Perl Documentation

16th December 2004

This compilation in one single PDF document has been conceived using the Perl pod2latex script to get Latex, then converted into PDF thanks to pdflatex. If you use the PDF version of this documentation (or a paper version stemming from the pdf one) for any other use than a personal one, I would be thankful if you could keep me informed by email (Paul.Gaborit@enstimac.fr), although you are under no obligation.

Cette compilation en un seul document PDF a été conçue en utilisant le script Perl `pod2latex` pour obtenir du LaTeX puis convertie en PDF grâce à `pdflatex`. Si vous utilisez la version PDF de cette documentation (ou une version papier issue de la version PDF) pour tout autre usage qu'un usage personnel, je vous serai reconnaissant de m'en informer par un petit message (Paul.Gaborit @ enstimac.fr) mais rien ne vous y oblige.

16th December 2004 – Paul Gaborit

Part I

Overview

Chapter 1

perl

Practical Extraction and Report Language

1.1 SYNOPSIS

perl [**-sTuU**] [**-hv**] [**-V**[:*configvar*]] [**-cw**] [**-d**[:*debugger*]] [**-D**[*number/list*]]
[**-pna**] [**-F***pattern*] [**-l**[*octal*]] [**-0**[*octal*]] [**-I***dir*] [**-m**[-]*module*] [**-M**[-]*'module...'*] [**-P**] [**-S**] [**-x**[*dir*]]
[**-i**[*extension*]] [**-e** *'command'*] [–] [*programfile*] [*argument*]...

If you're new to Perl, you should start with *perlintro*, which is a general intro for beginners and provides some background to help you navigate the rest of Perl's extensive documentation.

For ease of access, the Perl manual has been split up into several sections.

1.1.1 Overview

```
    perl                Perl overview (this section)
    perlintro           Perl introduction for beginners
    perltoc             Perl documentation table of contents
```

1.1.2 Tutorials

```
    perlreftut          Perl references short introduction
    perldsc             Perl data structures intro
    perllol             Perl data structures: arrays of arrays

    perlrequick         Perl regular expressions quick start
    perlretut           Perl regular expressions tutorial

    perlboot            Perl OO tutorial for beginners
    perltoot            Perl OO tutorial, part 1
    perltooc            Perl OO tutorial, part 2
    perlbot             Perl OO tricks and examples

    perlstyle           Perl style guide

    perlcheat           Perl cheat sheet
    perltrap            Perl traps for the unwary
    perldebtut          Perl debugging tutorial
```

```
perlfaq             Perl frequently asked questions
  perlfaq1          General Questions About Perl
  perlfaq2          Obtaining and Learning about Perl
  perlfaq3          Programming Tools
  perlfaq4          Data Manipulation
  perlfaq5          Files and Formats
  perlfaq6          Regexes
  perlfaq7          Perl Language Issues
  perlfaq8          System Interaction
  perlfaq9          Networking
```

1.1.3 Reference Manual

```
perlsyn             Perl syntax
perldata            Perl data structures
perlop              Perl operators and precedence
perlsub             Perl subroutines
perlfunc            Perl built-in functions
  perlopentut       Perl open() tutorial
  perlpacktut       Perl pack() and unpack() tutorial
perlpod             Perl plain old documentation
perlpodspec         Perl plain old documentation format specification
perlrun             Perl execution and options
perldiag            Perl diagnostic messages
perllexwarn         Perl warnings and their control
perldebug           Perl debugging
perlvar             Perl predefined variables
perlre              Perl regular expressions, the rest of the story
perlreref           Perl regular expressions quick reference
perlref             Perl references, the rest of the story
perlform            Perl formats
perlobj             Perl objects
perltie             Perl objects hidden behind simple variables
  perldbmfilter     Perl DBM filters

perlipc             Perl interprocess communication
perlfork            Perl fork() information
perlnumber          Perl number semantics

perlthrtut          Perl threads tutorial
  perlothrtut       Old Perl threads tutorial

perlport            Perl portability guide
perllocale          Perl locale support
perluniintro        Perl Unicode introduction
perlunicode         Perl Unicode support
perlebcdic          Considerations for running Perl on EBCDIC platforms

perlsec             Perl security

perlmod             Perl modules: how they work
perlmodlib          Perl modules: how to write and use
perlmodstyle        Perl modules: how to write modules with style
perlmodinstall      Perl modules: how to install from CPAN
perlnewmod          Perl modules: preparing a new module for distribution
```

```
    perlutil            utilities packaged with the Perl distribution

    perlcompile         Perl compiler suite intro

    perlfilter          Perl source filters
```

1.1.4 Internals and C Language Interface

```
    perlembed           Perl ways to embed perl in your C or C++ application
    perldebguts         Perl debugging guts and tips
    perlxstut           Perl XS tutorial
    perlxs              Perl XS application programming interface
    perlclib            Internal replacements for standard C library functions
    perlguts            Perl internal functions for those doing extensions
    perlcall            Perl calling conventions from C

    perlapi             Perl API listing (autogenerated)
    perlintern          Perl internal functions (autogenerated)
    perliol             C API for Perl's implementation of IO in Layers
    perlapio            Perl internal IO abstraction interface

    perlhack            Perl hackers guide
```

1.1.5 Miscellaneous

```
    perlbook            Perl book information
    perltodo            Perl things to do

    perldoc             Look up Perl documentation in Pod format

    perlhist            Perl history records
    perldelta           Perl changes since previous version
    perl584delta        Perl changes in version 5.8.4
    perl583delta        Perl changes in version 5.8.3
    perl582delta        Perl changes in version 5.8.2
    perl581delta        Perl changes in version 5.8.1
    perl58delta         Perl changes in version 5.8.0
    perl573delta        Perl changes in version 5.7.3
    perl572delta        Perl changes in version 5.7.2
    perl571delta        Perl changes in version 5.7.1
    perl570delta        Perl changes in version 5.7.0

perlwin32	Perl notes for Windows

By default, the manpages listed above are installed in the */usr/local/man/* directory.

Extensive additional documentation for Perl modules is available. The default configuration for perl will place this additional documentation in the */usr/local/lib/perl5/man* directory (or else in the *man* subdirectory of the Perl library directory). Some of this additional documentation is distributed standard with Perl, but you'll also find documentation for third-party modules there.

You should be able to view Perl's documentation with your man(1) program by including the proper directories in the appropriate start-up files, or in the MANPATH environment variable. To find out where the configuration has installed the manpages, type:

