from `BEGINLIBPATH` with `LIBPATHSTRICT=T` (available with kernels after September 2000).
4. Loads Perl library from `$exedir/../dll/lib/`.
5. Uses Bourne shell from `$exedir/../dll/sh/ksh.exe`.

For best results compile the C file below with the same options as the Perl DLL. However, a lot of functionality will work even if the executable is not an EMX applications, e.g., if compiled with

```
  gcc -Wall -DDOSISH -DOS2=1 -O2 -s -Zomf -Zsys perl-starter.c -DPERL_DLL_BASENAME=\"perl312F\" -Zstack
```

Here is the sample C file:

```
  #define INCL_DOS
  #define INCL_NOPM
  /* These are needed for compile if os2.h includes os2tk.h, not os2emx.h */
  #define INCL_DOSPROCESS
  #include <os2.h>

  #include "EXTERN.h"
  #define PERL_IN_MINIPERLMAIN_C
  #include "perl.h"

  static char *me;
  HMODULE handle;
```

```
static void
die_with(char *msg1, char *msg2, char *msg3, char *msg4)
{
   ULONG c;
   char *s = " error: ";

   DosWrite(2, me, strlen(me), &c);
   DosWrite(2, s, strlen(s), &c);
   DosWrite(2, msg1, strlen(msg1), &c);
   DosWrite(2, msg2, strlen(msg2), &c);
   DosWrite(2, msg3, strlen(msg3), &c);
   DosWrite(2, msg4, strlen(msg4), &c);
   DosWrite(2, "\r\n", 2, &c);
   exit(255);
}

typedef ULONG (*fill_extLibpath_t)(int type, char *pre, char *post, int replace, char *msg);
typedef int (*main_t)(int type, char *argv[], char *env[]);
typedef int (*handler_t)(void* data, int which);

#ifndef PERL_DLL_BASENAME
#  define PERL_DLL_BASENAME "perl"
#endif

static HMODULE
load_perl_dll(char *basename)
{
    char buf[300], fail[260];
    STRLEN l, dirl;
    fill_extLibpath_t f;
    ULONG rc_fullname;
    HMODULE handle, handle1;

    if (_execname(buf, sizeof(buf) - 13) != 0)
        die_with("Can't find full path: ", strerror(errno), "", "");
    /* XXXX Fill 'me' with new value */
    l = strlen(buf);
    while (l && buf[l-1] != '/' && buf[l-1] != '\\')
        l--;
    dirl = l - 1;
    strcpy(buf + l, basename);
    l += strlen(basename);
    strcpy(buf + l, ".dll");
    if ( (rc_fullname = DosLoadModule(fail, sizeof fail, buf, &handle)) != 0
         && DosLoadModule(fail, sizeof fail, basename, &handle) != 0 )
        die_with("Can't load DLL ", buf, "", "");
    if (rc_fullname)
        return handle;                /* was loaded with short name; all is fine */
    if (DosQueryProcAddr(handle, 0, "fill_extLibpath", (PFN*)&f))
        die_with(buf, ": DLL exports no symbol ", "fill_extLibpath", "");
    buf[dirl] = 0;
    if (f(0 /*BEGINLIBPATH*/, buf /* prepend */, NULL /* append */,
          0 /* keep old value */, me))
        die_with(me, ": prepending BEGINLIBPATH", "", "");
    if (DosLoadModule(fail, sizeof fail, basename, &handle1) != 0)
        die_with(me, ": finding perl DLL again via BEGINLIBPATH", "", "");
    buf[dirl] = '\\';
    if (handle1 != handle) {
        if (DosQueryModuleName(handle1, sizeof(fail), fail))
            strcpy(fail, "???");
        die_with(buf, ":\n\tperl DLL via BEGINLIBPATH is different: \n\t",
                 fail,
                 "\n\tYou may need to manipulate global BEGINLIBPATH and LIBPATHSTRICT"
                 "\n\tso that the other copy is loaded via BEGINLIBPATH.");
    }
    return handle;
}

int
main(int argc, char **argv, char **env)
{
    main_t f;
    handler_t h;

    me = argv[0];
    /**/
    handle = load_perl_dll(PERL_DLL_BASENAME);

    if (DosQueryProcAddr(handle, 0, "Perl_OS2_handler_install", (PFN*)&h))
        die_with(PERL_DLL_BASENAME, ": DLL exports no symbol ", "Perl_OS2_handler_install", "");
    if ( !h((void *)"~installprefix", Perlos2_handler_perllib_from)
         || !h((void *)"~dll", Perlos2_handler_perllib_to)
         || !h((void *)"~dll/sh/ksh.exe", Perlos2_handler_perl_sh) )
        die_with(PERL_DLL_BASENAME, ": Can't install @INC manglers", "", "");

    if (DosQueryProcAddr(handle, 0, "dll_perlmain", (PFN*)&f))
        die_with(PERL_DLL_BASENAME, ": DLL exports no symbol ", "dll_perlmain", "");
    return f(argc, argv, env);
}
```

117.9 Build FAQ

117.9.1 Some / became \ in pdksh.

You have a very old pdksh. See *Prerequisites*.

117.9.2 'errno' - unresolved external

You do not have MT-safe *db.lib*. See *Prerequisites*.

117.9.3 Problems with tr or sed

reported with very old version of tr and sed.

117.9.4 Some problem (forget which ;-)

You have an older version of *perl.dll* on your LIBPATH, which broke the build of extensions.

117.9.5 Library ... not found

You did not run `omflibs`. See *Prerequisites*.

117.9.6 Segfault in make

You use an old version of GNU make. See *Prerequisites*.

117.9.7 op/sprintf test failure

This can result from a bug in emx sprintf which was fixed in 0.9d fix 03.

117.10 Specific (mis)features of OS/2 port

117.10.1 `setpriority, getpriority`

Note that these functions are compatible with *nix, not with the older ports of '94 - 95. The priorities are absolute, go from 32 to -95, lower is quicker. 0 is the default priority.

WARNING. Calling `getpriority` on a non-existing process could lock the system before Warp3 fixpak22. Starting with Warp3, Perl will use a workaround: it aborts getpriority() if the process is not present. This is not possible on older versions `2.*`, and has a race condition anyway.

117.10.2 `system()`

Multi-argument form of `system()` allows an additional numeric argument. The meaning of this argument is described in *OS2::Process*.

When finding a program to run, Perl first asks the OS to look for executables on `PATH` (OS/2 adds extension *.exe* if no extension is present). If not found, it looks for a script with possible extensions added in this order: no extension, *.cmd*, *.btm*, *.bat*, *.pl*. If found, Perl checks the start of the file for magic strings `"#!"` and `"extproc "`. If found, Perl uses the rest of the first line as the beginning of the command line to run this script. The only mangling done to the first line is extraction of arguments (currently up to 3), and ignoring of the path-part of the "interpreter" name if it can't be found using the full path.

E.g., `system 'foo', 'bar', 'baz'` may lead Perl to finding *C:/emx/bin/foo.cmd* with the first line being

```
 extproc /bin/bash    -x   -c
```

If */bin/bash.exe* is not found, then Perl looks for an executable *bash.exe* on `PATH`. If found in *C:/emx.add/bin/bash.exe*, then the above system() is translated to

```
  system qw(C:/emx.add/bin/bash.exe -x -c C:/emx/bin/foo.cmd bar baz)
```

One additional translation is performed: instead of */bin/sh* Perl uses the hardwired-or-customized shell (see §`117.12.4`).

The above search for "interpreter" is recursive: if *bash* executable is not found, but *bash.btm* is found, Perl will investigate its first line etc. The only hardwired limit on the recursion depth is implicit: there is a limit 4 on the number of additional arguments inserted before the actual arguments given to system(). In particular, if no additional arguments are specified on the "magic" first lines, then the limit on the depth is 4.

If Perl finds that the found executable is of PM type when the current session is not, it will start the new process in a separate session of necessary type. Call via `OS2::Process` to disable this magic.

WARNING. Due to the described logic, you need to explicitly specify *.com* extension if needed. Moreover, if the executable *perl5.6.1* is requested, Perl will not look for *perl5.6.1.exe*. [This may change in the future.]

117.10.3 `extproc` on the first line

If the first chars of a Perl script are `"extproc "`, this line is treated as `#!`-line, thus all the switches on this line are processed (twice if script was started via cmd.exe). See DESCRIPTION in *perlrun*.

117.10.4 Additional modules:

OS2::Process, *OS2::DLL*, *OS2::REXX*, *OS2::PrfDB*, *OS2::ExtAttr*. These modules provide access to additional numeric argument for `system` and to the information about the running process, to DLLs having functions with REXX signature and to the REXX runtime, to OS/2 databases in the *.INI* format, and to Extended Attributes.

Two additional extensions by Andreas Kaiser, `OS2::UPM`, and `OS2::FTP`, are included into `ILYAZ` directory, mirrored on CPAN. Other OS/2-related extensions are available too.

117.10.5 Prebuilt methods:

`File::Copy::syscopy`

used by `File::Copy::copy`, see *File::Copy*.

`DynaLoader::mod2fname`

used by `DynaLoader` for DLL name mangling.

`Cwd::current_drive()`

Self explanatory.

`Cwd::sys_chdir(name)`

leaves drive as it is.

`Cwd::change_drive(name)`

chanes the "current" drive.

`Cwd::sys_is_absolute(name)`

means has drive letter and is_rooted.

`Cwd::sys_is_rooted(name)`

means has leading `[/\\]` (maybe after a drive-letter:).

`Cwd::sys_is_relative(name)`

means changes with current dir.

`Cwd::sys_cwd(name)`

Interface to cwd from EMX. Used by `Cwd::cwd`.

`Cwd::sys_abspath(name, dir)`

Really really odious function to implement. Returns absolute name of file which would have `name` if CWD were `dir`. `Dir` defaults to the current dir.

`Cwd::extLibpath([type])`

Get current value of extended library search path. If `type` is present and positive, works with `END_LIBPATH`, if negative, works with `LIBPATHSTRICT`, otherwise with `BEGIN_LIBPATH`.

`Cwd::extLibpath_set( path [, type ] )`

Set current value of extended library search path. If `type` is present and positive, works with <END_LIBPATH>, if negative, works with `LIBPATHSTRICT`, otherwise with `BEGIN_LIBPATH`.

`OS2::Error(do_harderror,do_exception)`

Returns `undef` if it was not called yet, otherwise bit 1 is set if on the previous call do_harderror was enabled, bit 2 is set if on previous call do_exception was enabled.

This function enables/disables error popups associated with hardware errors (Disk not ready etc.) and software exceptions.

I know of no way to find out the state of popups *before* the first call to this function.

`OS2::Errors2Drive(drive)`

Returns `undef` if it was not called yet, otherwise return false if errors were not requested to be written to a hard drive, or the drive letter if this was requested.

This function may redirect error popups associated with hardware errors (Disk not ready etc.) and software exceptions to the file POPUPLOG.OS2 at the root directory of the specified drive. Overrides OS2::Error() specified by individual programs. Given argument undef will disable redirection.

Has global effect, persists after the application exits.

I know of no way to find out the state of redirection of popups to the disk *before* the first call to this function.

OS2::SysInfo()

Returns a hash with system information. The keys of the hash are

```
        MAX_PATH_LENGTH, MAX_TEXT_SESSIONS, MAX_PM_SESSIONS,
        MAX_VDM_SESSIONS, BOOT_DRIVE, DYN_PRI_VARIATION,
        MAX_WAIT, MIN_SLICE, MAX_SLICE, PAGE_SIZE,
        VERSION_MAJOR, VERSION_MINOR, VERSION_REVISION,
        MS_COUNT, TIME_LOW, TIME_HIGH, TOTPHYSMEM, TOTRESMEM,
        TOTAVAILMEM, MAXPRMEM, MAXSHMEM, TIMER_INTERVAL,
        MAX_COMP_LENGTH, FOREGROUND_FS_SESSION,
        FOREGROUND_PROCESS
```

OS2::BootDrive()

Returns a letter without colon.

`OS2::MorphPM(serve)`, `OS2::UnMorphPM(serve)`

Transforms the current application into a PM application and back. The argument true means that a real message loop is going to be served. OS2::MorphPM() returns the PM message queue handle as an integer.

See §117.10.10 for additional details.

`OS2::Serve_Messages(force)`

Fake on-demand retrieval of outstanding PM messages. If `force` is false, will not dispatch messages if a real message loop is known to be present. Returns number of messages retrieved.

Dies with "QUITing..." if WM_QUIT message is obtained.

`OS2::Process_Messages(force [, cnt])`

Retrieval of PM messages until window creation/destruction. If `force` is false, will not dispatch messages if a real message loop is known to be present.

Returns change in number of windows. If `cnt` is given, it is incremented by the number of messages retrieved.

Dies with "QUITing..." if WM_QUIT message is obtained.

`OS2::_control87(new,mask)`

the same as _control87(3) of EMX. Takes integers as arguments, returns the previous coprocessor control word as an integer. Only bits in `new` which are present in `mask` are changed in the control word.

OS2::get_control87()

gets the coprocessor control word as an integer.

`OS2::set_control87_em(new=MCW_EM,mask=MCW_EM)`

The variant of OS2::_control87() with default values good for handling exception mask: if no `mask`, uses exception mask part of `new` only. If no `new`, disables all the floating point exceptions.

See §117.10.7 for details.

`OS2::DLLname([how [, \&xsub]])`

Gives the information about the Perl DLL or the DLL containing the C function bound to by `&xsub`. The meaning of `how` is: default (2): full name; 0: handle; 1: module name.

(Note that some of these may be moved to different libraries - eventually).

117.10.6 Prebuilt variables:

$ OS2::emx_rev

numeric value is the same as _emx_rev of EMX, a string value the same as _emx_vprt (similar to `0.9c`).

$ OS2::emx_env

same as _emx_env of EMX, a number similar to 0x8001.

$ OS2::os_ver

a number `OS_MAJOR + 0.001 * OS_MINOR`.

$ OS2::is_aout

true if the Perl library was compiled in AOUT format.

$ OS2::can_fork

true if the current executable is an AOUT EMX executable, so Perl can fork. Do not use this, use the portable check for $Config::Config{dfork}.

$ OS2::nsyserror

This variable (default is 1) controls whether to enforce the contents of $^E to start with `SYS0003`-like id. If set to 0, then the string value of $^E is what is available from the OS/2 message file. (Some messages in this file have an `SYS0003`-like id prepended, some not.)

117.10.7 Misfeatures

- Since *flock*(3) is present in EMX, but is not functional, it is emulated by perl. To disable the emulations, set environment variable `USE_PERL_FLOCK=0`.
- Here is the list of things which may be "broken" on EMX (from EMX docs):
  - The functions *recvmsg*(3), *sendmsg*(3), and *socketpair*(3) are not implemented.
  - sock_init(3) is not required and not implemented.
  - *flock*(3) is not yet implemented (dummy function). (Perl has a workaround.)
  - *kill*(3): Special treatment of PID=0, PID=1 and PID=-1 is not implemented.
  - *waitpid*(3):

```
WUNTRACED
        Not implemented.
waitpid() is not implemented for negative values of PID.
```

  Note that `kill -9` does not work with the current version of EMX.
- See §117.13.1.

- Unix-domain sockets on OS/2 live in a pseudo-file-system `/sockets/...`. To avoid a failure to create a socket with a name of a different form, `"/socket/"` is prepended to the socket name (unless it starts with this already).

  This may lead to problems later in case the socket is accessed via the "usual" file-system calls using the "initial" name.

- Apparently, IBM used a compiler (for some period of time around '95?) which changes FP mask right and left. This is not *that* bad for IBM's programs, but the same compiler was used for DLLs which are used with general-purpose applications. When these DLLs are used, the state of floating-point flags in the application is not predictable.

  What is much worse, some DLLs change the floating point flags when in _DLLInitTerm() (e.g., *TCP32IP*). This means that even if you do not *call* any function in the DLL, just the act of loading this DLL will reset your flags. What is worse, the same compiler was used to compile some HOOK DLLs. Given that HOOK dlls are executed in the context of *all* the applications in the system, this means a complete unpredictablity of floating point flags on systems using such HOOK DLLs. E.g., *GAMESRVR.DLL* of **DIVE** origin changes the floating point flags on each write to the TTY of a VIO (windowed text-mode) applications.

  Some other (not completely debugged) situations when FP flags change include some video drivers (?), and some operations related to creation of the windows. People who code **OpenGL** may have more experience on this.

  Perl is generally used in the situation when all the floating-point exceptions are ignored, as is the default under EMX. If they are not ignored, some benign Perl programs would get a `SIGFPE` and would die a horrible death.

  To circumvent this, Perl uses two hacks. They help against *one* type of damage only: FP flags changed when loading a DLL.

  One of the hacks is to disable floating point exceptions on Perl startup (as is the default with EMX). This helps only with compile-time-linked DLLs changing the flags before main() had a chance to be called.

  The other hack is to restore FP flags after a call to dlopen(). This helps against similar damage done by DLLs _DLLInitTerm() at runtime. Currently no way to switch these hacks off is provided.

117.10.8 Modifications

Perl modifies some standard C library calls in the following ways:

`popen`

`my_popen` uses *sh.exe* if shell is required, cf. §117.12.4.

`tmpnam`

is created using `TMP` or `TEMP` environment variable, via `tempnam`.

`tmpfile`

If the current directory is not writable, file is created using modified `tmpnam`, so there may be a race condition.

`ctermid`

a dummy implementation.

`stat`

`os2_stat` special-cases */dev/tty* and */dev/con*.

`mkdir`, `rmdir`

these EMX functions do not work if the path contains a trailing `/`. Perl contains a workaround for this.

`flock`

Since *flock*(3) is present in EMX, but is not functional, it is emulated by perl. To disable the emulations, set environment variable `USE_PERL_FLOCK=0`.

117.10.9 Identifying DLLs

All the DLLs built with the current versions of Perl have ID strings identifying the name of the extension, its version, and the version of Perl required for this DLL. Run `bldlevel DLL-name` to find this info.

117.10.10 Centralized management of resources

Since to call certain OS/2 API one needs to have a correctly initialized `Win` subsystem, OS/2-specific extensions may require getting `HAB`s and `HMQ`s. If an extension would do it on its own, another extension could fail to initialize.

Perl provides a centralized management of these resources:

`HAB`

To get the HAB, the extension should call `hab = perl_hab_GET()` in C. After this call is performed, `hab` may be accessed as `Perl_hab`. There is no need to release the HAB after it is used.

If by some reasons *perl.h* cannot be included, use

```
extern int Perl_hab_GET(void);
```

instead.

`HMQ`

There are two cases:

- the extension needs an `HMQ` only because some API will not work otherwise. Use `serve = 0` below.
- the extension needs an `HMQ` since it wants to engage in a PM event loop. Use `serve = 1` below.

To get an `HMQ`, the extension should call `hmq = perl_hmq_GET(serve)` in C. After this call is performed, `hmq` may be accessed as `Perl_hmq`.

To signal to Perl that HMQ is not needed any more, call `perl_hmq_UNSET(serve)`. Perl process will automatically morph/unmorph itself into/from a PM process if HMQ is needed/not-needed. Perl will automatically enable/disable `WM_QUIT` message during shutdown if the message queue is served/not-served.

NOTE. If during a shutdown there is a message queue which did not disable WM_QUIT, and which did not process the received WM_QUIT message, the shutdown will be automatically cancelled. Do not call `perl_hmq_GET(1)` unless you are going to process messages on an orderly basis.

*** Treating errors reported by OS/2 API**

There are two principal conventions (it is useful to call them `Dos*` and `Win*` - though this part of the function signature is not always determined by the name of the API) of reporting the error conditions of OS/2 API. Most of `Dos*` APIs report the error code as the result of the call (so 0 means success, and there are many types of errors). Most of `Win*` API report success/fail via the result being `TRUE`/`FALSE`; to find the reason for the failure one should call WinGetLastError() API.

Some `Win*` entry points also overload a "meaningful" return value with the error indicator; having a 0 return value indicates an error. Yet some other `Win*` entry points overload things even more, and 0 return value may mean a successful call returning a valid value 0, as well as an error condition; in the case of a 0 return value one should call WinGetLastError() API to distinguish a successful call from a failing one.

By convention, all the calls to OS/2 API should indicate their failures by resetting $ˆE. All the Perl-accessible functions which call OS/2 API may be broken into two classes: some die()s when an API error is encountered, the other report the error via a false return value (of course, this does not concern Perl-accessible functions which *expect* a failure of the OS/2 API call, having some workarounds coded).

Obviously, in the situation of the last type of the signature of an OS/2 API, it is must more convenient for the users if the failure is indicated by die()ing: one does not need to check $ˆE to know that something went wrong. If, however, this solution is not desirable by some reason, the code in question should reset $ˆE to 0 before making this OS/2 API call, so that the caller of this Perl-accessible function has a chance to distinguish a success-but-0-return value from a failure. (One may return undef as an alternative way of reporting an error.)

The macros to simplify this type of error propagation are

`CheckOSError(expr)`
Returns true on error, sets $ˆE. Expects expr() be a call of `Dos*`-style API.

`CheckWinError(expr)`
Returns true on error, sets $ˆE. Expects expr() be a call of `Win*`-style API.

`SaveWinError(expr)`
Returns `expr`, sets $ˆE from WinGetLastError() if `expr` is false.

`SaveCroakWinError(expr,die,name1,name2)`
Returns `expr`, sets $ˆE from WinGetLastError() if `expr` is false, and die()s if `die` and $ˆE are true. The message to die is the concatenated strings `name1` and `name2`, separated by `": "` from the contents of $ˆE.

`WinError_2_Perl_rc`
Sets `Perl_rc` to the return value of WinGetLastError().

`FillWinError`
Sets `Perl_rc` to the return value of WinGetLastError(), and sets $ˆE to the corresponding value.

`FillOSError(rc)`
Sets `Perl_rc` to `rc`, and sets $ˆE to the corresponding value.

*** Loading DLLs and ordinals in DLLs**

Some DLLs are only present in some versions of OS/2, or in some configurations of OS/2. Some exported entry points are present only in DLLs shipped with some versions of OS/2. If these DLLs and entry points were linked directly for a Perl executable/DLL or from a Perl extensions, this binary would work only with the specified versions/setups. Even if these entry points were not needed, the *load* of the executable (or DLL) would fail.

For example, many newer useful APIs are not present in OS/2 v2; many PM-related APIs require DLLs not available on floppy-boot setup.

To make these calls fail *only when the calls are executed*, one should call these API via a dynamic linking API. There is a subsystem in Perl to simplify such type of calls. A large number of entry points available for such linking is provided (see `entries_ordinals` - and also `PMWIN_entries` - in *os2ish.h*). These ordinals can be accessed via the APIs:

```
CallORD(), DeclFuncByORD(), DeclVoidFuncByORD(),
DeclOSFuncByORD(), DeclWinFuncByORD(), AssignFuncPByORD(),
DeclWinFuncByORD_CACHE(), DeclWinFuncByORD_CACHE_survive(),
DeclWinFuncByORD_CACHE_resetError_survive(),
DeclWinFunc_CACHE(), DeclWinFunc_CACHE_resetError(),
DeclWinFunc_CACHE_survive(), DeclWinFunc_CACHE_resetError_survive()
```

See the header files and the C code in the supplied OS/2-related modules for the details on usage of these functions.

Some of these functions also combine dynaloading semantic with the error-propagation semantic discussed above.

117.11 Perl flavors

Because of idiosyncrasies of OS/2 one cannot have all the eggs in the same basket (though EMX environment tries hard to overcome this limitations, so the situation may somehow improve). There are 4 executables for Perl provided by the distribution:

117.11.1 *perl.exe*

The main workhorse. This is a chimera executable: it is compiled as an `a.out`-style executable, but is linked with `omf`-style dynamic library *perl.dll*, and with dynamic CRT DLL. This executable is a VIO application.

It can load perl dynamic extensions, and it can fork().

Note. Keep in mind that fork() is needed to open a pipe to yourself.

117.11.2 *perl_.exe*

This is a statically linked `a.out`-style executable. It cannot load dynamic Perl extensions. The executable supplied in binary distributions has a lot of extensions prebuilt, thus the above restriction is important only if you use custom-built extensions. This executable is a VIO application.

This is the only executable with does not require OS/2. The friends locked into `M$` world would appreciate the fact that this executable runs under DOS, Win0.3*, Win0.95 and WinNT with an appropriate extender. See §117.2.2.

117.11.3 *perl__.exe*

This is the same executable as *perl___.exe*, but it is a PM application.

Note. Usually (unless explicitly redirected during the startup) STDIN, STDERR, and STDOUT of a PM application are redirected to *nul*. However, it is possible to *see* them if you start `perl__.exe` from a PM program which emulates a console window, like *Shell mode* of Emacs or EPM. Thus it *is possible* to use Perl debugger (see *perldebug*) to debug your PM application (but beware of the message loop lockups - this will not work if you have a message queue to serve, unless you hook the serving into the getc() function of the debugger).

Another way to see the output of a PM program is to run it as

```
pm_prog args 2>&1 | cat -
```

with a shell *different* from *cmd.exe*, so that it does not create a link between a VIO session and the session of `pm_porg`. (Such a link closes the VIO window.) E.g., this works with *sh.exe* - or with Perl!

```
open P, 'pm_prog args 2>&1 |' or die;
print while <P>;
```

The flavor *perl__.exe* is required if you want to start your program without a VIO window present, but not `detached` (run `help detach` for more info). Very useful for extensions which use PM, like `Perl/Tk` or `OpenGL`.

Note also that the differences between PM and VIO executables are only in the *default* behaviour. One can start *any* executable in *any* kind of session by using the arguments `/fs`, `/pm` or `/win` switches of the command `start` (of *CMD.EXE* or a similar shell). Alternatively, one can use the numeric first argument of the `system` Perl function (see `OS2::Process`).

117.11.4 *perl___.exe*

This is an `omf`-style executable which is dynamically linked to *perl.dll* and CRT DLL. I know no advantages of this executable over `perl.exe`, but it cannot fork() at all. Well, one advantage is that the build process is not so convoluted as with `perl.exe`.

It is a VIO application.

117.11.5 Why strange names?

Since Perl processes the `#!`-line (cf. DESCRIPTION in *perlrun*, Switches in *perlrun*, Not a perl script in *perldiag*, No Perl script found in input in *perldiag*), it should know when a program *is a Perl*. There is some naming convention which allows Perl to distinguish correct lines from wrong ones. The above names are almost the only names allowed by this convention which do not contain digits (which have absolutely different semantics).

117.11.6 Why dynamic linking?

Well, having several executables dynamically linked to the same huge library has its advantages, but this would not substantiate the additional work to make it compile. The reason is the complicated-to-developers but very quick and convenient-to-users "hard" dynamic linking used by OS/2.

There are two distinctive features of the dyna-linking model of OS/2: first, all the references to external functions are resolved at the compile time; second, there is no runtime fixup of the DLLs after they are loaded into memory. The first feature is an enormous advantage over other models: it avoids conflicts when several DLLs used by an application export entries with the same name. In such cases "other" models of dyna-linking just choose between these two entry points using some random criterion - with predictable disasters as results. But it is the second feature which requires the build of *perl.dll*.

The address tables of DLLs are patched only once, when they are loaded. The addresses of the entry points into DLLs are guaranteed to be the same for all the programs which use the same DLL. This removes the runtime fixup - once DLL is loaded, its code is read-only.

While this allows some (significant?) performance advantages, this makes life much harder for developers, since the above scheme makes it impossible for a DLL to be "linked" to a symbol in the *.EXE* file. Indeed, this would need a DLL to have different relocations tables for the (different) executables which use this DLL.

However, a dynamically loaded Perl extension is forced to use some symbols from the perl executable, e.g., to know how to find the arguments to the functions: the arguments live on the perl internal evaluation stack. The solution is to put the main code of the interpreter into a DLL, and make the *.EXE* file which just loads this DLL into memory and supplies command-arguments. The extension DLL cannot link to symbols in *.EXE*, but it has no problem linking to symbols in the *.DLL*.

This *greatly* increases the load time for the application (as well as complexity of the compilation). Since interpreter is in a DLL, the C RTL is basically forced to reside in a DLL as well (otherwise extensions would not be able to use CRT). There are some advantages if you use different flavors of perl, such as running *perl.exe* and *perl__.exe* simultaneously: they share the memory of *perl.dll*.

NOTE. There is one additional effect which makes DLLs more wasteful: DLLs are loaded in the shared memory region, which is a scarse resource given the 512M barrier of the "standard" OS/2 virtual memory. The code of *.EXE* files is also shared by all the processes which use the particular *.EXE*, but they are "shared in the private address space of the process"; this is possible because the address at which different sections of the *.EXE* file are loaded is decided at compile-time, thus all the processes have these sections loaded at same addresses, and no fixup of internal links inside the *.EXE* is needed.

Since DLLs may be loaded at run time, to have the same mechanism for DLLs one needs to have the address range of *any of the loaded* DLLs in the system to be available *in all the processes* which did not load a particular DLL yet. This is why the DLLs are mapped to the shared memory region.

117.11.7 Why chimera build?

Current EMX environment does not allow DLLs compiled using Unixish `a.out` format to export symbols for data (or at least some types of data). This forces `omf`-style compile of *perl.dll*.

Current EMX environment does not allow *.EXE* files compiled in `omf` format to fork(). fork() is needed for exactly three Perl operations:

- explicit fork() in the script,
- `open FH, "|-"`
- `open FH, "-|"`, in other words, opening pipes to itself.

While these operations are not questions of life and death, they are needed for a lot of useful scripts. This forces `a.out`-style compile of *perl.exe*.

117.12 ENVIRONMENT

Here we list environment variables with are either OS/2- and DOS- and Win*-specific, or are more important under OS/2 than under other OSes.

117.12.1 PERLLIB_PREFIX

Specific for EMX port. Should have the form

```
path1;path2
```

or

```
path1 path2
```

If the beginning of some prebuilt path matches *path1*, it is substituted with *path2*.

Should be used if the perl library is moved from the default location in preference to `PERL(5)LIB`, since this would not leave wrong entries in @INC. For example, if the compiled version of perl looks for @INC in *f:/perllib/lib*, and you want to install the library in *h:/opt/gnu*, do

```
set PERLLIB_PREFIX=f:/perllib/lib;h:/opt/gnu
```

This will cause Perl with the prebuilt @INC of

```
f:/perllib/lib/5.00553/os2
f:/perllib/lib/5.00553
f:/perllib/lib/site_perl/5.00553/os2
f:/perllib/lib/site_perl/5.00553
.
```

to use the following @INC:

```
h:/opt/gnu/5.00553/os2
h:/opt/gnu/5.00553
h:/opt/gnu/site_perl/5.00553/os2
h:/opt/gnu/site_perl/5.00553
.
```

117.12.2 PERL_BADLANG

If 0, perl ignores setlocale() failing. May be useful with some strange *locale*s.

117.12.3 PERL_BADFREE

If 0, perl would not warn of in case of unwarranted free(). With older perls this might be useful in conjunction with the module DB_File, which was buggy when dynamically linked and OMF-built.

Should not be set with newer Perls, since this may hide some *real* problems.

117.12.4 PERL_SH_DIR

Specific for EMX port. Gives the directory part of the location for *sh.exe*.

117.12.5 `USE_PERL_FLOCK`

Specific for EMX port. Since *flock*(3) is present in EMX, but is not functional, it is emulated by perl. To disable the emulations, set environment variable `USE_PERL_FLOCK=0`.

117.12.6 `TMP` or `TEMP`

Specific for EMX port. Used as storage place for temporary files.

117.13 Evolution

Here we list major changes which could make you by surprise.

117.13.1 Text-mode filehandles

Starting from version 5.8, Perl uses a builtin translation layer for text-mode files. This replaces the efficient well-tested EMX layer by some code which should be best characterized as a "quick hack".

In addition to possible bugs and an inability to follow changes to the translation policy with off/on switches of TERMIO translation, this introduces a serious incompatible change: before sysread() on text-mode filehandles would go through the translation layer, now it would not.

117.13.2 Priorities

`setpriority` and `getpriority` are not compatible with earlier ports by Andreas Kaiser. See "`setpriority, getpriority`".

117.13.3 DLL name mangling: pre 5.6.2

With the release 5.003_01 the dynamically loadable libraries should be rebuilt when a different version of Perl is compiled. In particular, DLLs (including *perl.dll*) are now created with the names which contain a checksum, thus allowing workaround for OS/2 scheme of caching DLLs.

It may be possible to code a simple workaround which would

- find the old DLLs looking through the old @INC;
- mangle the names according to the scheme of new perl and copy the DLLs to these names;
- edit the internal `LX` tables of DLL to reflect the change of the name (probably not needed for Perl extension DLLs, since the internally coded names are not used for "specific" DLLs, they used only for "global" DLLs).
- edit the internal `IMPORT` tables and change the name of the "old" *perl????.dll* to the "new" *perl????.dll*.

117.13.4 DLL name mangling: 5.6.2 and beyond

In fact mangling of *extension* DLLs was done due to misunderstanding of the OS/2 dynaloading model. OS/2 (effectively) maintains two different tables of loaded DLL:

Global DLLs

those loaded by the base name from `LIBPATH`; including those associated at link time;

specific DLLs

loaded by the full name.

When resolving a request for a global DLL, the table of already-loaded specific DLLs is (effectively) ignored; moreover, specific DLLs are *always* loaded from the prescribed path.

There is/was a minor twist which makes this scheme fragile: what to do with DLLs loaded from

`BEGINLIBPATH` and `ENDLIBPATH`

(which depend on the process)

. from `LIBPATH`

which *effectively* depends on the process (although `LIBPATH` is the same for all the processes).

Unless `LIBPATHSTRICT` is set to `T` (and the kernel is after 2000/09/01), such DLLs are considered to be global. When loading a global DLL it is first looked in the table of already-loaded global DLLs. Because of this the fact that one executable loaded a DLL from `BEGINLIBPATH` and `ENDLIBPATH`, or . from `LIBPATH` may affect *which* DLL is loaded when *another* executable requests a DLL with the same name. *This* is the reason for version-specific mangling of the DLL name for perl DLL.

Since the Perl extension DLLs are always loaded with the full path, there is no need to mangle their names in a version-specific ways: their directory already reflects the corresponding version of perl, and @INC takes into account binary compatibility with older version. Starting from `5.6.2` the name mangling scheme is fixed to be the same as for Perl 5.005_53 (same as in a popular binary release). Thus new Perls will be able to *resolve the names* of old extension DLLs if @INC allows finding their directories.

However, this still does not guarantee that these DLL may be loaded. The reason is the mangling of the name of the *Perl DLL*. And since the extension DLLs link with the Perl DLL, extension DLLs for older versions would load an older Perl DLL, and would most probably segfault (since the data in this DLL is not properly initialized).

There is a partial workaround (which can be made complete with newer OS/2 kernels): create a forwarder DLL with the same name as the DLL of the older version of Perl, which forwards the entry points to the newer Perl's DLL. Make this DLL accessible on (say) the `BEGINLIBPATH` of the new Perl executable. When the new executable accesses old Perl's extension DLLs, they would request the old Perl's DLL by name, get the forwarder instead, so effectively will link with the currently running (new) Perl DLL.

This may break in two ways:

- Old perl executable is started when a new executable is running has loaded an extension compiled for the old executable (ouph!). In this case the old executable will get a forwarder DLL instead of the old perl DLL, so would link with the new perl DLL. While not directly fatal, it will behave the same as new executable. This beats the whole purpose of explicitly starting an old executable.
- A new executable loads an extension compiled for the old executable when an old perl executable is running. In this case the extension will not pick up the forwarder - with fatal results.

With support for `LIBPATHSTRICT` this may be circumvented - unless one of DLLs is started from . from `LIBPATH` (I do not know whether `LIBPATHSTRICT` affects this case).

REMARK. Unless newer kernels allow . in `BEGINLIBPATH` (older do not), this mess cannot be completely cleaned. (It turns out that as of the beginning of 2002, . is not allowed, but .\. is - and it has the same effect.)

REMARK. `LIBPATHSTRICT`, `BEGINLIBPATH` and `ENDLIBPATH` are not environment variables, although *cmd.exe* emulates them on `SET ...` lines. From Perl they may be accessed by *Cwd::extLibpath* and Cwd::extLibpath_set.

117.13.5 DLL forwarder generation

Assume that the old DLL is named *perlE0AC.dll* (as is one for 5.005_53), and the new version is 5.6.1. Create a file *perl5shim.def-leader* with

```
LIBRARY 'perlE0AC' INITINSTANCE TERMINSTANCE
DESCRIPTION '@#perl5-porters@perl.org:5.006001#@ Perl module for 5.00553 -> Perl 5.6.1 forwarder'
CODE LOADONCALL
DATA LOADONCALL NONSHARED MULTIPLE
EXPORTS
```

modifying the versions/names as needed. Run

```
perl -wnle "next if 0../EXPORTS/; print qq(  \"$1\") if /\"(\w+)\"/" perl5.def >lst
```

in the Perl build directory (to make the DLL smaller replace perl5.def with the definition file for the older version of Perl if present).

```
cat perl5shim.def-leader lst >perl5shim.def
gcc -Zomf -Zdll -o perlE0AC.dll perl5shim.def -s -llibperl
```

(ignore multiple `warning L4085`).

117.13.6 Threading

As of release 5.003_01 perl is linked to multithreaded C RTL DLL. If perl itself is not compiled multithread-enabled, so will not be perl's malloc(). However, extensions may use multiple thread on their own risk.

This was needed to compile `Perl/Tk` for XFree86-OS/2 out-of-the-box, and link with DLLs for other useful libraries, which typically are compiled with `-Zmt -Zcrtdll`.

117.13.7 Calls to external programs

Due to a popular demand the perl external program calling has been changed wrt Andreas Kaiser's port. *If* perl needs to call an external program *via shell*, the *f:/bin/sh.exe* will be called, or whatever is the override, see §117.12.4.

Thus means that you need to get some copy of a *sh.exe* as well (I use one from pdksh). The path *F:/bin* above is set up automatically during the build to a correct value on the builder machine, but is overridable at runtime,

Reasons: a consensus on `perl5-porters` was that perl should use one non-overridable shell per platform. The obvious choices for OS/2 are *cmd.exe* and *sh.exe*. Having perl build itself would be impossible with *cmd.exe* as a shell, thus I picked up `sh.exe`. This assures almost 100% compatibility with the scripts coming from *nix. As an added benefit this works as well under DOS if you use DOS-enabled port of pdksh (see §117.6.2).

Disadvantages: currently *sh.exe* of pdksh calls external programs via fork()/exec(), and there is *no* functioning exec() on OS/2. exec() is emulated by EMX by an asynchronous call while the caller waits for child completion (to pretend that the `pid` did not change). This means that 1 *extra* copy of *sh.exe* is made active via fork()/exec(), which may lead to some resources taken from the system (even if we do not count extra work needed for fork()ing).

Note that this a lesser issue now when we do not spawn *sh.exe* unless needed (metachars found).

One can always start *cmd.exe* explicitly via

```
  system 'cmd', '/c', 'mycmd', 'arg1', 'arg2', ...
```

If you need to use *cmd.exe*, and do not want to hand-edit thousands of your scripts, the long-term solution proposed on p5-p is to have a directive

```
  use OS2::Cmd;
```

which will override system(), exec(), ", and `open(,'...|')`. With current perl you may override only system(), readpipe() - the explicit version of ", and maybe exec(). The code will substitute the one-argument call to system() by `CORE::system('cmd.exe', '/c', shift)`.

If you have some working code for `OS2::Cmd`, please send it to me, I will include it into distribution. I have no need for such a module, so cannot test it.

For the details of the current situation with calling external programs, see Starting OS/2 (and DOS) programs under Perl. Set us mention a couple of features:

- External scripts may be called by their basename. Perl will try the same extensions as when processing **-S** command-line switch.
- External scripts starting with `#!` or `extproc` will be executed directly, without calling the shell, by calling the program specified on the rest of the first line.

117.13.8 Memory allocation

Perl uses its own malloc() under OS/2 - interpreters are usually malloc-bound for speed, but perl is not, since its malloc is lightning-fast. Perl-memory-usage-tuned benchmarks show that Perl's malloc is 5 times quicker than EMX one. I do not have convincing data about memory footprint, but a (pretty random) benchmark showed that Perl's one is 5% better.

Combination of perl's malloc() and rigid DLL name resolution creates a special problem with library functions which expect their return value to be free()d by system's free(). To facilitate extensions which need to call such functions, system memory-allocation functions are still available with the prefix `emx_` added. (Currently only DLL perl has this, it should propagate to *perl_.exe* shortly.)

117.13.9 Threads

One can build perl with thread support enabled by providing `-D usethreads` option to *Configure*. Currently OS/2 support of threads is very preliminary.

Most notable problems:

`COND_WAIT`

may have a race condition (but probably does not due to edge-triggered nature of OS/2 Event semaphores). (Needs a reimplementation (in terms of chaining waiting threads, with the linked list stored in per-thread structure?)?)

os2.c

has a couple of static variables used in OS/2-specific functions. (Need to be moved to per-thread structure, or serialized?)

Note that these problems should not discourage experimenting, since they have a low probability of affecting small programs.

117.14 BUGS

This description is not updated often (since 5.6.1?), see *./os2/Changes* (*perlos2delta*) for more info.

README.os390

Building and installing Perl for OS/390 and z/OS

118.1 SYNOPSIS

This document will help you Configure, build, test and install Perl on OS/390 (aka z/OS) Unix System Services.

118.2 DESCRIPTION

This is a fully ported Perl for OS/390 Version 2 Release 3, 5, 6, 7, 8, and 9. It may work on other versions or releases, but those are the ones we've tested it on.
You may need to carry out some system configuration tasks before running the Configure script for Perl.