```
    perl -V:man.dir
```

If the directories have a common stem, such as */usr/local/man/man1* and */usr/local/man/man3*, you need only to add that stem (*/usr/local/man*) to your man(1) configuration files or your MANPATH environment variable. If they do not share a stem, you'll have to add both stems.

If that doesn't work for some reason, you can still use the supplied *perldoc* script to view module information. You might also look into getting a replacement man program.

If something strange has gone wrong with your program and you're not sure where you should look for help, try the **-w** switch first. It will often point out exactly where the trouble is.

1.2 DESCRIPTION

Perl is a language optimized for scanning arbitrary text files, extracting information from those text files, and printing reports based on that information. It's also a good language for many system management tasks. The language is intended to be practical (easy to use, efficient, complete) rather than beautiful (tiny, elegant, minimal).

Perl combines (in the author's opinion, anyway) some of the best features of C, **sed**, **awk**, and **sh**, so people familiar with those languages should have little difficulty with it. (Language historians will also note some vestiges of **csh**, Pascal, and even BASIC-PLUS.) Expression syntax corresponds closely to C expression syntax. Unlike most Unix utilities, Perl does not arbitrarily limit the size of your data–if you've got the memory, Perl can slurp in your whole file as a single string. Recursion is of unlimited depth. And the tables used by hashes (sometimes called "associative arrays") grow as necessary to prevent degraded performance. Perl can use sophisticated pattern matching techniques to scan large amounts of data quickly. Although optimized for scanning text, Perl can also deal with binary data, and can make dbm files look like hashes. Setuid Perl scripts are safer than C programs through a dataflow tracing mechanism that prevents many stupid security holes.

If you have a problem that would ordinarily use **sed** or **awk** or **sh**, but it exceeds their capabilities or must run a little faster, and you don't want to write the silly thing in C, then Perl may be for you. There are also translators to turn your **sed** and **awk** scripts into Perl scripts.

But wait, there's more...

Begun in 1993 (see *perlhist*), Perl version 5 is nearly a complete rewrite that provides the following additional benefits:

- modularity and reusability using innumerable modules

  Described in *perlmod*, *perlmodlib*, and *perlmodinstall*.

- embeddable and extensible

  Described in *perlembed*, *perlxstut*, *perlxs*, *perlcall*, *perlguts*, and *xsubpp*.

- roll-your-own magic variables (including multiple simultaneous DBM implementations)

  Described in *perltie* and AnyDBM_File.

- subroutines can now be overridden, autoloaded, and prototyped

  Described in *perlsub*.

- arbitrarily nested data structures and anonymous functions

  Described in *perlreftut*, *perlref*, *perldsc*, and *perllol*.

- object-oriented programming

  Described in *perlobj*, *perlboot*, *perltoot*, *perltooc*, and *perlbot*.

- support for light-weight processes (threads)

  Described in *perlthrtut* and *threads*.

- support for Unicode, internationalization, and localization

  Described in *perluniintro*, *perllocale* and *Locale::Maketext*.

- lexical scoping

  Described in *perlsub*.

- regular expression enhancements

  Described in *perlre*, with additional examples in *perlop*.

- enhanced debugger and interactive Perl environment, with integrated editor support

  Described in *perldebtut*, *perldebug* and *perldebguts*.

- POSIX 1003.1 compliant library

  Described in *POSIX*.

Okay, that's *definitely* enough hype.

1.3 AVAILABILITY

Perl is available for most operating systems, including virtually all Unix-like platforms. See Supported Platforms in *perlport* for a listing.

1.4 ENVIRONMENT

See *perlrun*.

1.5 AUTHOR

Larry Wall <larry@wall.org>, with the help of oodles of other folks.

If your Perl success stories and testimonials may be of help to others who wish to advocate the use of Perl in their applications, or if you wish to simply express your gratitude to Larry and the Perl developers, please write to perl-thanks@perl.org .

1.6 FILES

```

1.8 DIAGNOSTICS

The `use warnings` pragma (and the **-w** switch) produces some lovely diagnostics.

See *perldiag* for explanations of all Perl's diagnostics. The `use diagnostics` pragma automatically turns Perl's normally terse warnings and errors into these longer forms.

Compilation errors will tell you the line number of the error, with an indication of the next token or token type that was to be examined. (In a script passed to Perl via **-e** switches, each **-e** is counted as one line.)

Setuid scripts have additional constraints that can produce error messages such as "Insecure dependency". See *perlsec*.

Did we mention that you should definitely consider using the **-w** switch?

1.9 BUGS

The **-w** switch is not mandatory.

Perl is at the mercy of your machine's definitions of various operations such as type casting, atof(), and floating-point output with sprintf().

If your stdio requires a seek or eof between reads and writes on a particular stream, so does Perl. (This doesn't apply to sysread() and syswrite().)

While none of the built-in data types have any arbitrary size limits (apart from memory size), there are still a few arbitrary limits: a given variable name may not be longer than 251 characters. Line numbers displayed by diagnostics are internally stored as short integers, so they are limited to a maximum of 65535 (higher numbers usually being affected by wraparound).

You may mail your bug reports (be sure to include full configuration information as output by the myconfig program in the perl source tree, or by `perl -V`) to perlbug@perl.org . If you've succeeded in compiling perl, the **perlbug** script in the *utils/* subdirectory can be used to help mail in a bug report.

Perl actually stands for Pathologically Eclectic Rubbish Lister, but don't tell anyone I said that.

1.10 NOTES

The Perl motto is "There's more than one way to do it." Divining how many more is left as an exercise to the reader.

The three principal virtues of a programmer are Laziness, Impatience, and Hubris. See the Camel Book for why.

Chapter 2

perlintro – a brief introduction and overview of Perl

2.1 DESCRIPTION

This document is intended to give you a quick overview of the Perl programming language, along with pointers to further documentation. It is intended as a "bootstrap" guide for those who are new to the language, and provides just enough information for you to be able to read other peoples' Perl and understand roughly what it's doing, or write your own simple scripts.

This introductory document does not aim to be complete. It does not even aim to be entirely accurate. In some cases perfection has been sacrificed in the goal of getting the general idea across. You are *strongly* advised to follow this introduction with more information from the full Perl manual, the table of contents to which can be found in *perltoc*.

Throughout this document you'll see references to other parts of the Perl documentation. You can read that documentation using the `perldoc` command or whatever method you're using to read this document.

2.1.1 What is Perl?

Perl is a general-purpose programming language originally developed for text manipulation and now used for a wide range of tasks including system administration, web development, network programming, GUI development, and more.

The language is intended to be practical (easy to use, efficient, complete) rather than beautiful (tiny, elegant, minimal). Its major features are that it's easy to use, supports both procedural and object-oriented (OO) programming, has powerful built-in support for text processing, and has one of the world's most impressive collections of third-party modules.

Different definitions of Perl are given in *perl*, *perlfaq1* and no doubt other places. From this we can determine that Perl is different things to different people, but that lots of people think it's at least worth writing about.

2.1.2 Running Perl programs

To run a Perl program from the Unix command line:

```
    perl progname.pl
```

Alternatively, put this as the first line of your script:

```
    #!/usr/bin/env perl
```

... and run the script as `/path/to/script.pl`. Of course, it'll need to be executable first, so `chmod 755 script.pl` (under Unix).

For more information, including instructions for other platforms such as Windows and Mac OS, read *perlrun*.

2.1.3 Basic syntax overview

A Perl script or program consists of one or more statements. These statements are simply written in the script in a straightforward fashion. There is no need to have a `main()` function or anything of that kind.

Perl statements end in a semi-colon:

```
    print "Hello, world";
```

Comments start with a hash symbol and run to the end of the line

```
    # This is a comment
```

Whitespace is irrelevant:

```
    print
        "Hello, world"
        ;
```

... except inside quoted strings:

```
    # this would print with a linebreak in the middle
    print "Hello
    world";
```

Double quotes or single quotes may be used around literal strings:

```
    print "Hello, world";
    print ’Hello, world’;
```

However, only double quotes "interpolate" variables and special characters such as newlines (`\n`):

```
    print "Hello, $name\n";     # works fine
    print ’Hello, $name\n’;     # prints $name\n literally
```

Numbers don’t need quotes around them:

```
    print 42;
```

You can use parentheses for functions’ arguments or omit them according to your personal taste. They are only required occasionally to clarify issues of precedence.

```
    print("Hello, world\n");
    print "Hello, world\n";
```

More detailed information about Perl syntax can be found in *perlsyn*.

2.1.4 Perl variable types

Perl has three main variable types: scalars, arrays, and hashes.

Scalars

A scalar represents a single value:

```
my $animal = "camel";
my $answer = 42;
```

Scalar values can be strings, integers or floating point numbers, and Perl will automatically convert between them as required. There is no need to pre-declare your variable types.

Scalar values can be used in various ways:

```
print $animal;
print "The animal is $animal\n";
print "The square of $answer is ", $answer * $answer, "\n";
```

There are a number of "magic" scalars with names that look like punctuation or line noise. These special variables are used for all kinds of purposes, and are documented in *perlvar*. The only one you need to know about for now is `$_` which is the "default variable". It's used as the default argument to a number of functions in Perl, and it's set implicitly by certain looping constructs.

```
print;          # prints contents of $_ by default
```

Arrays

An array represents a list of values:

```
my @animals = ("camel", "llama", "owl");
my @numbers = (23, 42, 69);
my @mixed   = ("camel", 42, 1.23);
```

Arrays are zero-indexed. Here's how you get at elements in an array:

```
print $animals[0];              # prints "camel"
print $animals[1];              # prints "llama"
```

The special variable `$#array` tells you the index of the last element of an array:

```
print $mixed[$#mixed];       # last element, prints 1.23
```

You might be tempted to use `$#array + 1` to tell you how many items there are in an array. Don't bother. As it happens, using `@array` where Perl expects to find a scalar value ("in scalar context") will give you the number of elements in the array:

```
if (@animals < 5) { ... }
```

The elements we're getting from the array start with a `$` because we're getting just a single value out of the array – you ask for a scalar, you get a scalar.