118.2.1 Tools

The z/OS Unix Tools and Toys list may prove helpful and contains links to ports of much of the software helpful for building Perl. http://www-1.ibm.com/servers/eserver/zseries/zos/unix/bpxa1toy.html

118.2.2 Unpacking Perl distribution on OS/390

If using ftp remember to transfer the distribution in binary format.
Gunzip/gzip for OS/390 is discussed at:

```
  http://www-1.ibm.com/servers/eserver/zseries/zos/unix/faq/bpxqp1.html
```

to extract an ASCII tar archive on OS/390, try this:

```
   pax -o to=IBM-1047,from=ISO8859-1 -r < latest.tar
```

or

```
   zcat latest.tar.Z | pax -o to=IBM-1047,from=ISO8859-1 -r
```

If you get lots of errors of the form

```
  tar: FSUM7171 ...: cannot set uid/gid: EDC5139I Operation not permitted.
```

you didn't read the above and tried to use tar instead of pax, you'll first have to remove the (now corrupt) perl directory

```
   rm -rf perl-...
```

and then use pax.

118.2.3 Setup and utilities for Perl on OS/390

Be sure that your yacc installation is in place including any necessary parser template files. If you have not already done so then be sure to:

```
  cp /samples/yyparse.c /etc
```

This may also be a good time to ensure that your /etc/protocol file and either your /etc/resolv.conf or /etc/hosts files are in place. The IBM document that described such USS system setup issues was SC28-1890-07 "OS/390 UNIX System Services Planning", in particular Chapter 6 on customizing the OE shell.

GNU make for OS/390, which is recommended for the build of perl (as well as building CPAN modules and extensions), is available from the Tools.

Some people have reported encountering "Out of memory!" errors while trying to build Perl using GNU make binaries. If you encounter such trouble then try to download the source code kit and build GNU make from source to eliminate any such trouble. You might also find GNU make (as well as Perl and Apache) in the red-piece/book "Open Source Software for OS/390 UNIX", SG24-5944-00 from IBM.

If instead of the recommended GNU make you would like to use the system supplied make program then be sure to install the default rules file properly via the shell command:

```
    cp /samples/startup.mk /etc
```

and be sure to also set the environment variable _C89_CCMODE=1 (exporting _C89_CCMODE=1 is also a good idea for users of GNU make).

You might also want to have GNU groff for OS/390 installed before running the ‘make install‘ step for Perl.

There is a syntax error in the /usr/include/sys/socket.h header file that IBM supplies with USS V2R7, V2R8, and possibly V2R9. The problem with the header file is that near the definition of the SO_REUSEPORT constant there is a spurious extra ’/’ character outside of a comment like so:

```
 #define SO_REUSEPORT    0x0200    /* allow local address & port
                                      reuse */                    /
```

You could edit that header yourself to remove that last ’/’, or you might note that Language Environment (LE) APAR PQ39997 describes the problem and PTF’s UQ46272 and UQ46271 are the (R8 at least) fixes and apply them. If left unattended that syntax error will turn up as an inability for Perl to build its "Socket" extension.

For successful testing you may need to turn on the sticky bit for your world readable /tmp directory if you have not already done so (see man chmod).

118.2.4 Configure Perl on OS/390

Once you’ve unpacked the distribution, run "sh Configure" (see INSTALL for a full discussion of the Configure options). There is a "hints" file for os390 that specifies the correct values for most things. Some things to watch out for include:

- A message of the form:

  ```
   (I see you are using the Korn shell.  Some ksh’s blow up on Configure,
   mainly on older exotic systems.  If yours does, try the Bourne shell instead.)
  ```

  is nothing to worry about at all.

- Some of the parser default template files in /samples are needed in /etc. In particular be sure that you at least copy /samples/yyparse.c to /etc before running Perl’s Configure. This step ensures successful extraction of EBCDIC versions of parser files such as perly.c, perly.h, and x2p/a2p.c. This has to be done before running Configure the first time. If you failed to do so then the easiest way to re-Configure Perl is to delete your misconfigured build root and re-extract the source from the tar ball. Then you must ensure that /etc/yyparse.c is properly in place before attempting to re-run Configure.

- This port will support dynamic loading, but it is not selected by default. If you would like to experiment with dynamic loading then be sure to specify -Dusedl in the arguments to the Configure script. See the comments in hints/os390.sh for more information on dynamic loading. If you build with dynamic loading then you will need to add the $archlibexp/CORE directory to your LIBPATH environment variable in order for perl to work. See the config.sh file for the value of $archlibexp. If in trying to use Perl you see an error message similar to:

  ```
  CEE3501S The module libperl.dll was not found.
          From entry point __dllstaticinit at compile unit offset +00000194 at
  ```

  then your LIBPATH does not have the location of libperl.x and either libperl.dll or libperl.so in it. Add that directory to your LIBPATH and proceed.
- Do not turn on the compiler optimization flag "-O". There is a bug in either the optimizer or perl that causes perl to not work correctly when the optimizer is on.
- Some of the configuration files in /etc used by the networking APIs are either missing or have the wrong names. In particular, make sure that there's either an /etc/resolv.conf or an /etc/hosts, so that gethostbyname() works, and make sure that the file /etc/proto has been renamed to /etc/protocol (NOT /etc/protocols, as used by other Unix systems). You may have to look for things like HOSTNAME and DOMAINORIGIN in the "//'SYS1.TCPPARMS(TCPDATA)'" PDS member in order to properly set up your /etc networking files.

118.2.5 Build, Test, Install Perl on OS/390

Simply put:

```
    sh Configure
    make
    make test
```

if everything looks ok (see the next section for test/IVP diagnosis) then:

```
    make install
```

this last step may or may not require UID=0 privileges depending on how you answered the questions that Configure asked and whether or not you have write access to the directories you specified.

118.2.6 Build Anomalies with Perl on OS/390

"Out of memory!" messages during the build of Perl are most often fixed by re building the GNU make utility for OS/390 from a source code kit.

Another memory limiting item to check is your MAXASSIZE parameter in your 'SYS1.PARMLIB(BPXPRMxx)' data set (note too that as of V2R8 address space limits can be set on a per user ID basis in the USS segment of a RACF profile). People have reported successful builds of Perl with MAXASSIZE parameters as small as 503316480 (and it may be possible to build Perl with a MAXASSIZE smaller than that).

Within USS your /etc/profile or $HOME/.profile may limit your ulimit settings. Check that the following command returns reasonable values:

```
    ulimit -a
```

To conserve memory you should have your compiler modules loaded into the Link Pack Area (LPA/ELPA) rather than in a link list or step lib.

If the c89 compiler complains of syntax errors during the build of the Socket extension then be sure to fix the syntax error in the system header /usr/include/sys/socket.h.

118.2.7 Testing Anomalies with Perl on OS/390

The ‘make test‘ step runs a Perl Verification Procedure, usually before installation. You might encounter STDERR messages even during a successful run of ‘make test‘. Here is a guide to some of the more commonly seen anomalies:

- A message of the form:

  ```
  comp/cpp.............ERROR CBC3191 ./.301989890.c:1     The character $ is not a
   valid C source character.
  FSUM3065 The COMPILE step ended with return code 12.
  FSUM3017 Could not compile .301989890.c. Correct the errors and try again.
  ok
  ```

  indicates that the t/comp/cpp.t test of Perl’s -P command line switch has passed but that the particular invocation of c89 -E in the cpp script does not suppress the C compiler check of source code validity.

- A message of the form:

  ```
  io/openpid...........CEE5210S The signal SIGHUP was received.
  CEE5210S The signal SIGHUP was received.
  CEE5210S The signal SIGHUP was received.
  ok
  ```

  indicates that the t/io/openpid.t test of Perl has passed but done so with extraneous messages on stderr from CEE.

- A message of the form:

  ```
  lib/ftmp-security....File::Temp::_gettemp: Parent directory (/tmp/) is not safe
  (sticky bit not set when world writable?) at lib/ftmp-security.t line 100
  File::Temp::_gettemp: Parent directory (/tmp/) is not safe (sticky bit not
  set when world writable?) at lib/ftmp-security.t line 100
  ok
  ```

  indicates a problem with the permissions on your /tmp directory within the HFS. To correct that problem issue the command:

  ```
      chmod a+t /tmp
  ```

  from an account with write access to the directory entry for /tmp.

- Out of Memory!

  Recent perl test suite is quite memory hunrgy. In addition to the comments above on memory limitations it is also worth checking for _CEE_RUNOPTS in your environment. Perl now has (in miniperlmain.c) a C #pragma to set CEE run options, but the environment variable wins.

  The C code asks for:

  ```
  #pragma runopts(HEAP(2M,500K,ANYWHERE,KEEP,8K,4K) STACK(,,ANY,) ALL31(ON))
  ```

  The important parts of that are the second argument (the increment) to HEAP, and allowing the stack to be "Above the (16M) line". If the heap increment is too small then when perl (for example loading unicode/Name.pl) tries to create a "big" (400K+) string it cannot fit in a single segment and you get "Out of Memory!" - even if there is still plenty of memory available.

  A related issue is use with perl’s malloc. Perl’s malloc uses `sbrk()` to get memory, and `sbrk()` is limited to the first allocation so in this case something like:

  ```
   HEAP(8M,500K,ANYWHERE,KEEP,8K,4K)
  ```

  is needed to get through the test suite.

118.2.8 Installation Anomalies with Perl on OS/390

The installman script will try to run on OS/390. There will be fewer errors if you have a roff utility installed. You can obtain GNU groff from the Redbook SG24-5944-00 ftp site.

118.2.9 Usage Hints for Perl on OS/390

When using perl on OS/390 please keep in mind that the EBCDIC and ASCII character sets are different. See perlebcdic.pod for more on such character set issues. Perl builtin functions that may behave differently under EBCDIC are also mentioned in the perlport.pod document.

Open Edition (UNIX System Services) from V2R8 onward does support #!/path/to/perl script invocation. There is a PTF available from IBM for V2R7 that will allow shell/kernel support for #!. USS releases prior to V2R7 did not support the #! means of script invocation. If you are running V2R6 or earlier then see:

```
    head `whence perldoc`
```

for an example of how to use the "eval exec" trick to ask the shell to have Perl run your scripts on those older releases of Unix System Services.

If you are having trouble with square brackets then consider switching your rlogin or telnet client. Try to avoid older 3270 emulators and ISHELL for working with Perl on USS.

118.2.10 Floating Point Anomalies with Perl on OS/390

There appears to be a bug in the floating point implementation on S/390 systems such that calling int() on the product of a number and a small magnitude number is not the same as calling int() on the quotient of that number and a large magnitude number. For example, in the following Perl code:

```
    my $x = 100000.0;
    my $y = int($x * 1e-5) * 1e5; # '0'
    my $z = int($x / 1e+5) * 1e5;  # '100000'
    print "\$y is $y and \$z is $z\n"; # $y is 0 and $z is 100000
```

Although one would expect the quantities $y and $z to be the same and equal to 100000 they will differ and instead will be 0 and 100000 respectively.

The problem can be further examined in a roughly equivalent C program:

```
    #include <stdio.h>
    #include <math.h>
    main()
    {
    double r1,r2;
    double x = 100000.0;
    double y = 0.0;
    double z = 0.0;
    x = 100000.0 * 1e-5;
    r1 = modf (x,&y);
    x = 100000.0 / 1e+5;
    r2 = modf (x,&z);
    printf("y is %e and z is %e\n",y*1e5,z*1e5);
    /* y is 0.000000e+00 and z is 1.000000e+05 (with c89) */
    }
```

118.2.11 Modules and Extensions for Perl on OS/390

Pure pure (that is non xs) modules may be installed via the usual:

```
perl Makefile.PL
make
make test
make install
```

If you built perl with dynamic loading capability then that would also be the way to build xs based extensions. However, if you built perl with the default static linking you can still build xs based extensions for OS/390 but you will need to follow the instructions in ExtUtils::MakeMaker for building statically linked perl binaries. In the simplest configurations building a static perl + xs extension boils down to:

```
perl Makefile.PL
make
make perl
make test
make install
make -f Makefile.aperl inst_perl MAP_TARGET=perl
```

In most cases people have reported better results with GNU make rather than the system's /bin/make program, whether for plain modules or for xs based extensions.

If the make process encounters trouble with either compilation or linking then try setting the _C89_CCMODE to 1. Assuming sh is your login shell then run:

```
export _C89_CCMODE=1
```

If tcsh is your login shell then use the setenv command.

118.3 AUTHORS

David Fiander and Peter Prymmer with thanks to Dennis Longnecker and William Raffloer for valuable reports, LPAR and PTF feedback. Thanks to Mike MacIsaac and Egon Terwedow for SG24-5944-00. Thanks to Ignasi Roca for pointing out the floating point problems. Thanks to John Goodyear for dynamic loading help.

118.5 HISTORY

This document was originally written by David Fiander for the 5.005 release of Perl.

This document was podified for the 5.005_03 release of Perl 11 March 1999.

Updated 28 November 2001 for broken URLs.

Updated 12 November 2000 for the 5.7.1 release of Perl.

Updated 15 January 2001 for the 5.7.1 release of Perl.

Updated 24 January 2001 to mention dynamic loading.

Updated 12 March 2001 to mention //'SYS1.TCPPARMS(TCPDATA)'.

Chapter 119

README.os400

Perl version 5 on OS/400

119.1 DESCRIPTION

This document describes various features of IBM's OS/400 operating system that will affect how Perl version 5 (hereafter just Perl) is compiled and/or runs.

By far the easiest way to build Perl for OS/400 is to use the PASE (Portable Application Solutions Environment), for more information see http://www.iseries.ibm.com/developer/factory/pase/index.html This environment allows one to use AIX APIs while programming, and it provides a runtime that allows AIX binaries to execute directly on the PowerPC iSeries.

119.1.1 Compiling Perl for OS/400 PASE

The recommended way to build Perl for the OS/400 PASE is to build the Perl 5 source code (release 5.8.1 or later) under AIX.

The trick is to give a special parameter to the Configure shell script when running it on AIX:

```
  sh Configure -DPASE ...
```

The default installation directory of Perl under PASE is /QOpenSys/perl. This can be modified if needed with Configure parameter -Dprefix=/some/dir.

Starting from OS/400 V5R2 the IBM Visual Age compiler is supported on OS/400 PASE, so it is possible to build Perl natively on OS/400. The easier way, however, is to compile in AIX, as just described.

If you don't want to install the compiled Perl in AIX into /QOpenSys (for packaging it before copying it to PASE), you can use a Configure parameter: -Dinstallprefix=/tmp/QOpenSys/perl. This will cause the "make install" to install everything into that directory, while the installed files still think they are (will be) in /QOpenSys/perl.

If building natively on PASE, please do the build under the /QOpenSys directory, since Perl is happier when built on a case sensitive filesystem.

119.1.2 Installing Perl in OS/400 PASE

If you are compiling on AIX, simply do a "make install" on the AIX box. Once the install finishes, tar up the /QOpenSys/perl directory. Transfer the tarball to the OS/400 using FTP with the following commands:

```
  > binary
  > site namefmt 1
  > put perl.tar /QOpenSys
```

Once you have it on, simply bring up a PASE shell and extract the tarball.

If you are compiling in PASE, then "make install" is the only thing you will need to do.

The default path for perl binary is /QOpenSys/perl/bin/perl. You'll want to symlink /QOpenSys/usr/bin/perl to this file so you don't have to modify your path.

119.1.3 Using Perl in OS/400 PASE

Perl in PASE may be used in the same manner as you would use Perl on AIX.

Scripts starting with #!/usr/bin/perl should work if you have /QOpenSys/usr/bin/perl symlinked to your perl binary. This will not work if you've done a setuid/setgid or have environment variable PASE_EXEC_QOPENSYS="N". If you have V5R1, you'll need to get the latest PTFs to have this feature. Scripts starting with #!/QOpenSys/perl/bin/perl should always work.

119.1.4 Known Problems

When compiling in PASE, there is no "oslevel" command. Therefore, you may want to create a script called "oslevel" that echoes the level of AIX that your version of PASE runtime supports. If you're unsure, consult your documentation or use "4.3.3.0".

If you have test cases that fail, check for the existence of spool files. The test case may be trying to use a syscall that is not implemented in PASE. To avoid the SIGILL, try setting the PASE_SYSCALL_NOSIGILL environment variable or have a handler for the SIGILL. If you can compile programs for PASE, run the config script and edit config.sh when it gives you the option. If you want to remove fchdir(), which isn't implement in V5R1, simply change the line that says:

d_fchdir='define'

to

d_fchdir='undef'

and then compile Perl. The places where fchdir() is used have alternatives for systems that do not have fchdir() available.

119.1.5 Perl on ILE

There exists a port of Perl to the ILE environment. This port, however, is based quite an old release of Perl, Perl 5.00502 (August 1998). (As of July 2002 the latest release of Perl is 5.8.0, and even 5.6.1 has been out since April 2001.) If you need to run Perl on ILE, though, you may need this older port: http://www.cpan.org/ports/#os400 Note that any Perl release later than 5.00502 has not been ported to ILE.

If you need to use Perl in the ILE environment, you may want to consider using Qp2RunPase() to call the PASE version of Perl.

Chapter 120

perlplan9

Plan 9-specific documentation for Perl

120.1 DESCRIPTION

These are a few notes describing features peculiar to Plan 9 Perl. As such, it is not intended to be a replacement for the rest of the Perl 5 documentation (which is both copious and excellent). If you have any questions to which you can't find answers in these man pages, contact Luther Huffman at lutherh@stratcom.com and we'll try to answer them.

120.1.1 Invoking Perl

Perl is invoked from the command line as described in *perl*. Most perl scripts, however, do have a first line such as "#!/usr/local/bin/perl". This is known as a shebang (shell-bang) statement and tells the OS shell where to find the perl interpreter. In Plan 9 Perl this statement should be "#!/bin/perl" if you wish to be able to directly invoke the script by its name. Alternatively, you may invoke perl with the command "Perl" instead of "perl". This will produce Acme-friendly error messages of the form "filename:18".
Some scripts, usually identified with a *.PL extension, are self-configuring and are able to correctly create their own shebang path from config information located in Plan 9 Perl. These you won't need to be worried about.

120.1.2 What's in Plan 9 Perl

Although Plan 9 Perl currently only provides static loading, it is built with a number of useful extensions. These include Opcode, FileHandle, Fcntl, and POSIX. Expect to see others (and DynaLoading!) in the future.

120.1.3 What's not in Plan 9 Perl

As mentioned previously, dynamic loading isn't currently available nor is MakeMaker. Both are high-priority items.

120.1.4 Perl5 Functions not currently supported in Plan 9 Perl

Some, such as `chown` and `umask` aren't provided because the concept does not exist within Plan 9. Others, such as some of the socket-related functions, simply haven't been written yet. Many in the latter category may be supported in the future.
The functions not currently implemented include:

```
    chown, chroot, dbmclose, dbmopen, getsockopt,
    setsockopt, recvmsg, sendmsg, getnetbyname,
    getnetbyaddr, getnetent, getprotoent, getservent,
    sethostent, setnetent, setprotoent, setservent,
    endservent, endnetent, endprotoent, umask
```

There may be several other functions that have undefined behavior so this list shouldn't be considered complete.

120.1.5 Signals in Plan 9 Perl

For compatibility with perl scripts written for the Unix environment, Plan 9 Perl uses the POSIX signal emulation provided in Plan 9's ANSI POSIX Environment (APE). Signal stacking isn't supported. The signals provided are:

```
    SIGHUP, SIGINT, SIGQUIT, SIGILL, SIGABRT,
    SIGFPE, SIGKILL, SIGSEGV, SIGPIPE, SIGPIPE, SIGALRM,
    SIGTERM, SIGUSR1, SIGUSR2, SIGCHLD, SIGCONT,
    SIGSTOP, SIGTSTP, SIGTTIN, SIGTTOU
```

120.2 COMPILING AND INSTALLING PERL ON PLAN 9

WELCOME to Plan 9 Perl, brave soul!

```
   This is a preliminary alpha version of Plan 9 Perl. Still to be
implemented are MakeMaker and DynaLoader. Many perl commands are
missing or currently behave in an inscrutable manner. These gaps will,
with perseverance and a modicum of luck, be remedied in the near
future.To install this software:
```

1. Create the source directories and libraries for perl by running the plan9/setup.rc command (i.e., located in the plan9 subdirectory). Note: the setup routine assumes that you haven't dearchived these files into /sys/src/cmd/perl. After running setup.rc you may delete the copy of the source you originally detarred, as source code has now been installed in /sys/src/cmd/perl. If you plan on installing perl binaries for all architectures, run "setup.rc -a".
2. After making sure that you have adequate privileges to build system software, from /sys/src/cmd/perl/5.00301 (adjust version appropriately) run:

```
        mk install
```

If you wish to install perl versions for all architectures (68020, mips, sparc and 386) run:

```
        mk installall
```

3. Wait. The build process will take a *long* time because perl bootstraps itself. A 75MHz Pentium, 16MB RAM machine takes roughly 30 minutes to build the distribution from scratch.