To get multiple values from an array:

```
@animals[0,1];                  # gives ("camel", "llama");
@animals[0..2];                 # gives ("camel", "llama", "owl");
@animals[1..$#animals];         # gives all except the first element
```

This is called an "array slice".

You can do various useful things to lists:

```
my @sorted    = sort @animals;
my @backwards = reverse @numbers;
```

There are a couple of special arrays too, such as `@ARGV` (the command line arguments to your script) and `@_` (the arguments passed to a subroutine). These are documented in *perlvar*.

Hashes

A hash represents a set of key/value pairs:

```
my %fruit_color = ("apple", "red", "banana", "yellow");
```

You can use whitespace and the => operator to lay them out more nicely:

```
my %fruit_color = (
    apple  => "red",
    banana => "yellow",
);
```

To get at hash elements:

```
$fruit_color{"apple"};           # gives "red"
```

You can get at lists of keys and values with `keys()` and `values()`.

```
my @fruits = keys %fruit_colors;
my @colors = values %fruit_colors;
```

Hashes have no particular internal order, though you can sort the keys and loop through them.

Just like special scalars and arrays, there are also special hashes. The most well known of these is `%ENV` which contains environment variables. Read all about it (and other special variables) in *perlvar*.

Scalars, arrays and hashes are documented more fully in *perldata*.

More complex data types can be constructed using references, which allow you to build lists and hashes within lists and hashes.

A reference is a scalar value and can refer to any other Perl data type. So by storing a reference as the value of an array or hash element, you can easily create lists and hashes within lists and hashes. The following example shows a 2 level hash of hash structure using anonymous hash references.

```
my $variables = {
    scalar  =>  {
                 description => "single item",
                 sigil => '$',
                },
    array   =>  {
                 description => "ordered list of items",
                 sigil => '@',
                },
    hash    =>  {
                 description => "key/value pairs",
                 sigil => '%',
                },
};

print "Scalars begin with a $variables->{'scalar'}->{'sigil'}\n";
```

Exhaustive information on the topic of references can be found in *perlreftut*, *perllol*, *perlref* and *perldsc*.

2.1.5 Variable scoping

Throughout the previous section all the examples have used the syntax:

```
my $var = "value";
```

The `my` is actually not required; you could just use:

```
$var = "value";
```

However, the above usage will create global variables throughout your program, which is bad programming practice. `my` creates lexically scoped variables instead. The variables are scoped to the block (i.e. a bunch of statements surrounded by curly-braces) in which they are defined.

```
my $a = "foo";
if ($some_condition) {
    my $b = "bar";
    print $a;           # prints "foo"
    print $b;           # prints "bar"
}
print $a;               # prints "foo"
print $b;               # prints nothing; $b has fallen out of scope
```

Using `my` in combination with a `use strict;` at the top of your Perl scripts means that the interpreter will pick up certain common programming errors. For instance, in the example above, the final `print $b` would cause a compile-time error and prevent you from running the program. Using `strict` is highly recommended.

2.1.6 Conditional and looping constructs

Perl has most of the usual conditional and looping constructs except for case/switch (but if you really want it, there is a Switch module in Perl 5.8 and newer, and on CPAN. See the section on modules, below, for more information about modules and CPAN).

The conditions can be any Perl expression. See the list of operators in the next section for information on comparison and boolean logic operators, which are commonly used in conditional statements.

if

```
if ( condition ) {
    ...
} elsif ( other condition ) {
    ...
} else {
    ...
}
```

There's also a negated version of it:

```
unless ( condition ) {
    ...
}
```

This is provided as a more readable version of `if (!`*`condition`*`)`.

Note that the braces are required in Perl, even if you've only got one line in the block. However, there is a clever way of making your one-line conditional blocks more English like:

```
    # the traditional way
    if ($zippy) {
        print "Yow!";
    }

    # the Perlish post-condition way
    print "Yow!" if $zippy;
    print "We have no bananas" unless $bananas;
```

while

```
    while ( condition ) {
        ...
    }
```

There's also a negated version, for the same reason we have `unless`:

```
    until ( condition ) {
        ...
    }
```

You can also use `while` in a post-condition:

```
    print "LA LA LA\n" while 1;          # loops forever
```

for

Exactly like C:

```
    for ($i=0; $i <= $max; $i++) {
        ...
    }
```

The C style for loop is rarely needed in Perl since Perl provides the more friendly list scanning `foreach` loop.

foreach

```
    foreach (@array) {
        print "This element is $_\n";
    }

    # you don't have to use the default $_ either...
    foreach my $key (keys %hash) {
        print "The value of $key is $hash{$key}\n";
    }
```

For more detail on looping constructs (and some that weren't mentioned in this overview) see *perlsyn*.

2.1.7 Builtin operators and functions

Perl comes with a wide selection of builtin functions. Some of the ones we've already seen include `print`, `sort` and `reverse`. A list of them is given at the start of *perlfunc* and you can easily read about any given function by using `perldoc -f` *`functionname`*.

Perl operators are documented in full in *perlop*, but here are a few of the most common ones:

Arithmetic

```
+   addition
-   subtraction
*   multiplication
/   division
```

Numeric comparison

```
==  equality
!=  inequality
<   less than
>   greater than
<=  less than or equal
>=  greater than or equal
```

String comparison

```
eq  equality
ne  inequality
lt  less than
gt  greater than
le  less than or equal
ge  greater than or equal
```

(Why do we have separate numeric and string comparisons? Because we don't have special variable types, and Perl needs to know whether to sort numerically (where 99 is less than 100) or alphabetically (where 100 comes before 99).

Boolean logic

```
&&  and
||  or
!   not
```

(`and`, `or` and `not` aren't just in the above table as descriptions of the operators – they're also supported as operators in their own right. They're more readable than the C-style operators, but have different precedence to && and friends. Check *perlop* for more detail.)

Miscellaneous

```
=   assignment
.   string concatenation
x   string multiplication
..  range operator (creates a list of numbers)
```

Many operators can be combined with a = as follows:

```
$a += 1;        # same as $a = $a + 1
$a -= 1;        # same as $a = $a - 1
$a .= "\n";     # same as $a = $a . "\n";
```

2.1.8 Files and I/O

You can open a file for input or output using the `open()` function. It's documented in extravagant detail in *perlfunc* and *perlopentut*, but in short:

```
open(INFILE,  "input.txt")   or die "Can't open input.txt: $!";
open(OUTFILE, ">output.txt") or die "Can't open output.txt: $!";
open(LOGFILE, ">>my.log")    or die "Can't open logfile: $!";
```

You can read from an open filehandle using the <> operator. In scalar context it reads a single line from the filehandle, and in list context it reads the whole file in, assigning each line to an element of the list:

```
my $line  = <INFILE>;
my @lines = <INFILE>;
```

Reading in the whole file at one time is called slurping. It can be useful but it may be a memory hog. Most text file processing can be done a line at a time with Perl's looping constructs.

The <> operator is most often seen in a `while` loop:

```
while (<INFILE>) {     # assigns each line in turn to $_
    print "Just read in this line: $_";
}
```

We've already seen how to print to standard output using `print()`. However, `print()` can also take an optional first argument specifying which filehandle to print to:

```
print STDERR "This is your final warning.\n";
print OUTFILE $record;
print LOGFILE $logmessage;
```

When you're done with your filehandles, you should `close()` them (though to be honest, Perl will clean up after you if you forget):

```
close INFILE;
```

2.1.9 Regular expressions

Perl's regular expression support is both broad and deep, and is the subject of lengthy documentation in *perlrequick*, *perlretut*, and elsewhere. However, in short:

Simple matching

```
if (/foo/)       { ... }  # true if $_ contains "foo"
if ($a =~ /foo/) { ... }  # true if $a contains "foo"
```

The `//` matching operator is documented in *perlop*. It operates on `$_` by default, or can be bound to another variable using the =˜ binding operator (also documented in *perlop*).