120.2.1 Installing Perl Documentation on Plan 9

This perl distribution comes with a tremendous amount of documentation. To add these to the built-in manuals that come with Plan 9, from /sys/src/cmd/perl/5.00301 (adjust version appropriately) run:

```
        mk man
```

To begin your reading, start with:

```
        man perl
```

This is a good introduction and will direct you towards other man pages that may interest you.

(Note: "mk man" may produce some extraneous noise. Fear not.)

120.3 BUGS

"As many as there are grains of sand on all the beaches of the world . . ." - Carl Sagan

120.4 Revision date

This document was revised 09-October-1996 for Perl 5.003_7.

Chapter 121

README.qnx

Perl version 5 on QNX

121.1 DESCRIPTION

As of perl5.7.2 all tests pass under:

```
  QNX 4.24G
  Watcom 10.6 with Beta/970211.wcc.update.tar.F
  socket3r.lib Nov21 1996.
```

As of perl5.8.1 there is at least one test still failing.
Some tests may complain under known circumstances.
See below and hints/qnx.sh for more information.
Under QNX 6.2.0 there are still a few tests which fail. See below and hints/qnx.sh for more information.

121.1.1 Required Software for Compiling Perl on QNX4

As with many unix ports, this one depends on a few "standard" unix utilities which are not necessarily standard for QNX4.

/bin/sh
: This is used heavily by Configure and then by perl itself. QNX4's version is fine, but Configure will choke on the 16-bit version, so if you are running QNX 4.22, link /bin/sh to /bin32/ksh

ar
: This is the standard unix library builder. We use wlib. With Watcom 10.6, when wlib is linked as "ar", it behaves like ar and all is fine. Under 9.5, a cover is required. One is included in ../qnx

nm
: This is used (optionally) by configure to list the contents of libraries. I will generate a cover function on the fly in the UU directory.

cpp
: Configure and perl need a way to invoke a C preprocessor. I have created a simple cover for cc which does the right thing. Without this, Configure will create its own wrapper which works, but it doesn't handle some of the command line arguments that perl will throw at it.

make
: You really need GNU make to compile this. GNU make ships by default with QNX 4.23, but you can get it from quics for earlier versions.

121.1.2 Outstanding Issues with Perl on QNX4

There is no support for dynamically linked libraries in QNX4.

If you wish to compile with the Socket extension, you need to have the TCP/IP toolkit, and you need to make sure that -lsocket locates the correct copy of socket3r.lib. Beware that the Watcom compiler ships with a stub version of socket3r.lib which has very little functionality. Also beware the order in which wlink searches directories for libraries. You may have /usr/lib/socket3r.lib pointing to the correct library, but wlink may pick up /usr/watcom/10.6/usr/lib/socket3r.lib instead. Make sure they both point to the correct library, that is, /usr/tcptk/current/usr/lib/socket3r.lib.

The following tests may report errors under QNX4:

ext/Cwd/Cwd.t will complain if ‘pwd‘ and cwd don’t give the same results. cwd calls ‘fullpath -t‘, so if you cd ‘fullpath -t‘ before running the test, it will pass.

lib/File/Find/taint.t will complain if ’.’ is in your PATH. The PATH test is triggered because cwd calls ‘fullpath -t‘.

ext/IO/lib/IO/t/io_sock.t: Subtests 14 and 22 are skipped due to the fact that the functionality to read back the non-blocking status of a socket is not implemented in QNX’s TCP/IP. This has been reported to QNX and it may work with later versions of TCP/IP.

t/io/tell.t: Subtest 27 is failing. We are still investigating.

121.1.3 QNX auxiliary files

The files in the "qnx" directory are:

qnx/ar

A script that emulates the standard unix archive (aka library) utility. Under Watcom 10.6, ar is linked to wlib and provides the expected interface. With Watcom 9.5, a cover function is required. This one is fairly crude but has proved adequate for compiling perl.

qnx/cpp

A script that provides C preprocessing functionality. Configure can generate a similar cover, but it doesn’t handle all the command-line options that perl throws at it. This might be reasonably placed in /usr/local/bin.

121.1.4 Outstanding issues with perl under QNX6

The following tests are still failing for Perl 5.8.1 under QNX 6.2.0:

```
  op/sprintf.........................FAILED at test 91
  lib/Benchmark......................FAILED at test 26
```

This is due to a bug in the C library’s printf routine. printf("’%e’", 0.) produces ’0.000000e+0’, but ANSI requires ’0.000000e+00’. QNX has acknowledged the bug.

Chapter 122

README.solaris

Perl version 5 on Solaris systems

122.1 DESCRIPTION

This document describes various features of Sun's Solaris operating system that will affect how Perl version 5 (hereafter just perl) is compiled and/or runs. Some issues relating to the older SunOS 4.x are also discussed, though they may be out of date.

For the most part, everything should just work.

Starting with Solaris 8, perl5.00503 (or higher) is supplied with the operating system, so you might not even need to build a newer version of perl at all. The Sun-supplied version is installed in /usr/perl5 with /usr/bin/perl pointing to /usr/perl5/bin/perl. Do not disturb that installation unless you really know what you are doing. If you remove the perl supplied with the OS, you will render some bits of your system inoperable. If you wish to install a newer version of perl, install it under a different prefix from /usr/perl5. Common prefixes to use are /usr/local and /opt/perl.

You may wish to put your version of perl in the PATH of all users by changing the link /usr/bin/perl. This is OK, as all perl scripts shipped with Solaris use an explicit path. Solaris ships with a range of Solaris-specific modules. If you choose to install your own version of perl you will find the source of many of these modules is available on CPAN under the Sun::Solaris:: namespace.

Solaris may include two versions of perl, e.g. Solaris 9 includes both 5.005_03 and 5.6.1. This is to provide stability across Solaris releases, in cases where a later perl version has incompatibilities with the version included in the preceeding Solaris release. The default perl version will always be the most recent, and in general the old version will only be retained for one Solaris release. Note also that the default perl will NOT be configured to search for modules in the older version, again due to compatibility/stability concerns. As a consequence if you upgrade Solaris, you will have to rebuild/reinstall any additional CPAN modules that you installed for the previous Solaris version. See the CPAN manpage under 'autobundle' for a quick way of doing this.

As an interim measure, you may either change the #! line of your scripts to specifically refer to the old perl version, e.g. on Solaris 9 use #!/usr/perl5/5.00503/bin/perl to use the perl version that was the default for Solaris 8, or if you have a large number of scripts it may be more convenient to make the old version of perl the default on your system. You can do this by changing the appropriate symlinks under /usr/perl5 as follows (example for Solaris 9):

```
# cd /usr/perl5
# rm bin man pod
# ln -s ./5.00503/bin
# ln -s ./5.00503/man
# ln -s ./5.00503/lib/pod
# rm /usr/bin/perl
# ln -s ../perl5/5.00503/bin/perl /usr/bin/perl
```

In both cases this should only be considered to be a temporary measure - you should upgrade to the later version of perl as soon as is practicable.

Note also that the perl command-line utilities (e.g. perldoc) and any that are added by modules that you install will be under /usr/perl5/bin, so that directory should be added to your PATH.

122.1.1 Solaris Version Numbers.

For consistency with common usage, perl's Configure script performs some minor manipulations on the operating system name and version number as reported by uname. Here's a partial translation table:

```
         Sun:                      perl's Configure:
 uname    uname -r   Name          osname     osvers
 SunOS    4.1.3     Solaris 1.1    sunos      4.1.3
 SunOS    5.6       Solaris 2.6    solaris    2.6
 SunOS    5.8       Solaris 8      solaris    2.8
 SunOS    5.9       Solaris 9      solaris    2.9
 SunOS    5.10      Solaris 10     solaris    2.10
```

The complete table can be found in the Sun Managers' FAQ ftp://ftp.cs.toronto.edu/pub/jdd/sunmanagers/faq under "9.1) Which Sun models run which versions of SunOS?".

122.2 RESOURCES

There are many, many sources for Solaris information. A few of the important ones for perl:

Solaris FAQ

The Solaris FAQ is available at http://www.science.uva.nl/pub/solaris/solaris2.html.

The Sun Managers' FAQ is available at ftp://ftp.cs.toronto.edu/pub/jdd/sunmanagers/faq

Precompiled Binaries

Precompiled binaries, links to many sites, and much, much more are available at http://www.sunfreeware.com/ and http://www.blastwave.org/.

Solaris Documentation

All Solaris documentation is available on-line at http://docs.sun.com/.

122.3 SETTING UP

122.3.1 File Extraction Problems on Solaris.

Be sure to use a tar program compiled under Solaris (not SunOS 4.x) to extract the perl-5.x.x.tar.gz file. Do not use GNU tar compiled for SunOS4 on Solaris. (GNU tar compiled for Solaris should be fine.) When you run SunOS4 binaries on Solaris, the run-time system magically alters pathnames matching m#lib/locale# so that when tar tries to create lib/locale.pm, a file named lib/oldlocale.pm gets created instead. If you found this advice too late and used a SunOS4-compiled tar anyway, you must find the incorrectly renamed file and move it back to lib/locale.pm.

122.3.2 Compiler and Related Tools on Solaris.

You must use an ANSI C compiler to build perl. Perl can be compiled with either Sun's add-on C compiler or with gcc. The C compiler that shipped with SunOS4 will not do.

Include /usr/ccs/bin/ in your PATH.

Several tools needed to build perl are located in /usr/ccs/bin/: ar, as, ld, and make. Make sure that /usr/ccs/bin/ is in your PATH.

You need to make sure the following packages are installed (this info is extracted from the Solaris FAQ):

for tools (sccs, lex, yacc, make, nm, truss, ld, as): SUNWbtool, SUNWsprot, SUNWtoo

for libraries & headers: SUNWhea, SUNWarc, SUNWlibm, SUNWlibms, SUNWdfbh, SUNWcg6h, SUNWxwinc, SUNWolinc

for 64 bit development: SUNWarcx, SUNWbtoox, SUNWdplx, SUNWscpux, SUNWsprox, SUNWtoox, SUNWlmsx, SUNWlmx, SUNWlibCx

If you are in doubt which package contains a file you are missing, try to find an installation that has that file. Then do a

```
 $ grep /my/missing/file /var/sadm/install/contents
```

This will display a line like this:

/usr/include/sys/errno.h f none 0644 root bin 7471 37605 956241356 SUNWhea

The last item listed (SUNWhea in this example) is the package you need.

Avoid /usr/ucb/cc.

You don't need to have /usr/ucb/ in your PATH to build perl. If you want /usr/ucb/ in your PATH anyway, make sure that /usr/ucb/ is NOT in your PATH before the directory containing the right C compiler.

Sun's C Compiler

If you use Sun's C compiler, make sure the correct directory (usually /opt/SUNWspro/bin/) is in your PATH (before /usr/ucb/).

GCC

If you use gcc, make sure your installation is recent and complete. perl versions since 5.6.0 build fine with gcc > 2.8.1 on Solaris >= 2.6.

You must Configure perl with

```
 $ sh Configure -Dcc=gcc
```

If you don't, you may experience strange build errors.

If you have updated your Solaris version, you may also have to update your gcc. For example, if you are running Solaris 2.6 and your gcc is installed under /usr/local, check in /usr/local/lib/gcc-lib and make sure you have the appropriate directory, sparc-sun-solaris2.6/ or i386-pc-solaris2.6/. If gcc's directory is for a different version of Solaris than you are running, then you will need to rebuild gcc for your new version of Solaris.

You can get a precompiled version of gcc from http://www.sunfreeware.com/ or http://www.blastwave.org/. Make sure you pick up the package for your Solaris release.

If you wish to use gcc to build add-on modules for use with the perl shipped with Solaris, you should use the Solaris::PerlGcc module which is available from CPAN. The perl shipped with Solaris is configured and built with the Sun compilers, and the compiler configuration information stored in Config.pm is therefore only relevant to the Sun compilers. The Solaris:PerlGcc module contains a replacement Config.pm that is correct for gcc - see the module for details.

GNU as and GNU ld

The following information applies to gcc version 2. Volunteers to update it as appropropriate for gcc version 3 would be appreciated.

The versions of as and ld supplied with Solaris work fine for building perl. There is normally no need to install the GNU versions to compile perl.

If you decide to ignore this advice and use the GNU versions anyway, then be sure that they are relatively recent. Versions newer than 2.7 are apparently new enough. Older versions may have trouble with dynamic loading.

If you wish to use GNU ld, then you need to pass it the -Wl,-E flag. The hints/solaris_2.sh file tries to do this automatically by setting the following Configure variables:

```
ccdlflags="$ccdlflags -Wl,-E"
lddlflags="$lddlflags -Wl,-E -G"
```

However, over the years, changes in gcc, GNU ld, and Solaris ld have made it difficult to automatically detect which ld ultimately gets called. You may have to manually edit config.sh and add the -Wl,-E flags yourself, or else run Configure interactively and add the flags at the appropriate prompts.

If your gcc is configured to use GNU as and ld but you want to use the Solaris ones instead to build perl, then you'll need to add -B/usr/ccs/bin/ to the gcc command line. One convenient way to do that is with

```
$ sh Configure -Dcc='gcc -B/usr/ccs/bin/'
```

Note that the trailing slash is required. This will result in some harmless warnings as Configure is run:

```
gcc: file path prefix `/usr/ccs/bin/' never used
```

These messages may safely be ignored. (Note that for a SunOS4 system, you must use -B/bin/ instead.)

Alternatively, you can use the GCC_EXEC_PREFIX environment variable to ensure that Sun's as and ld are used. Consult your gcc documentation for further information on the -B option and the GCC_EXEC_PREFIX variable.

Sun and GNU make

The make under /usr/ccs/bin works fine for building perl. If you have the Sun C compilers, you will also have a parallel version of make (dmake). This works fine to build perl, but can sometimes cause problems when running 'make test' due to underspecified dependencies between the different test harness files. The same problem can also affect the building of some add-on modules, so in those cases either specify '-m serial' on the dmake command line, or use /usr/ccs/bin/make instead. If you wish to use GNU make, be sure that the set-group-id bit is not set. If it is, then arrange your PATH so that /usr/ccs/bin/make is before GNU make or else have the system administrator disable the set-group-id bit on GNU make.

Avoid libucb.

Solaris provides some BSD-compatibility functions in /usr/ucblib/libucb.a. Perl will not build and run correctly if linked against -lucb since it contains routines that are incompatible with the standard Solaris libc. Normally this is not a problem since the solaris hints file prevents Configure from even looking in /usr/ucblib for libraries, and also explicitly omits -lucb.

122.3.3 Environment for Compiling perl on Solaris

PATH

Make sure your PATH includes the compiler (/opt/SUNWspro/bin/ if you're using Sun's compiler) as well as /usr/ccs/bin/ to pick up the other development tools (such as make, ar, as, and ld). Make sure your path either doesn't include /usr/ucb or that it includes it after the compiler and compiler tools and other standard Solaris directories. You definitely don't want /usr/ucb/cc.

LD_LIBRARY_PATH

If you have the LD_LIBRARY_PATH environment variable set, be sure that it does NOT include /lib or /usr/lib. If you will be building extensions that call third-party shared libraries (e.g. Berkeley DB) then make sure that your LD_LIBRARY_PATH environment variable includes the directory with that library (e.g. /usr/local/lib).

If you get an error message

```
 dlopen: stub interception failed
```

it is probably because your LD_LIBRARY_PATH environment variable includes a directory which is a symlink to /usr/lib (such as /lib). The reason this causes a problem is quite subtle. The file libdl.so.1.0 actually *only* contains functions which generate 'stub interception failed' errors! The runtime linker intercepts links to "/usr/lib/libdl.so.1.0" and links in internal implementations of those functions instead. [Thanks to Tim Bunce for this explanation.]

122.4 RUN CONFIGURE.

See the INSTALL file for general information regarding Configure. Only Solaris-specific issues are discussed here. Usually, the defaults should be fine.

122.4.1 64-bit perl on Solaris.

See the INSTALL file for general information regarding 64-bit compiles. In general, the defaults should be fine for most people.

By default, perl-5.6.0 (or later) is compiled as a 32-bit application with largefile and long-long support.

General 32-bit vs. 64-bit issues.

Solaris 7 and above will run in either 32 bit or 64 bit mode on SPARC CPUs, via a reboot. You can build 64 bit apps whilst running 32 bit mode and vice-versa. 32 bit apps will run under Solaris running in either 32 or 64 bit mode. 64 bit apps require Solaris to be running 64 bit mode.

Existing 32 bit apps are properly known as LP32, i.e. Longs and Pointers are 32 bit. 64-bit apps are more properly known as LP64. The discriminating feature of a LP64 bit app is its ability to utilise a 64-bit address space. It is perfectly possible to have a LP32 bit app that supports both 64-bit integers (long long) and largefiles (> 2GB), and this is the default for perl-5.6.0.

For a more complete explanation of 64-bit issues, see the "Solaris 64-bit Developer's Guide" at http://docs.sun.com/

You can detect the OS mode using "isainfo -v", e.g.

```
 $ isainfo -v   # Ultra 30 in 64 bit mode
 64-bit sparcv9 applications
 32-bit sparc applications
```

By default, perl will be compiled as a 32-bit application. Unless you want to allocate more than ˜ 4GB of memory inside perl, or unless you need more than 255 open file descriptors, you probably don't need perl to be a 64-bit app.

Large File Support

For Solaris 2.6 and onwards, there are two different ways for 32-bit applications to manipulate large files (files whose size is > 2GByte). (A 64-bit application automatically has largefile support built in by default.)

First is the "transitional compilation environment", described in lfcompile64(5). According to the man page,

```
 The transitional compilation  environment  exports  all  the
 explicit 64-bit functions (xxx64()) and types in addition to
 all the regular functions (xxx()) and types. Both xxx()  and
 xxx64()  functions  are  available to the program source.  A
 32-bit application must use the xxx64() functions in  order
 to  access  large  files.  See the lf64(5) manual page for a
 complete listing of the 64-bit transitional interfaces.
```

The transitional compilation environment is obtained with the following compiler and linker flags:

```
 getconf LFS64_CFLAGS        -D_LARGEFILE64_SOURCE
 getconf LFS64_LDFLAG        # nothing special needed
 getconf LFS64_LIBS          # nothing special needed
```

Second is the "large file compilation environment", described in lfcompile(5). According to the man page,

```
 Each interface named xxx() that needs to access 64-bit entities
 to  access  large  files maps to a xxx64() call in the
 resulting binary. All relevant data types are defined to  be
 of correct size (for example, off_t has a typedef definition
 for a 64-bit entity).

 An application compiled in this environment is able  to  use
 the  xxx()  source interfaces to access both large and small
 files, rather than having to explicitly utilize the  transitional
 xxx64()  interface  calls to access large files.
```

Two exceptions are fseek() and ftell(). 32-bit applications should use fseeko(3C) and ftello(3C). These will get automatically mapped to fseeko64() and ftello64().

The large file compilation environment is obtained with

```
 getconf LFS_CFLAGS      -D_LARGEFILE_SOURCE -D_FILE_OFFSET_BITS=64
 getconf LFS_LDFLAGS     # nothing special needed
 getconf LFS_LIBS        # nothing special needed
```

By default, perl uses the large file compilation environment and relies on Solaris to do the underlying mapping of interfaces.

Building an LP64 perl

To compile a 64-bit application on an UltraSparc with a recent Sun Compiler, you need to use the flag "-xarch=v9". getconf(1) will tell you this, e.g.

```
 $ getconf -a | grep v9
 XBS5_LP64_OFF64_CFLAGS:         -xarch=v9
 XBS5_LP64_OFF64_LDFLAGS:        -xarch=v9
 XBS5_LP64_OFF64_LINTFLAGS:      -xarch=v9
 XBS5_LPBIG_OFFBIG_CFLAGS:       -xarch=v9
 XBS5_LPBIG_OFFBIG_LDFLAGS:      -xarch=v9
 XBS5_LPBIG_OFFBIG_LINTFLAGS:    -xarch=v9
 _XBS5_LP64_OFF64_CFLAGS:        -xarch=v9
 _XBS5_LP64_OFF64_LDFLAGS:       -xarch=v9
 _XBS5_LP64_OFF64_LINTFLAGS:     -xarch=v9
 _XBS5_LPBIG_OFFBIG_CFLAGS:      -xarch=v9
 _XBS5_LPBIG_OFFBIG_LDFLAGS:     -xarch=v9
 _XBS5_LPBIG_OFFBIG_LINTFLAGS:   -xarch=v9
```

This flag is supported in Sun WorkShop Compilers 5.0 and onwards (now marketed under the name Forte) when used on Solaris 7 or later on UltraSparc systems.

If you are using gcc, you would need to use -mcpu=v9 -m64 instead. This option is not yet supported as of gcc 2.95.2; from install/SPECIFIC in that release:

```
GCC version 2.95 is not able to compile code correctly for sparc64
targets. Users of the Linux kernel, at least, can use the sparc32
program to start up a new shell invocation with an environment that
causes configure to recognize (via uname -a) the system as sparc-*-*
instead.
```

All this should be handled automatically by the hints file, if requested.

Long Doubles.

As of 5.8.1, long doubles are working if you use the Sun compilers (needed for additional math routines not included in libm).

122.4.2 Threads in perl on Solaris.

It is possible to build a threaded version of perl on Solaris. The entire perl thread implementation is still experimental, however, so beware.

122.4.3 Malloc Issues with perl on Solaris.

Starting from perl 5.7.1 perl uses the Solaris malloc, since the perl malloc breaks when dealing with more than 2GB of memory, and the Solaris malloc also seems to be faster.

If you for some reason (such as binary backward compatibility) really need to use perl's malloc, you can rebuild perl from the sources and Configure the build with

```
$ sh Configure -Dusemymalloc
```

You should not use perl's malloc if you are building with gcc. There are reports of core dumps, especially in the PDL module. The problem appears to go away under -DDEBUGGING, so it has been difficult to track down. Sun's compiler appears to be okay with or without perl's malloc. [XXX further investigation is needed here.]

122.5 MAKE PROBLEMS.

Dynamic Loading Problems With GNU as and GNU ld

If you have problems with dynamic loading using gcc on SunOS or Solaris, and you are using GNU as and GNU ld, see the section §122.3.2 above.

ld.so.1: ./perl: fatal: relocation error:

If you get this message on SunOS or Solaris, and you're using gcc, it's probably the GNU as or GNU ld problem in the previous item §122.3.2.

dlopen: stub interception failed

The primary cause of the 'dlopen: stub interception failed' message is that the LD_LIBRARY_PATH environment variable includes a directory which is a symlink to /usr/lib (such as /lib). See §122.3.3 above.

#error "No DATAMODEL_NATIVE specified"

This is a common error when trying to build perl on Solaris 2.6 with a gcc installation from Solaris 2.5 or 2.5.1. The Solaris header files changed, so you need to update your gcc installation. You can either rerun the fixincludes script from gcc or take the opportunity to update your gcc installation.

sh: ar: not found

This is a message from your shell telling you that the command ’ar’ was not found. You need to check your PATH environment variable to make sure that it includes the directory with the ’ar’ command. This is a common problem on Solaris, where ’ar’ is in the /usr/ccs/bin/ directory.

122.6 MAKE TEST

122.6.1 op/stat.t test 4 in Solaris

op/stat.t test 4 may fail if you are on a tmpfs of some sort. Building in /tmp sometimes shows this behavior. The test suite detects if you are building in /tmp, but it may not be able to catch all tmpfs situations.

122.6.2 nss_delete core dump from op/pwent or op/grent

See nss_delete core dump from op/pwent or op/grent in *perlhpux*.

122.7 PREBUILT BINARIES OF PERL FOR SOLARIS.

You can pick up prebuilt binaries for Solaris from http://www.sunfreeware.com/, http://www.blastwave.org, ActiveState http://www.activestate.com/, and http://www.perl.com/ under the Binaries list at the top of the page. There are probably other sources as well. Please note that these sites are under the control of their respective owners, not the perl developers.

122.8 RUNTIME ISSUES FOR PERL ON SOLARIS.

122.8.1 Limits on Numbers of Open Files on Solaris.

The stdio(3C) manpage notes that for LP32 applications, only 255 files may be opened using fopen(), and only file descriptors 0 through 255 can be used in a stream. Since perl calls open() and then fdopen(3C) with the resulting file descriptor, perl is limited to 255 simultaneous open files, even if sysopen() is used. If this proves to be an insurmountable problem, you can compile perl as a LP64 application, see Building an LP64 perl for details. Note also that the default resource limit for open file descriptors on Solaris is 255, so you will have to modify your ulimit or rctl (Solaris 9 onwards) appropriately.

122.9 SOLARIS-SPECIFIC MODULES.

See the modules under the Solaris:: and Sun::Solaris namespaces on CPAN, see http://www.cpan.org/modules/by-module/Solaris/ and http://www.cpan.org/modules/by-module/Sun/.

122.10 SOLARIS-SPECIFIC PROBLEMS WITH MODULES.

122.10.1 Proc::ProcessTable on Solaris

Proc::ProcessTable does not compile on Solaris with perl5.6.0 and higher if you have LARGEFILES defined. Since largefile support is the default in 5.6.0 and later, you have to take special steps to use this module.

The problem is that various structures visible via procfs use off_t, and if you compile with largefile support these change from 32 bits to 64 bits. Thus what you get back from procfs doesn’t match up with the structures in perl, resulting in garbage. See proc(4) for further discussion.

A fix for Proc::ProcessTable is to edit Makefile to explicitly remove the largefile flags from the ones MakeMaker picks up from Config.pm. This will result in Proc::ProcessTable being built under the correct environment. Everything should then be OK as long as Proc::ProcessTable doesn’t try to share off_t’s with the rest of perl, or if it does they should be explicitly specified as off64_t.

122.10.2 BSD::Resource on Solaris

BSD::Resource versions earlier than 1.09 do not compile on Solaris with perl 5.6.0 and higher, for the same reasons as Proc::ProcessTable. BSD::Resource versions starting from 1.09 have a workaround for the problem.

122.10.3 Net::SSLeay on Solaris

Net::SSLeay requires a /dev/urandom to be present. This device is available from Solaris 9 onwards. For earlier Solaris versions you can either get the package SUNWski (packaged with several Sun software products, for example the Sun WebServer, which is part of the Solaris Server Intranet Extension, or the Sun Directory Services, part of Solaris for ISPs) or download the ANDIrand package from http://www.cosy.sbg.ac.at/˜andi/. If you use SUNWski, make a symbolic link /dev/urandom pointing to /dev/random.

It may be possible to use the Entropy Gathering Daemon (written in Perl!), available from http://www.lothar.com/tech/crypto/.

122.11 SunOS 4.x

In SunOS 4.x you most probably want to use the SunOS ld, /usr/bin/ld, since the more recent versions of GNU ld (like 2.13) do not seem to work for building Perl anymore. When linking the extensions, the GNU ld gets very unhappy and spews a lot of errors like this

```
  ... relocation truncated to fit: BASE13 ...
```

and dies. Therefore the SunOS 4.1 hints file explicitly sets the ld to be /usr/bin/ld.

As of Perl 5.8.1 the dynamic loading of libraries (DynaLoader, XSLoader) also seems to have become broken in in SunOS 4.x. Therefore the default is to build Perl statically.

Running the test suite in SunOS 4.1 is a bit tricky since the *lib/Tie/File/t/09_gen_rs* test hangs (subtest #51, FWIW) for some unknown reason. Just stop the test and kill that particular Perl process.

There are various other failures, that as of SunOS 4.1.4 and gcc 3.2.2 look a lot like gcc bugs. Many of the failures happen in the Encode tests, where for example when the test expects "0" you get "&#48;" which should after a little squinting look very odd indeed. Another example is earlier in *t/run/fresh_perl* where chr(0xff) is expected but the test fails because the result is chr(0xff). Exactly.

This is the "make test" result from the said combination:

```
  Failed 27 test scripts out of 745, 96.38% okay.
```

Running the `harness` is painful because of the many failing Unicode-related tests will output megabytes of failure messages, but if one patiently waits, one gets these results:

```
 Failed Test                     Stat Wstat Total Fail  Failed  List of Failed
 -----------------------------------------------------------------------------
 ...
 ../ext/Encode/t/at-cn.t            4  1024    29    4  13.79%  14-17

uni/tr_7jis.t                                ??   ??       %  ??
uni/tr_eucjp.t                   29  7424     6   12 200.00%  1-6
uni/tr_sjis.t                    29  7424     6   12 200.00%  1-6
56 tests and 467 subtests skipped.
Failed 27/811 test scripts, 96.67% okay. 1383/75399 subtests failed, 98.17% okay.
```

The alarm() test failure is caused by system() apparently blocking alarm(). That is probably a libc bug, and given that SunOS 4.x has been end-of-lifed years ago, don't hold your breath for a fix. In addition to that, don't try anything too Unicode-y, especially with Encode, and you should be fine in SunOS 4.x.

122.12 AUTHOR

The original was written by Andy Dougherty *doughera@lafayette.edu* drawing heavily on advice from Alan Burlison, Nick Ing-Simmons, Tim Bunce, and many other Solaris users over the years.

Chapter 123

perluts

Perl under UTS

123.1 SYNOPSIS

This document can be read *as is*: as *README.uts*, or you can read it after you build your package using "man perluts".

The purpose is to help you build Perl for UTS, which, if you follow these instructions, should be easy, and result in a solidly working installation.

123.2 DESCRIPTION

Perl 5.7.2 (Developmental) or Perl 5.8.x (forthcoming) for UTS

123.3 BUILDING PERL ON UTS

NOTE: Some sites have redefined the way uname works, and if yours does this, special steps must be taken so that Configure can recognize your system as a UTS system. To see if you are in this category, issue the command "uname -a". It should look something like:

```
  uts juno 4 4.4 9672 370
```

At any rate, the first field should be "uts". If this is not the case; supposing it is, say telcoUTS, create a script, uts/uname (i.e. uname, in the subdirectory "uts" of the main Perl source dir): # uname /usr/bin/uname "$@" | sed -e 's/^telcoUTS/uts/'

and when you execute Configure, do it as below, except for adding PATH=uts:$PATH as a prefix. I.e. do:

```
   PATH=uts:$PATH ./Configure ...
```

There is no need to do an interactive configure, just type

```
  ./Configure -de [-Dusedevel] [-Doptimize=-g ] 2>&1 | tee Conf.out
```

"-Dusedevel" may be required to configure Perl 5.7.2 non-interactively. Use -Doptimize=-g if you want to run Perl under sdb or gdb, OR if you want to be able to use the -D command line flags to perl, which are occasionally useful in debugging perl scripts.

In this and the following steps, the "2>&1 | tee XXX.out" records all output from the process, which will be useful if anything unexpected goes wrong.

Then do the compilation with

```
make 2>&1 | tee make.out
```

Finally, test using

```
make test 2>&1 | tee make-test.out
```

In the output, the only failures you should see should look like:

```
lib/Math/BigInt/t/bigfltpm.........Use of uninitialized value ...
FAILED at test 57
lib/Math/BigInt/t/bigintc..........ok
lib/Math/BigInt/t/bigintpm.........FAILED at test 204
lib/Math/BigInt/t/mbimbf...........Use of uninitialized value ...
Illegal division by zero at ../lib/Math/BigInt/Calc.pm line 314.
FAILED at test 71
lib/Math/Complex...................exp: OVERFLOW
FAILED at test 250
lib/Math/Trig......................exp: OVERFLOW
ok
lib/Memoize/t/array................ok
     ...
lib/Net/protoent...................ok
lib/Net/servent....................FAILED at test 0
```

This means that everything passes except for some problems in the packages "Math::BigInt", "Math::Complex", and "Math::Trig". The lib/Net/servent failure seems to be a bug in the test program. To confirm this, from the main Perl source dir, do:

```
LD_LIBRARY_PATH=‘pwd‘ ./perl -Ilib lib/Net/servent.t
```

and it should output

```
1..3
ok 1
ok 2
ok 3
```

123.4 Installing the built perl on UTS

Run the command "make install"

Chapter 124

README.vmesa

Building and installing Perl for VM/ESA.

124.1 SYNOPSIS

This document will help you Configure, build, test and install Perl on VM/ESA.

124.2 DESCRIPTION

This is a fully ported perl for VM/ESA 2.3.0. It may work on other versions, but that's the one we've tested it on.

If you've downloaded the binary distribution, it needs to be installed below /usr/local. Source code distributions have an automated ‘make install‘ step that means you do not need to extract the source code below /usr/local (though that is where it will be installed by default). You may need to worry about the networking configuration files discussed in the last bullet below.

124.2.1 Unpacking Perl Distribution on VM/ESA

To extract an ASCII tar archive on VM/ESA, try this:

```
   pax -o to=IBM-1047,from=ISO8859-1 -r < latest.tar
```

124.2.2 Setup Perl and utilities on VM/ESA

GNU make for VM/ESA, which may be required for the build of perl, is available from:

```
  http://vm.marist.edu/~neale/vmoe.html
```

124.2.3 Configure Perl on VM/ESA

Once you've unpacked the distribution, run Configure (see INSTALL for full discussion of the Configure options), and then run make, then "make test" then "make install" (this last step may require UID=0 privileges).

There is a "hints" file for vmesa that specifies the correct values for most things. Some things to watch out for are:

- this port does support dynamic loading but it's not had much testing
- Don't turn on the compiler optimization flag "-O". There's a bug in the compiler (APAR PQ18812) that generates some bad code the optimizer is on.

- As VM/ESA doesn't fully support the fork() API programs relying on this call will not work. I've replaced fork()/exec() with spawn() and the standalone exec() with spawn(). This has a side effect when opening unnamed pipes in a shell script: there is no child process generated under.
- At the moment the hints file for VM/ESA basically bypasses all of the automatic configuration process. This is because Configure relies on: 1. The header files living in the Byte File System (you could put the there if you want); 2. The C preprocessor including the #include statements in the preprocessor output (.i) file.

124.2.4 Testing Anomalies of Perl on VM/ESA

The 'make test' step runs a Perl Verification Procedure, usually before installation. As the 5.6.1 kit was being assembled the following "failures" were known to appear on some machines during 'make test' (mostly due to ASCII vs. EBCDIC conflicts), your results may differ:

[the list of failures being compiled]

124.2.5 Usage Hints for Perl on VM/ESA

When using perl on VM/ESA please keep in mind that the EBCDIC and ASCII character sets are different. Perl builtin functions that may behave differently under EBCDIC are mentioned in the perlport.pod document.

OpenEdition (UNIX System Services) does not (yet) support the #! means of script invocation. See:

```
    head `whence perldoc`
```

for an example of how to use the "eval exec" trick to ask the shell to have perl run your scripts for you.

```

Chapter 125

perlvms

VMS-specific documentation for Perl

125.1 DESCRIPTION

Gathered below are notes describing details of Perl 5's behavior on VMS. They are a supplement to the regular Perl 5 documentation, so we have focussed on the ways in which Perl 5 functions differently under VMS than it does under Unix, and on the interactions between Perl and the rest of the operating system. We haven't tried to duplicate complete descriptions of Perl features from the main Perl documentation, which can be found in the *[.pod]* subdirectory of the Perl distribution.

We hope these notes will save you from confusion and lost sleep when writing Perl scripts on VMS. If you find we've missed something you think should appear here, please don't hesitate to drop a line to vmsperl@perl.org.

125.2 Installation

Directions for building and installing Perl 5 can be found in the file *README.vms* in the main source directory of the Perl distribution..

125.3 Organization of Perl Images

125.3.1 Core Images

During the installation process, three Perl images are produced. *Miniperl.Exe* is an executable image which contains all of the basic functionality of Perl, but cannot take advantage of Perl extensions. It is used to generate several files needed to build the complete Perl and various extensions. Once you've finished installing Perl, you can delete this image.

Most of the complete Perl resides in the shareable image *PerlShr.Exe*, which provides a core to which the Perl executable image and all Perl extensions are linked. You should place this image in *Sys$ Share*, or define the logical name *PerlShr* to translate to the full file specification of this image. It should be world readable. (Remember that if a user has execute only access to *PerlShr*, VMS will treat it as if it were a privileged shareable image, and will therefore require all downstream shareable images to be INSTALLed, etc.)

Finally, *Perl.Exe* is an executable image containing the main entry point for Perl, as well as some initialization code. It should be placed in a public directory, and made world executable. In order to run Perl with command line arguments, you should define a foreign command to invoke this image.

125.3.2 Perl Extensions

Perl extensions are packages which provide both XS and Perl code to add new functionality to perl. (XS is a meta-language which simplifies writing C code which interacts with Perl, see *perlxs* for more details.) The Perl code for an extension is treated like any other library module - it's made available in your script through the appropriate `use` or `require` statement, and usually defines a Perl package containing the extension.

The portion of the extension provided by the XS code may be connected to the rest of Perl in either of two ways. In the **static** configuration, the object code for the extension is linked directly into *PerlShr.Exe*, and is initialized whenever Perl is invoked. In the **dynamic** configuration, the extension's machine code is placed into a separate shareable image, which is mapped by Perl's DynaLoader when the extension is `use`d or `require`d in your script. This allows you to maintain the extension as a separate entity, at the cost of keeping track of the additional shareable image. Most extensions can be set up as either static or dynamic.

The source code for an extension usually resides in its own directory. At least three files are generally provided: *Extshortname.xs* (where *Extshortname* is the portion of the extension's name following the last `::`), containing the XS code, *Extshortname.pm*, the Perl library module for the extension, and *Makefile.PL*, a Perl script which uses the `MakeMaker` library modules supplied with Perl to generate a *Descrip.MMS* file for the extension.

125.3.3 Installing static extensions

Since static extensions are incorporated directly into *PerlShr.Exe*, you'll have to rebuild Perl to incorporate a new extension. You should edit the main *Descrip.MMS* or *Makefile* you use to build Perl, adding the extension's name to the `ext` macro, and the extension's object file to the `extobj` macro. You'll also need to build the extension's object file, either by adding dependencies to the main *Descrip.MMS*, or using a separate *Descrip.MMS* for the extension. Then, rebuild *PerlShr.Exe* to incorporate the new code.

Finally, you'll need to copy the extension's Perl library module to the *[.Extname]* subdirectory under one of the directories in `@INC`, where *Extname* is the name of the extension, with all `::` replaced by `.` (e.g. the library module for extension Foo::Bar would be copied to a *[.Foo.Bar]* subdirectory).

125.3.4 Installing dynamic extensions

In general, the distributed kit for a Perl extension includes a file named Makefile.PL, which is a Perl program which is used to create a *Descrip.MMS* file which can be used to build and install the files required by the extension. The kit should be unpacked into a directory tree **not** under the main Perl source directory, and the procedure for building the extension is simply

```
    $ perl Makefile.PL  ! Create Descrip.MMS
    $ mmk               ! Build necessary files
    $ mmk test          ! Run test code, if supplied
    $ mmk install       ! Install into public Perl tree
```

N.B. The procedure by which extensions are built and tested creates several levels (at least 4) under the directory in which the extension's source files live. For this reason if you are runnning a version of VMS prior to V7.1 you shouldn't nest the source directory too deeply in your directory structure lest you exceed RMS' maximum of 8 levels of subdirectory in a filespec. (You can use rooted logical names to get another 8 levels of nesting, if you can't place the files near the top of the physical directory structure.)

VMS support for this process in the current release of Perl is sufficient to handle most extensions. However, it does not yet recognize extra libraries required to build shareable images which are part of an extension, so these must be added to the linker options file for the extension by hand. For instance, if the *PGPLOT* extension to Perl requires the *PGPLOTSHR.EXE* shareable image in order to properly link the Perl extension, then the line `PGPLOTSHR/Share` must be added to the linker options file *PGPLOT.Opt* produced during the build process for the Perl extension.

By default, the shareable image for an extension is placed in the *[.lib.site_perl.autoArch.Extname]* directory of the installed Perl directory tree (where *Arch* is *VMS_VAX* or *VMS_AXP*, and *Extname* is the name of the extension, with each `::` translated to `.`). (See the MakeMaker documentation for more details on installation options for extensions.) However, it can be manually placed in any of several locations:

- the *[.Lib.Auto.Arch$ PVersExtname]* subdirectory of one of the directories in `@INC` (where *PVers* is the version of Perl you're using, as supplied in `$]`, with '.' converted to '_'), or
- one of the directories in `@INC`, or
- a directory which the extensions Perl library module passes to the DynaLoader when asking it to map the shareable image, or
- *Sys$ Share* or *Sys$ Library*.

If the shareable image isn't in any of these places, you'll need to define a logical name *Extshortname*, where *Extshortname* is the portion of the extension's name after the last `::`, which translates to the full file specification of the shareable image.

125.4 File specifications

125.4.1 Syntax

We have tried to make Perl aware of both VMS-style and Unix- style file specifications wherever possible. You may use either style, or both, on the command line and in scripts, but you may not combine the two styles within a single file specification. VMS Perl interprets Unix pathnames in much the same way as the CRTL (*e.g.* the first component of an absolute path is read as the device name for the VMS file specification). There are a set of functions provided in the `VMS::Filespec` package for explicit interconversion between VMS and Unix syntax; its documentation provides more details.

Filenames are, of course, still case-insensitive. For consistency, most Perl routines return filespecs using lower case letters only, regardless of the case used in the arguments passed to them. (This is true only when running under VMS; Perl respects the case-sensitivity of OSs like Unix.)

We've tried to minimize the dependence of Perl library modules on Unix syntax, but you may find that some of these, as well as some scripts written for Unix systems, will require that you use Unix syntax, since they will assume that '/' is the directory separator, *etc.* If you find instances of this in the Perl distribution itself, please let us know, so we can try to work around them.

125.4.2 Wildcard expansion

File specifications containing wildcards are allowed both on the command line and within Perl globs (e.g. `<*.c>`). If the wildcard filespec uses VMS syntax, the resultant filespecs will follow VMS syntax; if a Unix-style filespec is passed in, Unix-style filespecs will be returned. Similar to the behavior of wildcard globbing for a Unix shell, one can escape command line wildcards with double quotation marks " around a perl program command line argument. However, owing to the stripping of " characters carried out by the C handling of argv you will need to escape a construct such as this one (in a directory containing the files *PERL.C*, *PERL.EXE*, *PERL.H*, and *PERL.OBJ*):