Simple substitution

```
s/foo/bar/;               # replaces foo with bar in $_
$a =~ s/foo/bar/;         # replaces foo with bar in $a
$a =~ s/foo/bar/g;        # replaces ALL INSTANCES of foo with bar in $a
```

The `s///` substitution operator is documented in *perlop*.

More complex regular expressions

You don't just have to match on fixed strings. In fact, you can match on just about anything you could dream of by using more complex regular expressions. These are documented at great length in *perlre*, but for the meantime, here's a quick cheat sheet:

```
    .                   a single character
    \s                  a whitespace character (space, tab, newline)
    \S                  non-whitespace character
    \d                  a digit (0-9)
    \D                  a non-digit
    \w                  a word character (a-z, A-Z, 0-9, _)
    \W                  a non-word character
    [aeiou]             matches a single character in the given set
    [^aeiou]            matches a single character outside the given set
    (foo|bar|baz)       matches any of the alternatives specified

    ^                   start of string
    $                   end of string
```

Quantifiers can be used to specify how many of the previous thing you want to match on, where "thing" means either a literal character, one of the metacharacters listed above, or a group of characters or metacharacters in parentheses.

```
    *                   zero or more of the previous thing
    +                   one or more of the previous thing
    ?                   zero or one of the previous thing
    {3}                 matches exactly 3 of the previous thing
    {3,6}               matches between 3 and 6 of the previous thing
    {3,}                matches 3 or more of the previous thing
```

Some brief examples:

```
    /^\d+/              string starts with one or more digits
    /^$/                nothing in the string (start and end are adjacent)
    /(\d\s){3}/         a three digits, each followed by a whitespace
                        character (eg "3 4 5 ")
    /(a.)+/             matches a string in which every odd-numbered letter
                        is a (eg "abacadaf")

    # This loop reads from STDIN, and prints non-blank lines:
    while (<>) {
        next if /^$/;
        print;
    }
```

Parentheses for capturing

As well as grouping, parentheses serve a second purpose. They can be used to capture the results of parts of the regexp match for later use. The results end up in $1, $2 and so on.

```
    # a cheap and nasty way to break an email address up into parts

    if ($email =~ /([^@])+@(.+)/) {
        print "Username is $1\n";
        print "Hostname is $2\n";
    }
```

Other regexp features

Perl regexps also support backreferences, lookaheads, and all kinds of other complex details. Read all about them in *perlrequick*, *perlretut*, and *perlre*.

2.1.10 Writing subroutines

Writing subroutines is easy:

```
    sub log {
        my $logmessage = shift;
        print LOGFILE $logmessage;
    }
```

What's that `shift`? Well, the arguments to a subroutine are available to us as a special array called `@_` (see *perlvar* for more on that). The default argument to the `shift` function just happens to be `@_`. So `my $logmessage = shift;` shifts the first item off the list of arguments and assigns it to `$logmessage`.

We can manipulate `@_` in other ways too:

```
    my ($logmessage, $priority) = @_;       # common
    my $logmessage = $_[0];                 # uncommon, and ugly
```

Subroutines can also return values:

```
    sub square {
        my $num = shift;
        my $result = $num * $num;
        return $result;
    }
```

For more information on writing subroutines, see *perlsub*.

2.1.11 OO Perl

OO Perl is relatively simple and is implemented using references which know what sort of object they are based on Perl's concept of packages. However, OO Perl is largely beyond the scope of this document. Read *perlboot*, *perltoot*, *perltooc* and *perlobj*.

As a beginning Perl programmer, your most common use of OO Perl will be in using third-party modules, which are documented below.

2.1.12 Using Perl modules

Perl modules provide a range of features to help you avoid reinventing the wheel, and can be downloaded from CPAN (http://www.cpan.org/). A number of popular modules are included with the Perl distribution itself.

Categories of modules range from text manipulation to network protocols to database integration to graphics. A categorized list of modules is also available from CPAN.

To learn how to install modules you download from CPAN, read *perlmodinstall*

To learn how to use a particular module, use `perldoc` ***`Module::Name`***. Typically you will want to `use` ***`Module::Name`***, which will then give you access to exported functions or an OO interface to the module.

perlfaq contains questions and answers related to many common tasks, and often provides suggestions for good CPAN modules to use.

perlmod describes Perl modules in general. *perlmodlib* lists the modules which came with your Perl installation.

If you feel the urge to write Perl modules, *perlnewmod* will give you good advice.

Chapter 3

perlreftut

Mark's very short tutorial about references

3.1 DESCRIPTION

One of the most important new features in Perl 5 was the capability to manage complicated data structures like multidimensional arrays and nested hashes. To enable these, Perl 5 introduced a feature called 'references', and using references is the key to managing complicated, structured data in Perl. Unfortunately, there's a lot of funny syntax to learn, and the main manual page can be hard to follow. The manual is quite complete, and sometimes people find that a problem, because it can be hard to tell what is important and what isn't.

Fortunately, you only need to know 10% of what's in the main page to get 90% of the benefit. This page will show you that 10%.

3.2 Who Needs Complicated Data Structures?

One problem that came up all the time in Perl 4 was how to represent a hash whose values were lists. Perl 4 had hashes, of course, but the values had to be scalars; they couldn't be lists.

Why would you want a hash of lists? Let's take a simple example: You have a file of city and country names, like this:

```
Chicago, USA
Frankfurt, Germany
Berlin, Germany
Washington, USA
Helsinki, Finland
New York, USA
```

and you want to produce an output like this, with each country mentioned once, and then an alphabetical list of the cities in that country:

```
Finland: Helsinki.
Germany: Berlin, Frankfurt.
USA:  Chicago, New York, Washington.
```

The natural way to do this is to have a hash whose keys are country names. Associated with each country name key is a list of the cities in that country. Each time you read a line of input, split it into a country and a city, look up the list of cities already known to be in that country, and append the new city to the list. When you're done reading the input, iterate over the hash as usual, sorting each list of cities before you print it out.

If hash values can't be lists, you lose. In Perl 4, hash values can't be lists; they can only be strings. You lose. You'd probably have to combine all the cities into a single string somehow, and then when time came to write the output, you'd have to break the string into a list, sort the list, and turn it back into a string. This is messy and error-prone. And it's frustrating, because Perl already has perfectly good lists that would solve the problem if only you could use them.

3.3 The Solution

By the time Perl 5 rolled around, we were already stuck with this design: Hash values must be scalars. The solution to this is references.

A reference is a scalar value that *refers to* an entire array or an entire hash (or to just about anything else). Names are one kind of reference that you're already familiar with. Think of the President of the United States: a messy, inconvenient bag of blood and bones. But to talk about him, or to represent him in a computer program, all you need is the easy, convenient scalar string "George Bush".

References in Perl are like names for arrays and hashes. They're Perl's private, internal names, so you can be sure they're unambiguous. Unlike "George Bush", a reference only refers to one thing, and you always know what it refers to. If you have a reference to an array, you can recover the entire array from it. If you have a reference to a hash, you can recover the entire hash. But the reference is still an easy, compact scalar value.

You can't have a hash whose values are arrays; hash values can only be scalars. We're stuck with that. But a single reference can refer to an entire array, and references are scalars, so you can have a hash of references to arrays, and it'll act a lot like a hash of arrays, and it'll be just as useful as a hash of arrays.

We'll come back to this city-country problem later, after we've seen some syntax for managing references.

3.4 Syntax

There are just two ways to make a reference, and just two ways to use it once you have it.

3.4.1 Making References

Make Rule 1

If you put a \ in front of a variable, you get a reference to that variable.

```
$aref = \@array;         # $aref now holds a reference to @array
$href = \%hash;          # $href now holds a reference to %hash
```

Once the reference is stored in a variable like $aref or $href, you can copy it or store it just the same as any other scalar value:

```
$xy = $aref;             # $xy now holds a reference to @array
$p[3] = $href;           # $p[3] now holds a reference to %hash
$z = $p[3];              # $z now holds a reference to %hash
```

These examples show how to make references to variables with names. Sometimes you want to make an array or a hash that doesn't have a name. This is analogous to the way you like to be able to use the string "`\n`" or the number 80 without having to store it in a named variable first.

Make Rule 2

`[ ITEMS ]` makes a new, anonymous array, and returns a reference to that array. `{ ITEMS }` makes a new, anonymous hash, and returns a reference to that hash.

```
$aref = [ 1, "foo", undef, 13 ];
# $aref now holds a reference to an array

$href = { APR => 4, AUG => 8 };
# $href now holds a reference to a hash
```

The references you get from rule 2 are the same kind of references that you get from rule 1:

```
# This:
$aref = [ 1, 2, 3 ];

# Does the same as this:
@array = (1, 2, 3);
$aref = \@array;
```

The first line is an abbreviation for the following two lines, except that it doesn't create the superfluous array variable `@array`.

If you write just `[]`, you get a new, empty anonymous array. If you write just `{}`, you get a new, empty anonymous hash.

3.4.2 Using References

What can you do with a reference once you have it? It's a scalar value, and we've seen that you can store it as a scalar and get it back again just like any scalar. There are just two more ways to use it:

Use Rule 1

You can always use an array reference, in curly braces, in place of the name of an array. For example, `@{$aref}` instead of `@array`.

Here are some examples of that:

Arrays:

```
@a              @{$aref}              An array
reverse @a      reverse @{$aref}      Reverse the array
$a[3]           ${$aref}[3]           An element of the array
$a[3] = 17;     ${$aref}[3] = 17      Assigning an element
```

On each line are two expressions that do the same thing. The left-hand versions operate on the array `@a`. The right-hand versions operate on the array that is referred to by `$aref`. Once they find the array they're operating on, both versions do the same things to the arrays.

Using a hash reference is *exactly* the same:

```
%h              %{$href}              A hash
keys %h         keys %{$href}         Get the keys from the hash
$h{'red'}       ${$href}{'red'}       An element of the hash
$h{'red'} = 17  ${$href}{'red'} = 17  Assigning an element
```

Whatever you want to do with a reference, **Use Rule 1** tells you how to do it. You just write the Perl code that you would have written for doing the same thing to a regular array or hash, and then replace the array or hash name with `{$reference}`. "How do I loop over an array when all I have is a reference?" Well, to loop over an array, you would write

```
for my $element (@array) {
   ...
}
```

so replace the array name, `@array`, with the reference:

```
for my $element (@{$aref}) {
   ...
}
```

"How do I print out the contents of a hash when all I have is a reference?" First write the code for printing out a hash:

```
for my $key (keys %hash) {
  print "$key => $hash{$key}\n";
}
```

And then replace the hash name with the reference:

```
for my $key (keys %{$href}) {
  print "$key => ${$href}{$key}\n";
}
```

Use Rule 2

Use Rule 1 is all you really need, because it tells you how to to absolutely everything you ever need to do with references. But the most common thing to do with an array or a hash is to extract a single element, and the **Use Rule 1** notation is cumbersome. So there is an abbreviation.

`${$aref}[3]` is too hard to read, so you can write `$aref->[3]` instead.

`${$href}{red}` is too hard to read, so you can write `$href->{red}` instead.

If `$aref` holds a reference to an array, then `$aref->[3]` is the fourth element of the array. Don't confuse this with `$aref[3]`, which is the fourth element of a totally different array, one deceptively named `@aref`. `$aref` and `@aref` are unrelated the same way that `$item` and `@item` are.

Similarly, `$href->{'red'}` is part of the hash referred to by the scalar variable `$href`, perhaps even one with no name. `$href{'red'}` is part of the deceptively named `%href` hash. It's easy to forget to leave out the `->`, and if you do, you'll get bizarre results when your program gets array and hash elements out of totally unexpected hashes and arrays that weren't the ones you wanted to use.

3.4.3 An Example

Let's see a quick example of how all this is useful.

First, remember that `[1, 2, 3]` makes an anonymous array containing `(1, 2, 3)`, and gives you a reference to that array.

Now think about

```
@a = ( [1, 2, 3],
       [4, 5, 6],
       [7, 8, 9]
     );
```

@a is an array with three elements, and each one is a reference to another array.

`$a[1]` is one of these references. It refers to an array, the array containing `(4, 5, 6)`, and because it is a reference to an array, **Use Rule 2** says that we can write `$a[1]->[2]` to get the third element from that array. `$a[1]->[2]` is the 6. Similarly, `$a[0]->[1]` is the 2. What we have here is like a two-dimensional array; you can write `$a[ROW]->[COLUMN]` to get or set the element in any row and any column of the array.

The notation still looks a little cumbersome, so there's one more abbreviation:

3.4.4 Arrow Rule

In between two **subscripts**, the arrow is optional.

Instead of `$a[1]->[2]`, we can write `$a[1][2]`; it means the same thing. Instead of `$a[0]->[1] = 23`, we can write `$a[0][1] = 23`; it means the same thing.

Now it really looks like two-dimensional arrays!

You can see why the arrows are important. Without them, we would have had to write `${$a[1]}[2]` instead of `$a[1][2]`. For three-dimensional arrays, they let us write `$x[2][3][5]` instead of the unreadable `${${$x[2]}[3]}[5]`.

3.5 Solution

Here's the answer to the problem I posed earlier, of reformatting a file of city and country names.

```
 1   my %table;

 2   while (<>) {
 3    chomp;
 4     my ($city, $country) = split /, /;
 5     $table{$country} = [] unless exists $table{$country};
 6     push @{$table{$country}}, $city;
 7   }

 8   foreach $country (sort keys %table) {
 9     print "$country: ";
10     my @cities = @{$table{$country}};
11     print join ', ', sort @cities;
12     print ".\n";
13   }
```

The program has two pieces: Lines 2–7 read the input and build a data structure, and lines 8-13 analyze the data and print out the report. We're going to have a hash, `%table`, whose keys are country names, and whose values are references to arrays of city names. The data structure will look like this:

```
   %table
+-------+---+
|       |   |   +-----------+--------+
|Germany| *---->| Frankfurt | Berlin |
|       |   |   +-----------+--------+
+-------+---+
|       |   |   +----------+
|Finland| *---->| Helsinki |
|       |   |   +----------+
+-------+---+
|       |   |   +---------+------------+----------+
|  USA  | *---->| Chicago | Washington | New York |
|       |   |   +---------+------------+----------+
+-------+---+
```

We'll look at output first. Supposing we already have this structure, how do we print it out?

```
 8   foreach $country (sort keys %table) {
 9     print "$country: ";
10     my @cities = @{$table{$country}};
11     print join ', ', sort @cities;
12     print ".\n";
13   }
```

`%table` is an ordinary hash, and we get a list of keys from it, sort the keys, and loop over the keys as usual. The only use of references is in line 10. `$table{$country}` looks up the key `$country` in the hash and gets the value, which is a reference to an array of cities in that country. **Use Rule 1** says that we can recover the array by saying `@{$table{$country}}`. Line 10 is just like

```
@cities = @array;
```

except that the name `array` has been replaced by the reference `{$table{$country}}`. The `@` tells Perl to get the entire array. Having gotten the list of cities, we sort it, join it, and print it out as usual.

Lines 2-7 are responsible for building the structure in the first place. Here they are again:

```
2   while (<>) {
3    chomp;
4     my ($city, $country) = split /, /;
5     $table{$country} = [] unless exists $table{$country};
6     push @{$table{$country}}, $city;
7   }
```

Lines 2-4 acquire a city and country name. Line 5 looks to see if the country is already present as a key in the hash. If it's not, the program uses the `[]` notation (**Make Rule 2**) to manufacture a new, empty anonymous array of cities, and installs a reference to it into the hash under the appropriate key.

Line 6 installs the city name into the appropriate array. `$table{$country}` now holds a reference to the array of cities seen in that country so far. Line 6 is exactly like

```
push @array, $city;
```

except that the name `array` has been replaced by the reference `{$table{$country}}`. The `push` adds a city name to the end of the referred-to array.