```
$ perl -e "print join(' ',@ARGV)" perl.*
perl.c perl.exe perl.h perl.obj
```

in the following triple quoted manner:

```
$ perl -e "print join(' ',@ARGV)" """perl.*"""
perl.*
```

In both the case of unquoted command line arguments or in calls to `glob()` VMS wildcard expansion is performed. (csh-style wildcard expansion is available if you use `File::Glob::glob`.) If the wildcard filespec contains a device or directory specification, then the resultant filespecs will also contain a device and directory; otherwise, device and directory information are removed. VMS-style resultant filespecs will contain a full device and directory, while Unix-style resultant filespecs will contain only as much of a directory path as was present in the input filespec. For example, if your default directory is Perl_Root:[000000], the expansion of `[.t]*.*` will yield filespecs like "perl_root:[t]base.dir", while the expansion of `t/*/*` will yield filespecs like "t/base.dir". (This is done to match the behavior of glob expansion performed by Unix shells.)

Similarly, the resultant filespec will contain the file version only if one was present in the input filespec.

125.4.3 Pipes

Input and output pipes to Perl filehandles are supported; the "file name" is passed to lib$spawn() for asynchronous execution. You should be careful to close any pipes you have opened in a Perl script, lest you leave any "orphaned" subprocesses around when Perl exits.

You may also use backticks to invoke a DCL subprocess, whose output is used as the return value of the expression. The string between the backticks is handled as if it were the argument to the `system` operator (see below). In this case, Perl will wait for the subprocess to complete before continuing.

The mailbox (MBX) that perl can create to communicate with a pipe defaults to a buffer size of 512. The default buffer size is adjustable via the logical name PERL_MBX_SIZE provided that the value falls between 128 and the SYSGEN parameter MAXBUF inclusive. For example, to double the MBX size from the default within a Perl program, use `$ENV{'PERL_MBX_SIZE'} = 1024;` and then open and use pipe constructs. An alternative would be to issue the command:

```
    $ Define PERL_MBX_SIZE 1024
```

before running your wide record pipe program. A larger value may improve performance at the expense of the BYTLM UAF quota.

125.5 PERL5LIB and PERLLIB

The PERL5LIB and PERLLIB logical names work as documented in *perl*, except that the element separator is '|' instead of ':'. The directory specifications may use either VMS or Unix syntax.

125.6 Command line

125.6.1 I/O redirection and backgrounding

Perl for VMS supports redirection of input and output on the command line, using a subset of Bourne shell syntax:

- `<file` reads stdin from `file`,
- `>file` writes stdout to `file`,
- `>>file` appends stdout to `file`,
- `2>file` writes stderr to `file`,
- `2>>file` appends stderr to `file`, and
- `2>&1` redirects stderr to stdout.

In addition, output may be piped to a subprocess, using the character '|'. Anything after this character on the command line is passed to a subprocess for execution; the subprocess takes the output of Perl as its input.

Finally, if the command line ends with '&', the entire command is run in the background as an asynchronous subprocess.

125.6.2 Command line switches

The following command line switches behave differently under VMS than described in *perlrun*. Note also that in order to pass uppercase switches to Perl, you need to enclose them in double-quotes on the command line, since the CRTL downcases all unquoted strings.

-i

If the `-i` switch is present but no extension for a backup copy is given, then inplace editing creates a new version of a file; the existing copy is not deleted. (Note that if an extension is given, an existing file is renamed to the backup file, as is the case under other operating systems, so it does not remain as a previous version under the original filename.)

-S

If the `"-S"` or `-"S"` switch is present *and* the script name does not contain a directory, then Perl translates the logical name DCL$PATH as a searchlist, using each translation as a directory in which to look for the script. In addition, if no file type is specified, Perl looks in each directory for a file matching the name specified, with a blank type, a type of *.pl*, and a type of *.com*, in that order.

-u

The `-u` switch causes the VMS debugger to be invoked after the Perl program is compiled, but before it has run. It does not create a core dump file.

125.7 Perl functions

As of the time this document was last revised, the following Perl functions were implemented in the VMS port of Perl (functions marked with * are discussed in more detail below):

```
file tests*, abs, alarm, atan, backticks*, binmode*, bless,
caller, chdir, chmod, chown, chomp, chop, chr,
close, closedir, cos, crypt*, defined, delete,
die, do, dump*, each, endpwent, eof, eval, exec*,
exists, exit, exp, fileno, getc, getlogin, getppid,
getpwent*, getpwnam*, getpwuid*, glob, gmtime*, goto,
grep, hex, import, index, int, join, keys, kill*,
last, lc, lcfirst, length, local, localtime, log, m//,
map, mkdir, my, next, no, oct, open, opendir, ord, pack,
pipe, pop, pos, print, printf, push, q//, qq//, qw//,
qx//*, quotemeta, rand, read, readdir, redo, ref, rename,
require, reset, return, reverse, rewinddir, rindex,
rmdir, s///, scalar, seek, seekdir, select(internal),
select (system call)*, setpwent, shift, sin, sleep,
sort, splice, split, sprintf, sqrt, srand, stat,
study, substr, sysread, system*, syswrite, tell,
telldir, tie, time, times*, tr///, uc, ucfirst, umask,
undef, unlink*, unpack, untie, unshift, use, utime*,
values, vec, wait, waitpid*, wantarray, warn, write, y///
```

The following functions were not implemented in the VMS port, and calling them produces a fatal error (usually) or undefined behavior (rarely, we hope):

```
chroot, dbmclose, dbmopen, flock, fork*,
getpgrp, getpriority, getgrent, getgrgid,
getgrnam, setgrent, endgrent, ioctl, link, lstat,
msgctl, msgget, msgsend, msgrcv, readlink, semctl,
semget, semop, setpgrp, setpriority, shmctl, shmget,
shmread, shmwrite, socketpair, symlink, syscall
```

The following functions are available on Perls compiled with Dec C 5.2 or greater and running VMS 7.0 or greater:

```
truncate
```

The following functions are available on Perls built on VMS 7.2 or greater:

```
fcntl (without locking)
```

The following functions may or may not be implemented, depending on what type of socket support you've built into your copy of Perl:

```
accept, bind, connect, getpeername,
gethostbyname, getnetbyname, getprotobyname,
getservbyname, gethostbyaddr, getnetbyaddr,
getprotobynumber, getservbyport, gethostent,
getnetent, getprotoent, getservent, sethostent,
setnetent, setprotoent, setservent, endhostent,
endnetent, endprotoent, endservent, getsockname,
getsockopt, listen, recv, select(system call)*,
send, setsockopt, shutdown, socket
```

File tests

The tests `-b`, `-B`, `-c`, `-C`, `-d`, `-e`, `-f`, `-o`, `-M`, `-s`, `-S`, `-t`, `-T`, and `-z` work as advertised. The return values for `-r`, `-w`, and `-x` tell you whether you can actually access the file; this may not reflect the UIC-based file protections. Since real and effective UIC don't differ under VMS, `-O`, `-R`, `-W`, and `-X` are equivalent to `-o`, `-r`, `-w`, and `-x`. Similarly, several other tests, including `-A`, `-g`, `-k`, `-l`, `-p`, and `-u`, aren't particularly meaningful under VMS, and the values returned by these tests reflect whatever your CRTL `stat()` routine does to the equivalent bits in the st_mode field. Finally, `-d` returns true if passed a device specification without an explicit directory (e.g. `DUA1:`), as well as if passed a directory.

Note: Some sites have reported problems when using the file-access tests (`-r`, `-w`, and `-x`) on files accessed via DEC's DFS. Specifically, since DFS does not currently provide access to the extended file header of files on remote volumes, attempts to examine the ACL fail, and the file tests will return false, with `$!` indicating that the file does not exist. You can use `stat` on these files, since that checks UIC-based protection only, and then manually check the appropriate bits, as defined by your C compiler's *stat.h*, in the mode value it returns, if you need an approximation of the file's protections.

backticks

Backticks create a subprocess, and pass the enclosed string to it for execution as a DCL command. Since the subprocess is created directly via `lib$spawn()`, any valid DCL command string may be specified.

binmode FILEHANDLE

The `binmode` operator will attempt to insure that no translation of carriage control occurs on input from or output to this filehandle. Since this involves reopening the file and then restoring its file position indicator, if this function returns FALSE, the underlying filehandle may no longer point to an open file, or may point to a different position in the file than before `binmode` was called.

Note that `binmode` is generally not necessary when using normal filehandles; it is provided so that you can control I/O to existing record-structured files when necessary. You can also use the `vmsfopen` function in the VMS::Stdio extension to gain finer control of I/O to files and devices with different record structures.

crypt PLAINTEXT, USER

The `crypt` operator uses the `sys$hash_password` system service to generate the hashed representation of PLAINTEXT. If USER is a valid username, the algorithm and salt values are taken from that user's UAF record. If it is not, then the preferred algorithm and a salt of 0 are used. The quadword encrypted value is returned as an 8-character string.

The value returned by `crypt` may be compared against the encrypted password from the UAF returned by the `getpw*` functions, in order to authenticate users. If you're going to do this, remember that the encrypted password in the UAF was generated using uppercase username and password strings; you'll have to upcase the arguments to `crypt` to insure that you'll get the proper value:

```
    sub validate_passwd {
        my($user,$passwd) = @_;
        my($pwdhash);
        if ( !($pwdhash = (getpwnam($user))[1]) ||
               $pwdhash ne crypt("\U$passwd","\U$name") ) {
            intruder_alert($name);
        }
        return 1;
    }
```

dump

Rather than causing Perl to abort and dump core, the `dump` operator invokes the VMS debugger. If you continue to execute the Perl program under the debugger, control will be transferred to the label specified as the argument to `dump`, or, if no label was specified, back to the beginning of the program. All other state of the program (*e.g.* values of variables, open file handles) are not affected by calling `dump`.

exec LIST

A call to `exec` will cause Perl to exit, and to invoke the command given as an argument to `exec` via `lib$do_command`. If the argument begins with '@' or '$' (other than as part of a filespec), then it is executed as a DCL command. Otherwise, the first token on the command line is treated as the filespec of an image to run, and an attempt is made to invoke it (using *.Exe* and the process defaults to expand the filespec) and pass the rest of `exec`'s argument to it as parameters. If the token has no file type, and matches a file with null type, then an attempt is made to determine whether the file is an executable image which should be invoked using `MCR` or a text file which should be passed to DCL as a command procedure.

fork

While in principle the `fork` operator could be implemented via (and with the same rather severe limitations as) the CRTL `vfork()` routine, and while some internal support to do just that is in place, the implementation has never been completed, making `fork` currently unavailable. A true kernel `fork()` is expected in a future version of VMS, and the pseudo-fork based on interpreter threads may be available in a future version of Perl on VMS (see *perlfork*). In the meantime, use `system`, backticks, or piped filehandles to create subprocesses.

getpwent

getpwnam

getpwuid

These operators obtain the information described in *perlfunc*, if you have the privileges necessary to retrieve the named user's UAF information via `sys$getuai`. If not, then only the `$name`, `$uid`, and `$gid` items are returned. The `$dir` item contains the login directory in VMS syntax, while the `$comment` item contains the login directory in Unix syntax. The `$gcos` item contains the owner field from the UAF record. The `$quota` item is not used.

gmtime

The `gmtime` operator will function properly if you have a working CRTL `gmtime()` routine, or if the logical name SYS$TIMEZONE_DIFFERENTIAL is defined as the number of seconds which must be added to UTC to yield local time. (This logical name is defined automatically if you are running a version of VMS with built-in UTC support.) If neither of these cases is true, a warning message is printed, and `undef` is returned.

kill

In most cases, `kill` is implemented via the CRTL's `kill()` function, so it will behave according to that function's documentation. If you send a SIGKILL, however, the $DELPRC system service is called directly. This insures that the target process is actually deleted, if at all possible. (The CRTL's `kill()` function is presently implemented via $FORCEX, which is ignored by supervisor-mode images like DCL.)

Also, negative signal values don't do anything special under VMS; they're just converted to the corresponding positive value.

qx//

See the entry on `backticks` above.

select (system call)

If Perl was not built with socket support, the system call version of `select` is not available at all. If socket support is present, then the system call version of `select` functions only for file descriptors attached to sockets. It will not provide information about regular files or pipes, since the CRTL `select()` routine does not provide this functionality.

stat EXPR

Since VMS keeps track of files according to a different scheme than Unix, it's not really possible to represent the file's ID in the `st_dev` and `st_ino` fields of a `struct stat`. Perl tries its best, though, and the values it uses are pretty unlikely to be the same for two different files. We can't guarantee this, though, so caveat scriptor.

system LIST

The `system` operator creates a subprocess, and passes its arguments to the subprocess for execution as a DCL command. Since the subprocess is created directly via `lib$spawn()`, any valid DCL command string may be specified. If the string begins with '@', it is treated as a DCL command unconditionally. Otherwise, if the first token contains a character used as a delimiter in file specification (e.g. `:` or `]`), an attempt is made to expand it using a default type of *.Exe* and the process defaults, and if successful, the resulting file is invoked via `MCR`. This allows you to invoke an image directly simply by passing the file specification to `system`, a common Unixish idiom. If the token has no file type, and matches a file with null type, then an attempt is made to determine whether the file is an executable image which should be invoked using `MCR` or a text file which should be passed to DCL as a command procedure.

If LIST consists of the empty string, `system` spawns an interactive DCL subprocess, in the same fashion as typing **SPAWN** at the DCL prompt.

Perl waits for the subprocess to complete before continuing execution in the current process. As described in *perlfunc*, the return value of `system` is a fake "status" which follows POSIX semantics unless the pragma `use vmsish 'status'` is in effect; see the description of `$?` in this document for more detail.

time

The value returned by `time` is the offset in seconds from 01-JAN-1970 00:00:00 (just like the CRTL's times() routine), in order to make life easier for code coming in from the POSIX/Unix world.

times

The array returned by the `times` operator is divided up according to the same rules the CRTL `times()` routine. Therefore, the "system time" elements will always be 0, since there is no difference between "user time" and "system" time under VMS, and the time accumulated by a subprocess may or may not appear separately in the "child time" field, depending on whether *times* keeps track of subprocesses separately. Note especially that the VAXCRTL (at least) keeps track only of subprocesses spawned using *fork* and *exec*; it will not accumulate the times of subprocesses spawned via pipes, *system*, or backticks.

unlink LIST

`unlink` will delete the highest version of a file only; in order to delete all versions, you need to say

```
    1 while unlink LIST;
```

You may need to make this change to scripts written for a Unix system which expect that after a call to `unlink`, no files with the names passed to `unlink` will exist. (Note: This can be changed at compile time; if you `use Config` and `$Config{'d_unlink_all_versions'}` is `define`, then `unlink` will delete all versions of a file on the first call.)

`unlink` will delete a file if at all possible, even if it requires changing file protection (though it won't try to change the protection of the parent directory). You can tell whether you've got explicit delete access to a file by using the `VMS::Filespec::candelete` operator. For instance, in order to delete only files to which you have delete access, you could say something like

```
    sub safe_unlink {
        my($file,$num);
        foreach $file (@_) {
            next unless VMS::Filespec::candelete($file);
            $num += unlink $file;
        }
        $num;
    }
```

(or you could just use `VMS::Stdio::remove`, if you've installed the VMS::Stdio extension distributed with Perl). If `unlink` has to change the file protection to delete the file, and you interrupt it in midstream, the file may be left intact, but with a changed ACL allowing you delete access.

utime LIST

Since ODS-2, the VMS file structure for disk files, does not keep track of access times, this operator changes only the modification time of the file (VMS revision date).

waitpid PID,FLAGS

If PID is a subprocess started by a piped `open()` (see *open*), `waitpid` will wait for that subprocess, and return its final status value in `$?`. If PID is a subprocess created in some other way (e.g. SPAWNed before Perl was invoked), `waitpid` will simply check once per second whether the process has completed, and return when it has. (If PID specifies a process that isn't a subprocess of the current process, and you invoked Perl with the `-w` switch, a warning will be issued.)

Returns PID on success, -1 on error. The FLAGS argument is ignored in all cases.

125.8 Perl variables

The following VMS-specific information applies to the indicated "special" Perl variables, in addition to the general information in *perlvar*. Where there is a conflict, this information takes precedence.

%ENV

The operation of the `%ENV` array depends on the translation of the logical name *PERL_ENV_TABLES*. If defined, it should be a search list, each element of which specifies a location for `%ENV` elements. If you tell Perl to read or set the element `$ENV{`*name*`}`, then Perl uses the translations of *PERL_ENV_TABLES* as follows:

CRTL_ENV

This string tells Perl to consult the CRTL's internal `environ` array of key-value pairs, using *name* as the key. In most cases, this contains only a few keys, but if Perl was invoked via the C `exec[lv]e()` function, as is the case for CGI processing by some HTTP servers, then the `environ` array may have been populated by the calling program.

CLISYM_[LOCAL]

A string beginning with `CLISYM_`tells Perl to consult the CLI's symbol tables, using *name* as the name of the symbol. When reading an element of `%ENV`, the local symbol table is scanned first, followed by the global symbol table.. The characters following `CLISYM_` are significant when an element of `%ENV` is set or deleted: if the complete string is `CLISYM_LOCAL`, the change is made in the local symbol table; otherwise the global symbol table is changed.

Any other string

If an element of *PERL_ENV_TABLES* translates to any other string, that string is used as the name of a logical name table, which is consulted using *name* as the logical name. The normal search order of access modes is used.

PERL_ENV_TABLES is translated once when Perl starts up; any changes you make while Perl is running do not affect the behavior of `%ENV`. If *PERL_ENV_TABLES* is not defined, then Perl defaults to consulting first the logical name tables specified by *LNM$ FILE_DEV*, and then the CRTL `environ` array.

In all operations on %ENV, the key string is treated as if it were entirely uppercase, regardless of the case actually specified in the Perl expression.

When an element of `%ENV` is read, the locations to which *PERL_ENV_TABLES* points are checked in order, and the value obtained from the first successful lookup is returned. If the name of the `%ENV` element contains a semi-colon, it and any characters after it are removed. These are ignored when the CRTL `environ` array or a CLI symbol table is consulted. However, the name is looked up in a logical name table, the suffix after the semi-colon is treated as the translation index to be used for the lookup. This lets you look up successive values for search list logical names. For instance, if you say

```
$  Define STORY  once,upon,a,time,there,was
$  perl -e "for ($i = 0; $i <= 6; $i++) " -
_$ -e "{ print $ENV{'story;'.$i},' '}"
```

Perl will print `ONCE UPON A TIME THERE WAS`, assuming, of course, that *PERL_ENV_TABLES* is set up so that the logical name `story` is found, rather than a CLI symbol or CRTL `environ` element with the same name.

When an element of `%ENV` is set to a defined string, the corresponding definition is made in the location to which the first translation of *PERL_ENV_TABLES* points. If this causes a logical name to be created, it is defined in supervisor mode. (The same is done if an existing logical name was defined in executive or kernel mode; an existing user or supervisor mode logical name is reset to the new value.) If the value is an empty string, the logical name's translation is defined as a single NUL (ASCII 00) character, since a logical name cannot translate to a zero-length string. (This restriction does not apply to CLI symbols or CRTL `environ` values; they are set to the empty string.) An element of the CRTL `environ` array can be set only if your copy of Perl knows about the CRTL's `setenv()` function. (This is present only in some versions of the DECCRTL; check `$Config{d_setenv}` to see whether your copy of Perl was built with a CRTL that has this function.)

When an element of `%ENV` is set to `undef`, the element is looked up as if it were being read, and if it is found, it is deleted. (An item "deleted" from the CRTL `environ` array is set to the empty string; this can only be done if your copy of Perl knows about the CRTL `setenv()` function.) Using `delete` to remove an element from `%ENV` has a similar effect, but after the element is deleted, another attempt is made to look up the element, so an inner-mode logical name or a name in another location will replace the logical name just deleted. In either case, only the first value found searching PERL_ENV_TABLES is altered. It is not possible at present to define a search list logical name via %ENV.

The element `$ENV{DEFAULT}` is special: when read, it returns Perl's current default device and directory, and when set, it resets them, regardless of the definition of *PERL_ENV_TABLES*. It cannot be cleared or deleted; attempts to do so are silently ignored.

Note that if you want to pass on any elements of the C-local environ array to a subprocess which isn't started by fork/exec, or isn't running a C program, you can "promote" them to logical names in the current process, which will then be inherited by all subprocesses, by saying