There's one fine point I skipped. Line 5 is unnecessary, and we can get rid of it.

```
2   while (<>) {
3    chomp;
4     my ($city, $country) = split /, /;
5   ####  $table{$country} = [] unless exists $table{$country};
6     push @{$table{$country}}, $city;
7   }
```

If there's already an entry in `%table` for the current `$country`, then nothing is different. Line 6 will locate the value in `$table{$country}`, which is a reference to an array, and push `$city` into the array. But what does it do when `$country` holds a key, say `Greece`, that is not yet in `%table`?

This is Perl, so it does the exact right thing. It sees that you want to push `Athens` onto an array that doesn't exist, so it helpfully makes a new, empty, anonymous array for you, installs it into `%table`, and then pushes `Athens` onto it. This is called 'autovivification'–bringing things to life automatically. Perl saw that they key wasn't in the hash, so it created a new hash entry automatically. Perl saw that you wanted to use the hash value as an array, so it created a new empty array and installed a reference to it in the hash automatically. And as usual, Perl made the array one element longer to hold the new city name.

3.6 The Rest

I promised to give you 90% of the benefit with 10% of the details, and that means I left out 90% of the details. Now that you have an overview of the important parts, it should be easier to read the *perlref* manual page, which discusses 100% of the details.

Some of the highlights of *perlref*:

- You can make references to anything, including scalars, functions, and other references.
- In **Use Rule 1**, you can omit the curly brackets whenever the thing inside them is an atomic scalar variable like `$aref`. For example, `@$aref` is the same as `@{$aref}`, and `$$aref[1]` is the same as `${$aref}[1]`. If you're just starting out, you may want to adopt the habit of always including the curly brackets.
- This doesn't copy the underlying array:

```
$aref2 = $aref1;
```

You get two references to the same array. If you modify `$aref1->[23]` and then look at `$aref2->[23]` you'll see the change.

To copy the array, use

```
$aref2 = [@{$aref1}];
```

This uses `[...]` notation to create a new anonymous array, and `$aref2` is assigned a reference to the new array. The new array is initialized with the contents of the array referred to by `$aref1`.

Similarly, to copy an anonymous hash, you can use

```
$href2 = {%{$href1}};
```

- To see if a variable contains a reference, use the `ref` function. It returns true if its argument is a reference. Actually it's a little better than that: It returns `HASH` for hash references and `ARRAY` for array references.
- If you try to use a reference like a string, you get strings like

  ```
  ARRAY(0x80f5dec)   or    HASH(0x826afc0)
  ```

  If you ever see a string that looks like this, you'll know you printed out a reference by mistake.

  A side effect of this representation is that you can use `eq` to see if two references refer to the same thing. (But you should usually use == instead because it's much faster.)
- You can use a string as if it were a reference. If you use the string `"foo"` as an array reference, it's taken to be a reference to the array `@foo`. This is called a *soft reference* or *symbolic reference*. The declaration `use strict 'refs'` disables this feature, which can cause all sorts of trouble if you use it by accident.

You might prefer to go on to *perllol* instead of *perlref*; it discusses lists of lists and multidimensional arrays in detail. After that, you should move on to *perldsc*; it's a Data Structure Cookbook that shows recipes for using and printing out arrays of hashes, hashes of arrays, and other kinds of data.

3.7 Summary

Everyone needs compound data structures, and in Perl the way you get them is with references. There are four important rules for managing references: Two for making references and two for using them. Once you know these rules you can do most of the important things you need to do with references.

Perl Data Structures Cookbook

4.1 DESCRIPTION

The single feature most sorely lacking in the Perl programming language prior to its 5.0 release was complex data structures. Even without direct language support, some valiant programmers did manage to emulate them, but it was hard work and not for the faint of heart. You could occasionally get away with the `$m{$AoA,$b}` notation borrowed from **awk** in which the keys are actually more like a single concatenated string `"$AoA$b"`, but traversal and sorting were difficult. More desperate programmers even hacked Perl's internal symbol table directly, a strategy that proved hard to develop and maintain–to put it mildly.

The 5.0 release of Perl let us have complex data structures. You may now write something like this and all of a sudden, you'd have an array with three dimensions!

```
for $x (1 .. 10) {
    for $y (1 .. 10) {
        for $z (1 .. 10) {
            $AoA[$x][$y][$z] =
                $x ** $y + $z;
        }
    }
}
```

Alas, however simple this may appear, underneath it's a much more elaborate construct than meets the eye!

How do you print it out? Why can't you say just `print @AoA`? How do you sort it? How can you pass it to a function or get one of these back from a function? Is it an object? Can you save it to disk to read back later? How do you access whole rows or columns of that matrix? Do all the values have to be numeric?

As you see, it's quite easy to become confused. While some small portion of the blame for this can be attributed to the reference-based implementation, it's really more due to a lack of existing documentation with examples designed for the beginner.

This document is meant to be a detailed but understandable treatment of the many different sorts of data structures you might want to develop. It should also serve as a cookbook of examples. That way, when you need to create one of these complex data structures, you can just pinch, pilfer, or purloin a drop-in example from here.

Let's look at each of these possible constructs in detail. There are separate sections on each of the following:

- arrays of arrays
- hashes of arrays

- arrays of hashes
- hashes of hashes
- more elaborate constructs

But for now, let's look at general issues common to all these types of data structures.

4.2 REFERENCES

The most important thing to understand about all data structures in Perl – including multidimensional arrays–is that even though they might appear otherwise, Perl `@ARRAY`s and `%HASH`es are all internally one-dimensional. They can hold only scalar values (meaning a string, number, or a reference). They cannot directly contain other arrays or hashes, but instead contain *references* to other arrays or hashes.

You can't use a reference to an array or hash in quite the same way that you would a real array or hash. For C or C++ programmers unused to distinguishing between arrays and pointers to the same, this can be confusing. If so, just think of it as the difference between a structure and a pointer to a structure.

You can (and should) read more about references in the perlref(1) man page. Briefly, references are rather like pointers that know what they point to. (Objects are also a kind of reference, but we won't be needing them right away–if ever.) This means that when you have something which looks to you like an access to a two-or-more-dimensional array and/or hash, what's really going on is that the base type is merely a one-dimensional entity that contains references to the next level. It's just that you can *use* it as though it were a two-dimensional one. This is actually the way almost all C multidimensional arrays work as well.

```
    $array[7][12]                       # array of arrays
    $array[7]{string}                   # array of hashes
    $hash{string}[7]                    # hash of arrays
    $hash{string}{'another string'}     # hash of hashes
```

Now, because the top level contains only references, if you try to print out your array in with a simple print() function, you'll get something that doesn't look very nice, like this:

```
    @AoA = ( [2, 3], [4, 5, 7], [0] );
    print $AoA[1][2];
  7
    print @AoA;
  ARRAY(0x83c38)ARRAY(0x8b194)ARRAY(0x8b1d0)
```

That's because Perl doesn't (ever) implicitly dereference your variables. If you want to get at the thing a reference is referring to, then you have to do this yourself using either prefix typing indicators, like `${$blah}`, `@{$blah}`, `@{$blah[$i]}`, or else postfix pointer arrows, like `$a->[3]`, `$h->{fred}`, or even `$ob->method()->[3]`.

4.3 COMMON MISTAKES

The two most common mistakes made in constructing something like an array of arrays is either accidentally counting the number of elements or else taking a reference to the same memory location repeatedly. Here's the case where you just get the count instead of a nested array:

```
    for $i (1..10) {
        @array = somefunc($i);
        $AoA[$i] = @array;      # WRONG!
    }
```

That's just the simple case of assigning an array to a scalar and getting its element count. If that's what you really and truly want, then you might do well to consider being a tad more explicit about it, like this:

```
for $i (1..10) {
    @array = somefunc($i);
    $counts[$i] = scalar @array;
}
```

Here's the case of taking a reference to the same memory location again and again:

```
for $i (1..10) {
    @array = somefunc($i);
    $AoA[$i] = \@array;     # WRONG!
}
```

So, what's the big problem with that? It looks right, doesn't it? After all, I just told you that you need an array of references, so by golly, you've made me one!