```
foreach my $key (qw[C-local keys you want promoted]) {
    my $temp = $ENV{$key}; # read from C-local array
    $ENV{$key} = $temp;    # and define as logical name
}
```

(You can't just say `$ENV{$key} = $ENV{$key}`, since the Perl optimizer is smart enough to elide the expression.)

Don't try to clear `%ENV` by saying `%ENV = ();`, it will throw a fatal error. This is equivalent to doing the following from DCL:

```
DELETE/LOGICAL *
```

You can imagine how bad things would be if, for example, the SYS$MANAGER or SYS$SYSTEM logicals were deleted.

At present, the first time you iterate over %ENV using `keys`, or `values`, you will incur a time penalty as all logical names are read, in order to fully populate %ENV. Subsequent iterations will not reread logical names, so they won't be as slow, but they also won't reflect any changes to logical name tables caused by other programs.

You do need to be careful with the logicals representing process-permanent files, such as `SYS$INPUT` and `SYS$OUTPUT`. The translations for these logicals are prepended with a two-byte binary value (0x1B 0x00) that needs to be stripped off if you want to use it. (In previous versions of Perl it wasn't possible to get the values of these logicals, as the null byte acted as an end-of-string marker)

$!

The string value of `$!` is that returned by the CRTL's strerror() function, so it will include the VMS message for VMS-specific errors. The numeric value of `$!` is the value of `errno`, except if errno is EVMSERR, in which case `$!` contains the value of vaxc$errno. Setting `$!` always sets errno to the value specified. If this value is EVMSERR, it also sets vaxc$errno to 4 (NONAME-F-NOMSG), so that the string value of `$!` won't reflect the VMS error message from before `$!` was set.

$ ˆE

This variable provides direct access to VMS status values in vaxc$errno, which are often more specific than the generic Unix-style error messages in `$!`. Its numeric value is the value of vaxc$errno, and its string value is the corresponding VMS message string, as retrieved by sys$getmsg(). Setting `$^E` sets vaxc$errno to the value specified.

$?

The "status value" returned in `$?` is synthesized from the actual exit status of the subprocess in a way that approximates POSIX wait(5) semantics, in order to allow Perl programs to portably test for successful completion of subprocesses. The low order 8 bits of `$?` are always 0 under VMS, since the termination status of a process may or may not have been generated by an exception. The next 8 bits are derived from the severity portion of the subprocess' exit status: if the severity was success or informational, these bits are all 0; if the severity was warning, they contain a value of 1; if the severity was error or fatal error, they contain the actual severity bits, which turns out to be a value of 2 for error and 4 for fatal error.

As a result, `$?` will always be zero if the subprocess' exit status indicated successful completion, and non-zero if a warning or error occurred. Conversely, when setting `$?` in an END block, an attempt is made to convert the POSIX value into a native status intelligible to the operating system upon exiting Perl. What this boils down to is that setting `$?` to zero results in the generic success value SS$_NORMAL, and setting `$?` to a non-zero value results in the generic failure status SS$_ABORT. See also exit in *perlport*.

The pragma `use vmsish 'status'` makes `$?` reflect the actual VMS exit status instead of the default emulation of POSIX status described above. This pragma also disables the conversion of non-zero values to SS$_ABORT when setting `$?` in an END block (but zero will still be converted to SS$_NORMAL).

$ |

Setting `$|` for an I/O stream causes data to be flushed all the way to disk on each write (*i.e.* not just to the underlying RMS buffers for a file). In other words, it's equivalent to calling fflush() and fsync() from C.

125.9 Standard modules with VMS-specific differences

125.9.1 SDBM_File

SDBM_File works properly on VMS. It has, however, one minor difference. The database directory file created has a *.sdbm_dir* extension rather than a *.dir* extension. *.dir* files are VMS filesystem directory files, and using them for other purposes could cause unacceptable problems.

125.10 Revision date

This document was last updated on 01-May-2002, for Perl 5, patchlevel 8.

Chapter 126

README.vos

Perl for Stratus VOS

126.1 SYNOPSIS

This file contains notes for building perl on the Stratus VOS operating system. Perl is a scripting or macro language that is popular on many systems. See *perlbook* for a number of good books on Perl.

These are instructions for building Perl from source. Most people can simply download a pre-compiled distribution from the VOS anonymous FTP site. If you are running VOS Release 14.2.0 or earlier, download Perl from ftp://ftp.stratus.com/pub/vos/posix/alpha/alpha.html If you are running VOS Release 14.3.0 or later, download Perl from ftp://ftp.stratus.com/pub/vos/posix/ga/ga.html Instructions for unbundling the Perl distribution file are at ftp://ftp.stratus.com/pub/vos/utility/utility.html

If you are running VOS Release 14.4.1 or later, you can obtain a pre-compiled, supported copy of perl by purchasing Release 2.0.1 (or later) of the VOS GNU C++ and GNU Tools product from Stratus Technologies.

126.1.1 Multiple methods to build perl for VOS

If you elect to build perl from its source code, you have several different ways that you can build perl. The method that you use depends on the version of VOS that you are using and on the architecture of your Stratus hardware platform.

1. If you have a Stratus XA2000 (Motorola 68k-based) platform, you must build perl using the alpha version of VOS POSIX support and using the VOS Standard C Cross-compiler. You must build perl on VOS Release 14.1.0 (or later) on an XA/R or Continuum platform.

   This version of perl is properly called "miniperl" because it does not contain the complete perl functionality.

   You must build perl with the compile_perl.cm command macro found in the vos subdirectory.

2. If you have a Stratus XA/R (Intel i860-based) platform, you must build perl using the alpha version of VOS POSIX support and using the VOS Standard C compiler or cross-compiler. You must build perl on VOS Release 14.1.0 (or later) on an XA/R or Continuum platform.

   This version of perl is properly called "miniperl" because it does not contain the complete perl functionality.

   You must build perl with the compile_perl.cm command macro found in the vos subdirectory.

3. If you have a Stratus Continuum (PA-RISC-based) platform that is running a version of VOS earlier than VOS 14.3.0, you must build perl using the alpha version of VOS POSIX support and using the VOS Standard C compiler or cross-compiler. You must build perl on VOS Release 14.1.0 (or later) on an XA/R or Continuum platform.

   This version of perl is properly called "miniperl" because it does not contain the complete perl functionality.

   You must build perl with the compile_perl.cm command macro found in the vos subdirectory.

4. If you have a Stratus Continuum (PA-RISC-based) platform that is running VOS Release 14.3.0 through VOS Release 14.4.1, you must build perl using the generally-available version of VOS POSIX support, and using either the VOS Standard C compiler or the VOS GNU C compiler. You must build perl on VOS Release 14.3.0 (or later) on a Continuum platform.

   This version of perl is properly called "miniperl" because it does not contain the complete perl functionality.

   You must build perl with the compile_perl.cm command macro found in the vos subdirectory.

5. If you have a Stratus Continuum (PA-RISC-based) platform that is running VOS Release 14.5.0 or later, you can either use the previous method to build "miniperl" or you can build "full perl", which contains the complete functionality of perl. I strongly recommend that you build full perl. To build full perl, you must use the generally-available version of VOS POSIX support. You must use the VOS GNU C compiler and the VOS GNU C/C++ and GNU Tools Release 2.0.1 (or later) product. You must build full perl on VOS Release 14.5.0 (or later) on a Continuum platform.

   You must build full perl with the compile_full_perl.cm command macro found in the vos subdirectory.

126.1.2 Stratus POSIX Support

Note that there are two different implementations of POSIX.1 support on VOS. There is an alpha version of POSIX that is available from the Stratus anonymous ftp site (ftp://ftp.stratus.com/pub/vos/posix/alpha/alpha.html). There is a generally-available version of POSIX that comes with VOS Release 14.3.0 or higher. This port of POSIX will compile and bind with either version of POSIX.

Most of the Perl features should work on VOS regardless of which version of POSIX that you are using. However, the alpha version of POSIX is missing a number of key functions, and therefore any attempt by perl.pm to call the following unimplemented POSIX functions will result in an error message and an immediate and fatal call to the VOS debugger. They are "dup", "fork", and "waitpid". The lack of these functions prevents you from starting VOS commands and grabbing their output in perl. The workaround is to run the commands outside of perl, then have perl process the output file. These functions are all available in the generally-available version of POSIX.

126.2 INSTALLING PERL IN VOS

126.2.1 Compiling Perl 5 on VOS

Before you can build Perl 5 on VOS, you need to have or acquire the following additional items.

1. The VOS Standard C Compiler (or the VOS Standard C Cross-Compiler) and the VOS C Runtime. If you are using the generally-available version of POSIX support, you may instead use the VOS GNU C/C++ Compiler. These are standard Stratus products.

2. Either the VOS OS TCP/IP or STCP product set. If you are building with the alpha version of POSIX you need the OS TCP/IP product set. If you are building with the generally-available version of POSIX you need the STCP product set. These are standard Stratus products.

3. Either the alpha or generally-available version of the VOS POSIX.1 environment.

   The alpha version of POSIX.1 support is available on the Stratus FTP site. Login anonymously to ftp.stratus.com and get the file /pub/vos/posix/alpha/posix.save.evf.gz in binary file-transfer mode. Or use the Uniform Resource Locator (URL) ftp://ftp.stratus.com/pub/vos/posix/alpha/posix.save.evf.gz from your web browser. Instructions for unbundling this file are at ftp://ftp.stratus.com/pub/vos/utility/utility.html This is NOT a standard Stratus product.

   In VOS Release 14.3.0, the generally-available version of POSIX.1 support is bundled with the VOS Standard C compiler (or Standard C Cross-Compiler). In VOS Release 14.4.0 or higher, it is also bundled with the VOS C Runtime. These are standard Stratus products.

4. You must compile this version of Perl 5 on VOS Release 14.1.0 or higher because some of the perl source files contain more than 32,767 source lines. Due to VOS release-compatibility rules, this port of perl may not execute on VOS Release 12 or earlier.

5. If you are using the generally-available version of VOS POSIX support, then you should also acquire the VOS GNU C/C++ Compiler and GNU Tools product. When perl is built with this version of POSIX support, it assumes that it can find "bash", "sed" and other POSIX-compatible commands in the directory /system/gnu_library/bin.

To build perl using the supplied VOS command macros, change to the "vos" subdirectory and type the command "compile_perl -processor X", where X is the processor type (mc68020, i80860, pa7100, pa8000) that you wish to use. Note that the generally-available version of POSIX.1 support is not available for the mc68020 or i80860 processors.

Use the "-version alpha" control argument to build perl with the alpha version of POSIX support, and use the "-version ga" control argument to build it with the generally-available version of POSIX. The default is "ga".

Use the "-compiler cc" control argument to build perl with the VOS Standard C compiler. Use the "-compiler gcc" control argument to build it with the GNU GCC compiler. The default is "cc".

You must have purchased the VOS Standard C Cross Compiler in order to compile perl for a processor type that is different from the processor type of the module.

Note that code compiled for the pa7100 processor type can execute on the PA7100, PA8000, PA8500 and PA8600 processors, and that code compiled for the pa8000 processor type can execute on the PA8000, PA8500 and PA8600 processors.

To build full perl using the supplied Configure script and makefiles, change to the "vos" subdirectory and type the command "compile_full_perl" or "start_process compile_full_perl". This will configure, build, and test perl.

126.2.2 Installing Perl 5 on VOS

1. If you have built perl using the Configure script, ensure that you have modify permission to `>system>ported` and type

   ```
   gmake install
   ```

2. If you have built perl using any of the other methods, type

   ```
   install_perl -processor PROCESSOR -name NAME
   ```

   where PROCESSOR is mc68020, i80860, pa7100, or pa8000, as appropriate, and NAME is perl or perl5, according to which name you wish to use.

   This command macro will install perl and all of its related files in the proper directories.

3. While there are currently no architecture-specific extensions or modules distributed with perl, the following directories can be used to hold such files:

   ```
   >system>ported>lib>perl5>5.8.0>68k
   >system>ported>lib>perl5>5.8.0>860
   >system>ported>lib>perl5>5.8.0>7100
   >system>ported>lib>perl5>5.8.0>8000
   ```

4. Site-specific perl extensions and modules can be installed in one of two places. Put architecture-independent files into:

   ```
   >system>ported>lib>perl5>site_perl>5.8.0
   ```

   Put site-specific architecture-dependent files into one of the following directories:

   ```
   >system>ported>lib>perl5>site_perl>5.8.0>68k
   >system>ported>lib>perl5>site_perl>5.8.0>860
   >system>ported>lib>perl5>site_perl>5.8.0>7100
   >system>ported>lib>perl5>site_perl>5.8.0>8000
   ```

5. You can examine the @INC variable from within a perl program to see the order in which Perl searches these directories.

126.3 USING PERL IN VOS

126.3.1 Unimplemented Features of Perl on VOS

If perl is built with the alpha version of VOS POSIX.1 support and if it attempts to call an unimplemented VOS POSIX.1 function, it will print a fatal error message and enter the VOS debugger. This error is not recoverable. See vos_dummies.c for a list of the unimplemented POSIX.1 functions. To see what functions are unimplemented and what the error message looks like, compile and execute "test_vos_dummies.c".

126.3.2 Restrictions of Perl on VOS

This port of Perl version 5 to VOS prefers Unix-style, slash-separated pathnames over VOS-style greater-than-separated pathnames. VOS-style pathnames should work in most contexts, but if you have trouble, replace all greater-than characters by slash characters. Because the slash character is used as a pathname delimiter, Perl cannot process VOS pathnames containing a slash character in a directory or file name; these must be renamed.

This port of Perl also uses Unix-epoch date values internally. As long as you are dealing with ASCII character string representations of dates, this should not be an issue. The supported epoch is January 1, 1980 to January 17, 2038.

See the file pod/perlport.pod for more information about the VOS port of Perl.

126.3.3 Handling of underflow and overflow

Prior to VOS Release 14.7.0, VOS does not support automatically mapping overflowed floating-point values to +infinity, nor automatically mapping underflowed floating-point values to zero, unlike many other platforms. The Perl pack function has been modified to perform such mapping in software on VOS. Performing other floating-point computations that underflow or overflow will probably result in SIGFPE. Don't push your luck.

As of VOS Release 14.7.0, the VOS POSIX runtime sets up the PA-RISC hardware floating-point status register so that the overflow and underflow exceptions do not trap, but instead automatically convert the result to infinity or zero, as appropriate. As of this writing, there are still floating-point operations that can trap, for example, subtracting two infinite values. This is recorded as suggestion posix-1022, which is not yet fixed.

126.4 TEST STATUS

When Perl 5.8.3 is built using the native build process on VOS Release 14.7.0 and GNU C++/GNU Tools 2.0.2a, all but three attempted tests either pass or result in TODO (ignored) failures. The tests that fail are:

t/io/tell.t, test 28 t/op/pack.t, test 39 lib/Net/ing/t/450_service.t, test 8

126.5 SUPPORT STATUS

I'm offering this port "as is". You can ask me questions, but I can't guarantee I'll be able to answer them. There are some excellent books available on the Perl language; consult a book seller.

If you want a supported version of perl for VOS, purchase the VOS GNU C++ and GNU Tools Release 2.0.1 (or later) product from Stratus Technologies, along with a support contract (or from anyone else who will sell you support).

Chapter 127

perlwin32

Perl under Windows

127.1 SYNOPSIS

These are instructions for building Perl under Windows 9x/NT/2000/XP on the Intel x86 and Itanium architectures.

127.2 DESCRIPTION

Before you start, you should glance through the README file found in the top-level directory to which the Perl distribution was extracted. Make sure you read and understand the terms under which this software is being distributed.

Also make sure you read BUGS AND CAVEATS below for the known limitations of this port.

The INSTALL file in the perl top-level has much information that is only relevant to people building Perl on Unix-like systems. In particular, you can safely ignore any information that talks about "Configure".

You may also want to look at two other options for building a perl that will work on Windows NT: the README.cygwin and README.os2 files, each of which give a different set of rules to build a Perl that will work on Win32 platforms. Those two methods will probably enable you to build a more Unix-compatible perl, but you will also need to download and use various other build-time and run-time support software described in those files.

This set of instructions is meant to describe a so-called "native" port of Perl to Win32 platforms. This includes both 32-bit and 64-bit Windows operating systems. The resulting Perl requires no additional software to run (other than what came with your operating system). Currently, this port is capable of using one of the following compilers on the Intel x86 architecture:

```
      Borland C++               version 5.02 or later
      Microsoft Visual C++      version 4.2 or later
      MinGW with gcc            gcc version 2.95.2 or later
```

The last of these is a high quality freeware compiler. Use version 3.2.x or later for the best results with this compiler.

This port can also be built on the Intel IA64 using:

```
      Microsoft Platform SDK    Nov 2001 (64-bit compiler and tools)
```

The MS Platform SDK can be downloaded from http://www.microsoft.com/.

This port fully supports MakeMaker (the set of modules that is used to build extensions to perl). Therefore, you should be able to build and install most extensions found in the CPAN sites. See Usage Hints for Perl on Win32 below for general hints about this.

127.2.1 Setting Up Perl on Win32

Make

You need a "make" program to build the sources. If you are using Visual C++ or the Platform SDK tools under Windows NT/2000/XP, nmake will work. All other builds need dmake.

dmake is a freely available make that has very nice macro features and parallelability.

A port of dmake for Windows is available from:

```
http://www.cpan.org/authors/id/GSAR/dmake-4.1pl1-win32.zip
```

(This is a fixed version of the original dmake sources obtained from http://www.wticorp.com/ As of version 4.1PL1, the original sources did not build as shipped and had various other problems. A patch is included in the above fixed version.)

Fetch and install dmake somewhere on your path (follow the instructions in the README.NOW file).

There exists a minor coexistence problem with dmake and Borland C++ compilers. Namely, if a distribution has C files named with mixed case letters, they will be compiled into appropriate .obj-files named with all lowercase letters, and every time dmake is invoked to bring files up to date, it will try to recompile such files again. For example, Tk distribution has a lot of such files, resulting in needless recompiles every time dmake is invoked. To avoid this, you may use the script "sync_ext.pl" after a successful build. It is available in the win32 subdirectory of the Perl source distribution.

Command Shell

Use the default "cmd" shell that comes with NT. Some versions of the popular 4DOS/NT shell have incompatibilities that may cause you trouble. If the build fails under that shell, try building again with the cmd shell.

The nmake Makefile also has known incompatibilities with the "command.com" shell that comes with Windows 9x. You will need to use dmake and makefile.mk to build under Windows 9x.

The surest way to build it is on Windows NT/2000/XP, using the cmd shell.

Make sure the path to the build directory does not contain spaces. The build usually works in this circumstance, but some tests will fail.

Borland C++

If you are using the Borland compiler, you will need dmake. (The make that Borland supplies is seriously crippled and will not work for MakeMaker builds.)

See §**??** above.

Microsoft Visual C++

The nmake that comes with Visual C++ will suffice for building. You will need to run the VCVARS32.BAT file, usually found somewhere like C:\MSDEV4.2\BIN. This will set your build environment.

You can also use dmake to build using Visual C++; provided, however, you set OSRELEASE to "microsft" (or whatever the directory name under which the Visual C dmake configuration lives) in your environment and edit win32/config.vc to change "make=nmake" into "make=dmake". The latter step is only essential if you want to use dmake as your default make for building extensions using MakeMaker.

Microsoft Platform SDK 64-bit Compiler

The nmake that comes with the Platform SDK will suffice for building Perl. Make sure you are building within one of the "Build Environment" shells available after you install the Platform SDK from the Start Menu.

MinGW release 3 with gcc

The latest release of MinGW at the time of writing is 3.1.0, which comes with gcc-3.2.3, and can be downloaded here:

```
http://www.mingw.org/
```

Perl also compiles with earlier releases of gcc (2.95.2 and up). See below for notes about using earlier versions of MinGW/gcc.

You also need dmake. See §**??** above on how to get it.

MinGW release 1 with gcc

The MinGW-1.1 bundle comes with gcc-2.95.3.

Make sure you install the binaries that work with MSVCRT.DLL as indicated in the README for the GCC bundle. You may need to set up a few environment variables (usually ran from a batch file).

There are a couple of problems with the version of gcc-2.95.2-msvcrt.exe released 7 November 1999:

- It left out a fix for certain command line quotes. To fix this, be sure to download and install the file fixes/quote-fix-msvcrt.exe from the above ftp location.
- The definition of the fpos_t type in stdio.h may be wrong. If your stdio.h has this problem, you will see an exception when running the test t/lib/io_xs.t. To fix this, change the typedef for fpos_t from "long" to "long long" in the file i386-mingw32msvc/include/stdio.h, and rebuild.

A potentially simpler to install (but probably soon-to-be-outdated) bundle of the above package with the mentioned fixes already applied is available here:

```
http://downloads.ActiveState.com/pub/staff/gsar/gcc-2.95.2-msvcrt.zip
ftp://ftp.ActiveState.com/pub/staff/gsar/gcc-2.95.2-msvcrt.zip
```

127.2.2 Building

- Make sure you are in the "win32" subdirectory under the perl toplevel. This directory contains a "Makefile" that will work with versions of nmake that come with Visual C++ or the Platform SDK, and a dmake "makefile.mk" that will work for all supported compilers. The defaults in the dmake makefile are setup to build using Microsoft Visual C++ 6.0 or newer.
- Edit the makefile.mk (or Makefile, if you're using nmake) and change the values of INST_DRV and INST_TOP. You can also enable various build flags. These are explained in the makefiles.

  Note that it is generally not a good idea to try to build a perl with INST_DRV and INST_TOP set to a path that already exists from a previous build. In particular, this may cause problems with the lib/ExtUtils/t/Embed.t test, which attempts to build a test program and may end up building against the installed perl's lib/CORE directory rather than the one being tested.

  You will have to make sure that CCTYPE is set correctly and that CCHOME points to wherever you installed your compiler.

  The default value for CCHOME in the makefiles for Visual C++ may not be correct for some versions. Make sure the default exists and is valid.

  If you have either the source or a library that contains des_fcrypt(), enable the appropriate option in the makefile. A ready-to-use version of fcrypt.c, based on the version originally written by Eric Young at ftp://ftp.funet.fi/pub/crypt/mirrors/dsi/libdes/, is bundled with the distribution. Set CRYPT_SRC to fcrypt.c to use this version. Alternatively, if you have built a library that contains des_fcrypt(), you can set CRYPT_LIB to point to the library name. Perl will also build without des_fcrypt(), but the crypt() builtin will fail at run time.

  Be sure to read the instructions near the top of the makefiles carefully.
- Type "dmake" (or "nmake" if you are using that make).

  This should build everything. Specifically, it will create perl.exe, perl58.dll at the perl toplevel, and various other extension dll's under the lib\auto directory. If the build fails for any reason, make sure you have done the previous steps correctly.

127.2.3 Testing Perl on Win32

Type "dmake test" (or "nmake test"). This will run most of the tests from the testsuite (many tests will be skipped).

There should be no test failures when running under Windows NT/2000/XP. Many tests *will* fail under Windows 9x due to the inferior command shell.

Some test failures may occur if you use a command shell other than the native "cmd.exe", or if you are building from a path that contains spaces. So don't do that.

If you are running the tests from a emacs shell window, you may see failures in op/stat.t. Run "dmake test-notty" in that case.

If you're using the Borland compiler, you may see a failure in op/taint.t arising from the inability to find the Borland Runtime DLLs on the system default path. You will need to copy the DLLs reported by the messages from where Borland chose to install it, into the Windows system directory (usually somewhere like C:\WINNT\SYSTEM32) and rerun the test.

If you're using Borland compiler versions 5.2 and below, you may run into problems finding the correct header files when building extensions. For example, building the "Tk" extension may fail because both perl and Tk contain a header file called "patchlevel.h". The latest Borland compiler (v5.5) is free of this misbehaviour, and it even supports an option -VI- for backward (bugward) compatibility for using the old Borland search algorithm to locate header files.

If you run the tests on a FAT partition, you may see some failures for `link()` related tests:

```
    Failed Test                    Stat Wstat Total Fail  Failed  List

    ../ext/IO/lib/IO/t/io_dup.t                   6    4  66.67%  2-5
    ../lib/File/Temp/t/mktemp.t                   9    1  11.11%  2
    ../lib/File/Temp/t/posix.t                    7    1  14.29%  3
    ../lib/File/Temp/t/security.t                13    1   7.69%  2
    ../lib/File/Temp/t/tempfile.t                20    2  10.00%  2 4
    comp/multiline.t                              6    2  33.33%  5-6
    io/dup.t                                      8    6  75.00%  2-7
    op/write.t                                   47    7  14.89%  1-3 6 9-11
```

Testing on NTFS avoids these errors.

Furthermore, you should make sure that during `make test` you do not have any GNU tool packages in your path: some toolkits like Unixutils include some tools (`type` for instance) which override the Windows ones and makes tests fail. Remove them from your path while testing to avoid these errors.

Please report any other failures as described under BUGS AND CAVEATS.

127.2.4 Installation of Perl on Win32

Type "dmake install" (or "nmake install"). This will put the newly built perl and the libraries under whatever `INST_TOP` points to in the Makefile. It will also install the pod documentation under `$INST_TOP\$VERSION\lib\pod` and HTML versions of the same under `$INST_TOP\$VERSION\lib\pod\html`. To use the Perl you just installed, you will need to add two components to your PATH environment variable, `$INST_TOP\$VERSION\bin` and `$INST_TOP\$VERSION\bin\$ARCHNAME`. For example:

```
    set PATH c:\perl\5.6.0\bin;c:\perl\5.6.0\bin\MSWin32-x86;%PATH%
```

If you opt to comment out INST_VER and INST_ARCH in the makefiles, the installation structure is much simpler. In that case, it will be sufficient to add a single entry to the path, for instance:

```
    set PATH c:\perl\bin;%PATH%
```

127.2.5 Usage Hints for Perl on Win32

Environment Variables

The installation paths that you set during the build get compiled into perl, so you don't have to do anything additional to start using that perl (except add its location to your PATH variable).

If you put extensions in unusual places, you can set PERL5LIB to a list of paths separated by semicolons where you want perl to look for libraries. Look for descriptions of other environment variables you can set in *perlrun*.

You can also control the shell that perl uses to run system() and backtick commands via PERL5SHELL. See *perlrun*.

Perl does not depend on the registry, but it can look up certain default values if you choose to put them there. Perl attempts to read entries from `HKEY_CURRENT_USER\Software\Perl` and `HKEY_LOCAL_MACHINE\Software\Perl`. Entries in the former override entries in the latter. One or more of the following entries (of type REG_SZ or REG_EXPAND_SZ) may be set:

```
    lib-$]              version-specific standard library path to add to @INC
    lib                 standard library path to add to @INC
    sitelib-$]          version-specific site library path to add to @INC
    sitelib             site library path to add to @INC
    vendorlib-$]        version-specific vendor library path to add to @INC
    vendorlib           vendor library path to add to @INC
    PERL*               fallback for all %ENV lookups that begin with "PERL"
```

Note the `$]` in the above is not literal. Substitute whatever version of perl you want to honor that entry, e.g. `5.6.0`. Paths must be separated with semicolons, as usual on win32.

File Globbing

By default, perl handles file globbing using the File::Glob extension, which provides portable globbing.

If you want perl to use globbing that emulates the quirks of DOS filename conventions, you might want to consider using File::DosGlob to override the internal glob() implementation. See *File::DosGlob* for details.

Using perl from the command line

If you are accustomed to using perl from various command-line shells found in UNIX environments, you will be less than pleased with what Windows offers by way of a command shell.

The crucial thing to understand about the Windows environment is that the command line you type in is processed twice before Perl sees it. First, your command shell (usually CMD.EXE on Windows NT, and COMMAND.COM on Windows 9x) preprocesses the command line, to handle redirection, environment variable expansion, and location of the executable to run. Then, the perl executable splits the remaining command line into individual arguments, using the C runtime library upon which Perl was built.

It is particularly important to note that neither the shell nor the C runtime do any wildcard expansions of command-line arguments (so wildcards need not be quoted). Also, the quoting behaviours of the shell and the C runtime are rudimentary at best (and may, if you are using a non-standard shell, be inconsistent). The only (useful) quote character is the double quote ("). It can be used to protect spaces and other special characters in arguments.

The Windows NT documentation has almost no description of how the quoting rules are implemented, but here are some general observations based on experiments: The C runtime breaks arguments at spaces and passes them to programs in argc/argv. Double quotes can be used to prevent arguments with spaces in them from being split up. You can put a double quote in an argument by escaping it with a backslash and enclosing the whole argument within double quotes. The backslash and the pair of double quotes surrounding the argument will be stripped by the C runtime.

The file redirection characters "<", ">", and "|" can be quoted by double quotes (although there are suggestions that this may not always be true). Single quotes are not treated as quotes by the shell or the C runtime, they don't get stripped by the shell (just to make this type of quoting completely useless). The caret "ˆ" has also been observed to behave as a quoting character, but this appears to be a shell feature, and the caret is not stripped from the command line, so Perl still sees it (and the C runtime phase does not treat the caret as a quote character).

Here are some examples of usage of the "cmd" shell:

This prints two doublequotes:

```
perl -e "print '\"\"' "
```

This does the same:

```
perl -e "print \"\\\"\\\"\" "
```

This prints "bar" and writes "foo" to the file "blurch":

```
perl -e "print 'foo'; print STDERR 'bar'" > blurch
```

This prints "foo" ("bar" disappears into nowhereland):

```
perl -e "print 'foo'; print STDERR 'bar'" 2> nul
```

This prints "bar" and writes "foo" into the file "blurch":

```
perl -e "print 'foo'; print STDERR 'bar'" 1> blurch
```

This pipes "foo" to the "less" pager and prints "bar" on the console:

```
perl -e "print 'foo'; print STDERR 'bar'" | less
```

This pipes "foo\nbar\n" to the less pager:

```
perl -le "print 'foo'; print STDERR 'bar'" 2>&1 | less
```

This pipes "foo" to the pager and writes "bar" in the file "blurch":

```
perl -e "print 'foo'; print STDERR 'bar'" 2> blurch | less
```

Discovering the usefulness of the "command.com" shell on Windows 9x is left as an exercise to the reader :)

One particularly pernicious problem with the 4NT command shell for Windows NT is that it (nearly) always treats a % character as indicating that environment variable expansion is needed. Under this shell, it is therefore important to always double any % characters which you want Perl to see (for example, for hash variables), even when they are quoted.

Building Extensions

The Comprehensive Perl Archive Network (CPAN) offers a wealth of extensions, some of which require a C compiler to build. Look in http://www.cpan.org/ for more information on CPAN.

Note that not all of the extensions available from CPAN may work in the Win32 environment; you should check the information at http://testers.cpan.org/ before investing too much effort into porting modules that don't readily build.

Most extensions (whether they require a C compiler or not) can be built, tested and installed with the standard mantra:

```
perl Makefile.PL
$MAKE
$MAKE test
$MAKE install
```

where $MAKE is whatever ’make’ program you have configured perl to use. Use "perl -V:make" to find out what this is. Some extensions may not provide a testsuite (so "$MAKE test" may not do anything or fail), but most serious ones do.

It is important that you use a supported ’make’ program, and ensure Config.pm knows about it. If you don’t have nmake, you can either get dmake from the location mentioned earlier or get an old version of nmake reportedly available from:

```
 http://download.microsoft.com/download/vc15/Patch/1.52/W95/EN-US/nmake15.exe
```

Another option is to use the make written in Perl, available from CPAN.

```
    http://www.cpan.org/modules/by-module/Make/
```

You may also use dmake. See §**??** above on how to get it.

Note that MakeMaker actually emits makefiles with different syntax depending on what ’make’ it thinks you are using. Therefore, it is important that one of the following values appears in Config.pm:

```
    make=’nmake’        # MakeMaker emits nmake syntax
    make=’dmake’        # MakeMaker emits dmake syntax
    any other value     # MakeMaker emits generic make syntax
                            (e.g GNU make, or Perl make)
```

If the value doesn’t match the ’make’ program you want to use, edit Config.pm to fix it.

If a module implements XSUBs, you will need one of the supported C compilers. You must make sure you have set up the environment for the compiler for command-line compilation.

If a module does not build for some reason, look carefully for why it failed, and report problems to the module author. If it looks like the extension building support is at fault, report that with full details of how the build failed using the perlbug utility.

Command-line Wildcard Expansion

The default command shells on DOS descendant operating systems (such as they are) usually do not expand wildcard arguments supplied to programs. They consider it the application’s job to handle that. This is commonly achieved by linking the application (in our case, perl) with startup code that the C runtime libraries usually provide. However, doing that results in incompatible perl versions (since the behavior of the argv expansion code differs depending on the compiler, and it is even buggy on some compilers). Besides, it may be a source of frustration if you use such a perl binary with an alternate shell that *does* expand wildcards.

Instead, the following solution works rather well. The nice things about it are 1) you can start using it right away; 2) it is more powerful, because it will do the right thing with a pattern like */*/*.c; 3) you can decide whether you do/don’t want to use it; and 4) you can extend the method to add any customizations (or even entirely different kinds of wildcard expansion).

```
        C:\> copy con c:\perl\lib\Wild.pm
        # Wild.pm - emulate shell @ARGV expansion on shells that don’t
        use File::DosGlob;
        @ARGV = map {
                      my @g = File::DosGlob::glob($_) if /[*?]/;
                      @g ? @g : $_;
                    } @ARGV;
        1;
        ^Z
        C:\> set PERL5OPT=-MWild
        C:\> perl -le "for (@ARGV) { print }" */*/perl*.c
        p4view/perl/perl.c
        p4view/perl/perlio.c
```

```
p4view/perl/perly.c
perl5.005/win32/perlglob.c
perl5.005/win32/perllib.c
perl5.005/win32/perlglob.c
perl5.005/win32/perllib.c
perl5.005/win32/perlglob.c
perl5.005/win32/perllib.c
```

Note there are two distinct steps there: 1) You'll have to create Wild.pm and put it in your perl lib directory. 2) You'll need to set the PERL5OPT environment variable. If you want argv expansion to be the default, just set PERL5OPT in your default startup environment.

If you are using the Visual C compiler, you can get the C runtime's command line wildcard expansion built into perl binary. The resulting binary will always expand unquoted command lines, which may not be what you want if you use a shell that does that for you. The expansion done is also somewhat less powerful than the approach suggested above.

Win32 Specific Extensions

A number of extensions specific to the Win32 platform are available from CPAN. You may find that many of these extensions are meant to be used under the Activeware port of Perl, which used to be the only native port for the Win32 platform. Since the Activeware port does not have adequate support for Perl's extension building tools, these extensions typically do not support those tools either and, therefore, cannot be built using the generic steps shown in the previous section.

To ensure smooth transitioning of existing code that uses the ActiveState port, there is a bundle of Win32 extensions that contains all of the ActiveState extensions and most other Win32 extensions from CPAN in source form, along with many added bugfixes, and with MakeMaker support. This bundle is available at:

```
http://www.cpan.org/authors/id/GSAR/libwin32-0.18.zip
```

See the README in that distribution for building and installation instructions. Look for later versions that may be available at the same location.

Notes on 64-bit Windows

Windows .NET Server supports the LLP64 data model on the Intel Itanium architecture.

The LLP64 data model is different from the LP64 data model that is the norm on 64-bit Unix platforms. In the former, `int` and `long` are both 32-bit data types, while pointers are 64 bits wide. In addition, there is a separate 64-bit wide integral type, `__int64`. In contrast, the LP64 data model that is pervasive on Unix platforms provides `int` as the 32-bit type, while both the `long` type and pointers are of 64-bit precision. Note that both models provide for 64-bits of addressability.

64-bit Windows running on Itanium is capable of running 32-bit x86 binaries transparently. This means that you could use a 32-bit build of Perl on a 64-bit system. Given this, why would one want to build a 64-bit build of Perl? Here are some reasons why you would bother:

*
A 64-bit native application will run much more efficiently on Itanium hardware.

*
There is no 2GB limit on process size.

*
Perl automatically provides large file support when built under 64-bit Windows.

*
Embedding Perl inside a 64-bit application.

127.2.6 Running Perl Scripts

Perl scripts on UNIX use the "#!" (a.k.a "shebang") line to indicate to the OS that it should execute the file using perl. Win32 has no comparable means to indicate arbitrary files are executables.

Instead, all available methods to execute plain text files on Win32 rely on the file "extension". There are three methods to use this to execute perl scripts:

1. There is a facility called "file extension associations" that will work in Windows NT 4.0. This can be manipulated via the two commands "assoc" and "ftype" that come standard with Windows NT 4.0. Type "ftype /?" for a complete example of how to set this up for perl scripts (Say what? You thought Windows NT wasn't perl-ready? :).

2. Since file associations don't work everywhere, and there are reportedly bugs with file associations where it does work, the old method of wrapping the perl script to make it look like a regular batch file to the OS, may be used. The install process makes available the "pl2bat.bat" script which can be used to wrap perl scripts into batch files. For example:

   ```
   pl2bat foo.pl
   ```

   will create the file "FOO.BAT". Note "pl2bat" strips any .pl suffix and adds a .bat suffix to the generated file.

   If you use the 4DOS/NT or similar command shell, note that "pl2bat" uses the "%*" variable in the generated batch file to refer to all the command line arguments, so you may need to make sure that construct works in batch files. As of this writing, 4DOS/NT users will need a "ParameterChar = *" statement in their 4NT.INI file or will need to execute "setdos /p*" in the 4DOS/NT startup file to enable this to work.

3. Using "pl2bat" has a few problems: the file name gets changed, so scripts that rely on `$0` to find what they must do may not run properly; running "pl2bat" replicates the contents of the original script, and so this process can be maintenance intensive if the originals get updated often. A different approach that avoids both problems is possible.

   A script called "runperl.bat" is available that can be copied to any filename (along with the .bat suffix). For example, if you call it "foo.bat", it will run the file "foo" when it is executed. Since you can run batch files on Win32 platforms simply by typing the name (without the extension), this effectively runs the file "foo", when you type either "foo" or "foo.bat". With this method, "foo.bat" can even be in a different location than the file "foo", as long as "foo" is available somewhere on the PATH. If your scripts are on a filesystem that allows symbolic links, you can even avoid copying "runperl.bat".

   Here's a diversion: copy "runperl.bat" to "runperl", and type "runperl". Explain the observed behavior, or lack thereof. :) Hint: .gnidnats llits er'uoy fi ,"lrepnur" eteled :tniH

4. Miscellaneous Things

   A full set of HTML documentation is installed, so you should be able to use it if you have a web browser installed on your system.

   `perldoc` is also a useful tool for browsing information contained in the documentation, especially in conjunction with a pager like `less` (recent versions of which have Win32 support). You may have to set the PAGER environment variable to use a specific pager. "perldoc -f foo" will print information about the perl operator "foo".

   One common mistake when using this port with a GUI library like `Tk` is assuming that Perl's normal behavior of opening a command-line window will go away. This isn't the case. If you want to start a copy of `perl` without opening a command-line window, use the `wperl` executable built during the installation process. Usage is exactly the same as normal `perl` on Win32, except that options like `-h` don't work (since they need a command-line window to print to).

   If you find bugs in perl, you can run `perlbug` to create a bug report (you may have to send it manually if `perlbug` cannot find a mailer on your system).

127.3 BUGS AND CAVEATS

Norton AntiVirus interferes with the build process, particularly if set to "AutoProtect, All Files, when Opened". Unlike large applications the perl build process opens and modifies a lot of files. Having the the AntiVirus scan each and every one slows build the process significantly. Worse, with PERLIO=stdio the build process fails with peculiar messages as the virus checker interacts badly with miniperl.exe writing configure files (it seems to either catch file part written and treat it as suspicious, or virus checker may have it "locked" in a way which inhibits miniperl updating it). The build does complete with

```
    set PERLIO=perlio
```

but that may be just luck. Other AntiVirus software may have similar issues.

Some of the built-in functions do not act exactly as documented in *perlfunc*, and a few are not implemented at all. To avoid surprises, particularly if you have had prior exposure to Perl in other operating environments or if you intend to write code that will be portable to other environments. See *perlport* for a reasonably definitive list of these differences.

Not all extensions available from CPAN may build or work properly in the Win32 environment. See §**??**.

Most `socket()` related calls are supported, but they may not behave as on Unix platforms. See *perlport* for the full list.

Signal handling may not behave as on Unix platforms (where it doesn't exactly "behave", either :). For instance, calling `die()` or `exit()` from signal handlers will cause an exception, since most implementations of `signal()` on Win32 are severely crippled. Thus, signals may work only for simple things like setting a flag variable in the handler. Using signals under this port should currently be considered unsupported.

Please send detailed descriptions of any problems and solutions that you may find to <*perlbug@perl.com*>, along with the output produced by `perl -V`.

127.7 HISTORY

This port was originally contributed by Gary Ng around 5.003_24, and borrowed from the Hip Communications port that was available at the time. Various people have made numerous and sundry hacks since then.

Borland support was added in 5.004_01 (Gurusamy Sarathy).

GCC/mingw32 support was added in 5.005 (Nick Ing-Simmons).

Support for PERL_OBJECT was added in 5.005 (ActiveState Tool Corp).

Support for fork() emulation was added in 5.6 (ActiveState Tool Corp).

Win9x support was added in 5.6 (Benjamin Stuhl).

Support for 64-bit Windows added in 5.8 (ActiveState Corp).