Unfortunately, while this is true, it's still broken. All the references in @AoA refer to the *very same place*, and they will therefore all hold whatever was last in @array! It's similar to the problem demonstrated in the following C program:

```
#include <pwd.h>
main() {
    struct passwd *getpwnam(), *rp, *dp;
    rp = getpwnam("root");
    dp = getpwnam("daemon");

    printf("daemon name is %s\nroot name is %s\n",
            dp->pw_name, rp->pw_name);
}
```

Which will print

```
daemon name is daemon
root name is daemon
```

The problem is that both `rp` and `dp` are pointers to the same location in memory! In C, you'd have to remember to malloc() yourself some new memory. In Perl, you'll want to use the array constructor `[]` or the hash constructor `{}` instead. Here's the right way to do the preceding broken code fragments:

```
for $i (1..10) {
    @array = somefunc($i);
    $AoA[$i] = [ @array ];
}
```

The square brackets make a reference to a new array with a *copy* of what's in @array at the time of the assignment. This is what you want.

Note that this will produce something similar, but it's much harder to read:

```
for $i (1..10) {
    @array = 0 .. $i;
    @{$AoA[$i]} = @array;
}
```

Is it the same? Well, maybe so–and maybe not. The subtle difference is that when you assign something in square brackets, you know for sure it's always a brand new reference with a new *copy* of the data. Something else could be going on in this new case with the `@{$AoA[$i]}}` dereference on the left-hand-side of the assignment. It all depends on whether `$AoA[$i]` had been undefined to start with, or whether it already contained a reference. If you had already populated @AoA with references, as in

```
    $AoA[3] = \@another_array;
```

Then the assignment with the indirection on the left-hand-side would use the existing reference that was already there:

```
    @{$AoA[3]} = @array;
```

Of course, this *would* have the "interesting" effect of clobbering @another_array. (Have you ever noticed how when a programmer says something is "interesting", that rather than meaning "intriguing", they're disturbingly more apt to mean that it's "annoying", "difficult", or both? :-)

So just remember always to use the array or hash constructors with `[]` or `{}`, and you'll be fine, although it's not always optimally efficient.

Surprisingly, the following dangerous-looking construct will actually work out fine:

```
    for $i (1..10) {
        my @array = somefunc($i);
        $AoA[$i] = \@array;
    }
```

That's because my() is more of a run-time statement than it is a compile-time declaration *per se*. This means that the my() variable is remade afresh each time through the loop. So even though it *looks* as though you stored the same variable reference each time, you actually did not! This is a subtle distinction that can produce more efficient code at the risk of misleading all but the most experienced of programmers. So I usually advise against teaching it to beginners. In fact, except for passing arguments to functions, I seldom like to see the gimme-a-reference operator (backslash) used much at all in code. Instead, I advise beginners that they (and most of the rest of us) should try to use the much more easily understood constructors `[]` and `{}` instead of relying upon lexical (or dynamic) scoping and hidden reference-counting to do the right thing behind the scenes.

In summary:

```
    $AoA[$i] = [ @array ];      # usually best
    $AoA[$i] = \@array;         # perilous; just how my() was that array?
    @{ $AoA[$i] } = @array;     # way too tricky for most programmers
```

4.4 CAVEAT ON PRECEDENCE

Speaking of things like `@{$AoA[$i]}`, the following are actually the same thing:

```
    $aref->[2][2]       # clear
    $$aref[2][2]        # confusing
```

That's because Perl's precedence rules on its five prefix dereferencers (which look like someone swearing: `$ @ * % &`) make them bind more tightly than the postfix subscripting brackets or braces! This will no doubt come as a great shock to the C or C++ programmer, who is quite accustomed to using `*a[i]` to mean what's pointed to by the *i'th* element of `a`. That is, they first take the subscript, and only then dereference the thing at that subscript. That's fine in C, but this isn't C.

The seemingly equivalent construct in Perl, `$$aref[$i]` first does the deref of $aref, making it take $aref as a reference to an array, and then dereference that, and finally tell you the *i'th* value of the array pointed to by $AoA. If you wanted the C notion, you'd have to write `${$AoA[$i]}` to force the `$AoA[$i]` to get evaluated first before the leading `$` dereferencer.

4.5 WHY YOU SHOULD ALWAYS `use strict`

If this is starting to sound scarier than it's worth, relax. Perl has some features to help you avoid its most common pitfalls. The best way to avoid getting confused is to start every program like this:

```
#!/usr/bin/perl -w
use strict;
```

This way, you'll be forced to declare all your variables with my() and also disallow accidental "symbolic dereferencing". Therefore if you'd done this:

```
my $aref = [
    [ "fred", "barney", "pebbles", "bambam", "dino", ],
    [ "homer", "bart", "marge", "maggie", ],
    [ "george", "jane", "elroy", "judy", ],
];

print $aref[2][2];
```

The compiler would immediately flag that as an error *at compile time*, because you were accidentally accessing `@aref`, an undeclared variable, and it would thereby remind you to write instead:

```
print $aref->[2][2]
```

4.6 DEBUGGING

Before version 5.002, the standard Perl debugger didn't do a very nice job of printing out complex data structures. With 5.002 or above, the debugger includes several new features, including command line editing as well as the `x` command to dump out complex data structures. For example, given the assignment to $AoA above, here's the debugger output:

```
DB<1> x $AoA
$AoA = ARRAY(0x13b5a0)
   0  ARRAY(0x1f0a24)
      0  'fred'
      1  'barney'
      2  'pebbles'
      3  'bambam'
      4  'dino'
   1  ARRAY(0x13b558)
      0  'homer'
      1  'bart'
      2  'marge'
      3  'maggie'
   2  ARRAY(0x13b540)
      0  'george'
      1  'jane'
      2  'elroy'
      3  'judy'
```

4.7 CODE EXAMPLES

Presented with little comment (these will get their own manpages someday) here are short code examples illustrating access of various types of data structures.

4.8 ARRAYS OF ARRAYS

4.8.1 Declaration of an ARRAY OF ARRAYS

```
@AoA = (
       [ "fred", "barney" ],
       [ "george", "jane", "elroy" ],
       [ "homer", "marge", "bart" ],
     );
```

4.8.2 Generation of an ARRAY OF ARRAYS

```
# reading from file
while ( <> ) {
    push @AoA, [ split ];
}

# calling a function
for $i ( 1 .. 10 ) {
    $AoA[$i] = [ somefunc($i) ];
}

# using temp vars
for $i ( 1 .. 10 ) {
    @tmp = somefunc($i);
    $AoA[$i] = [ @tmp ];
}

# add to an existing row
push @{ $AoA[0] }, "wilma", "betty";
```

4.8.3 Access and Printing of an ARRAY OF ARRAYS

```
# one element
$AoA[0][0] = "Fred";

# another element
$AoA[1][1] =~ s/(\w)/\u$1/;

# print the whole thing with refs
for $aref ( @AoA ) {
    print "\t [ @$aref ],\n";
}

# print the whole thing with indices
for $i ( 0 .. $#AoA ) {
    print "\t [ @{$AoA[$i]} ],\n";
}

# print the whole thing one at a time
for $i ( 0 .. $#AoA ) {
    for $j ( 0 .. $#{ $AoA[$i] } ) {
        print "elt $i $j is $AoA[$i][$j]\n";
    }
}
```

4.9 HASHES OF ARRAYS

4.9.1 Declaration of a HASH OF ARRAYS

```
%HoA = (
       flintstones        => [ "fred", "barney" ],
       jetsons            => [ "george", "jane", "elroy" ],
       simpsons           => [ "homer", "marge", "bart" ],
     );
```

4.9.2 Generation of a HASH OF ARRAYS

```
# reading from file
# flintstones: fred barney wilma dino
while ( <> ) {
    next unless s/^(.*?):\s*//;
    $HoA{$1} = [ split ];
}

# reading from file; more temps
# flintstones: fred barney wilma dino
while ( $line = <> ) {
    ($who, $rest) = split /:\s*/, $line, 2;
    @fields = split ' ', $rest;
    $HoA{$who} = [ @fields ];
}

# calling a function that returns a list
for $group ( "simpsons", "jetsons", "flintstones" ) {
    $HoA{$group} = [ get_family($group) ];
}

# likewise, but using temps
for $group ( "simpsons", "jetsons", "flintstones" ) {
    @members = get_family($group);
    $HoA{$group} = [ @members ];
}

# append new members to an existing family
push @{ $HoA{"flintstones"} }, "wilma", "betty";
```

4.9.3 Access and Printing of a HASH OF ARRAYS

```
# one element
$HoA{flintstones}[0] = "Fred";

# another element
$HoA{simpsons}[1] =~ s/(\w)/\u$1/;

# print the whole thing
foreach $family ( keys %HoA ) {
    print "$family: @{ $HoA{$family} }\n"
}
```

```
# print the whole thing with indices
foreach $family ( keys %HoA ) {
    print "family: ";
    foreach $i ( 0 .. $#{ $HoA{$family} } ) {
        print " $i = $HoA{$family}[$i]";
    }
    print "\n";
}

# print the whole thing sorted by number of members
foreach $family ( sort { @{$HoA{$b}} <=> @{$HoA{$a}} } keys %HoA ) {
    print "$family: @{ $HoA{$family} }\n"
}

# print the whole thing sorted by number of members and name
foreach $family ( sort {
                           @{$HoA{$b}} <=> @{$HoA{$a}}
                                       ||
                                   $a cmp $b
           } keys %HoA )
{
    print "$family: ", join(", ", sort @{ $HoA{$family} }), "\n";
}
```

4.10 ARRAYS OF HASHES

4.10.1 Declaration of an ARRAY OF HASHES

```
@AoH = (
       {
           Lead     => "fred",
           Friend   => "barney",
       },
       {
           Lead     => "george",
           Wife     => "jane",
           Son      => "elroy",
       },
       {
           Lead     => "homer",
           Wife     => "marge",
           Son      => "bart",
       }
 );
```

4.10.2 Generation of an ARRAY OF HASHES

```
# reading from file
# format: LEAD=fred FRIEND=barney
while ( <> ) {
    $rec = {};
    for $field ( split ) {
        ($key, $value) = split /=/, $field;
        $rec->{$key} = $value;
    }
    push @AoH, $rec;
}

# reading from file
# format: LEAD=fred FRIEND=barney
# no temp
while ( <> ) {
    push @AoH, { split /[\s+=]/ };
}

# calling a function  that returns a key/value pair list, like
# "lead","fred","daughter","pebbles"
while ( %fields = getnextpairset() ) {
    push @AoH, { %fields };
}

# likewise, but using no temp vars
while (<>) {
    push @AoH, { parsepairs($_) };
}

# add key/value to an element
$AoH[0]{pet} = "dino";
$AoH[2]{pet} = "santa's little helper";
```

4.10.3 Access and Printing of an ARRAY OF HASHES

```
# one element
$AoH[0]{lead} = "fred";

# another element
$AoH[1]{lead} =~ s/(\w)/\u$1/;

# print the whole thing with refs
for $href ( @AoH ) {
    print "{ ";
    for $role ( keys %$href ) {
        print "$role=$href->{$role} ";
    }
    print "}\n";
}

# print the whole thing with indices
for $i ( 0 .. $#AoH ) {
    print "$i is { ";
    for $role ( keys %{ $AoH[$i] } ) {
        print "$role=$AoH[$i]{$role} ";
    }
    print "}\n";
}

# print the whole thing one at a time
for $i ( 0 .. $#AoH ) {
    for $role ( keys %{ $AoH[$i] } ) {
        print "elt $i $role is $AoH[$i]{$role}\n";
    }
}
```

4.11 HASHES OF HASHES

4.11.1 Declaration of a HASH OF HASHES

```
%HoH = (
       flintstones => {
               lead      => "fred",
               pal       => "barney",
       },
       jetsons     => {
               lead      => "george",
               wife      => "jane",
               "his boy" => "elroy",
       },
       simpsons    => {
               lead      => "homer",
               wife      => "marge",
               kid       => "bart",
       },
);
```

4.11.2 Generation of a HASH OF HASHES

```
# reading from file
# flintstones: lead=fred pal=barney wife=wilma pet=dino
while ( <> ) {
    next unless s/^(.*?):\s*//;
    $who = $1;
    for $field ( split ) {
        ($key, $value) = split /=/, $field;
        $HoH{$who}{$key} = $value;
    }

# reading from file; more temps
while ( <> ) {
    next unless s/^(.*?):\s*//;
    $who = $1;
    $rec = {};
    $HoH{$who} = $rec;
    for $field ( split ) {
        ($key, $value) = split /=/, $field;
        $rec->{$key} = $value;
    }
}

# calling a function  that returns a key,value hash
for $group ( "simpsons", "jetsons", "flintstones" ) {
    $HoH{$group} = { get_family($group) };
}

# likewise, but using temps
for $group ( "simpsons", "jetsons", "flintstones" ) {
    %members = get_family($group);
    $HoH{$group} = { %members };
}
```

```
# append new members to an existing family
%new_folks = (
    wife => "wilma",
    pet  => "dino",
);

for $what (keys %new_folks) {
    $HoH{flintstones}{$what} = $new_folks{$what};
}
```

4.11.3 Access and Printing of a HASH OF HASHES

```
# one element
$HoH{flintstones}{wife} = "wilma";

# another element
$HoH{simpsons}{lead} =~ s/(\w)/\u$1/;

# print the whole thing
foreach $family ( keys %HoH ) {
    print "$family: { ";
    for $role ( keys %{ $HoH{$family} } ) {
        print "$role=$HoH{$family}{$role} ";
    }
    print "}\n";
}

# print the whole thing  somewhat sorted
foreach $family ( sort keys %HoH ) {
    print "$family: { ";
    for $role ( sort keys %{ $HoH{$family} } ) {
        print "$role=$HoH{$family}{$role} ";
    }
    print "}\n";
}

# print the whole thing sorted by number of members
foreach $family ( sort { keys %{$HoH{$b}} <=> keys %{$HoH{$a}} } keys %HoH ) {
    print "$family: { ";
    for $role ( sort keys %{ $HoH{$family} } ) {
        print "$role=$HoH{$family}{$role} ";
    }
    print "}\n";
}

# establish a sort order (rank) for each role
$i = 0;
for ( qw(lead wife son daughter pal pet) ) { $rank{$_} = ++$i }

# now print the whole thing sorted by number of members
foreach $family ( sort { keys %{ $HoH{$b} } <=> keys %{ $HoH{$a} } } keys %HoH ) {
    print "$family: { ";
    # and print these according to rank order
    for $role ( sort { $rank{$a} <=> $rank{$b} }  keys %{ $HoH{$family} } ) {
        print "$role=$HoH{$family}{$role} ";
    }
    print "}\n";
}
```

4.12 MORE ELABORATE RECORDS

4.12.1 Declaration of MORE ELABORATE RECORDS

Here’s a sample showing how to create and use a record whose fields are of many different sorts:

```
$rec = {
    TEXT      => $string,
    SEQUENCE  => [ @old_values ],
    LOOKUP    => { %some_table },
    THATCODE  => \&some_function,
    THISCODE  => sub { $_[0] ** $_[1] },
    HANDLE    => \*STDOUT,
};

print $rec->{TEXT};

print $rec->{SEQUENCE}[0];
$last = pop @ { $rec->{SEQUENCE} };

print $rec->{LOOKUP}{"key"};
($first_k, $first_v) = each %{ $rec->{LOOKUP} };

$answer = $rec->{THATCODE}->($arg);
$answer = $rec->{THISCODE}->($arg1, $arg2);

# careful of extra block braces on fh ref
print { $rec->{HANDLE} } "a string\n";

use FileHandle;
$rec->{HANDLE}->autoflush(1);
$rec->{HANDLE}->print(" a string\n");
```

4.12.2 Declaration of a HASH OF COMPLEX RECORDS

```
%TV = (
   flintstones => {
       series   => "flintstones",
       nights   => [ qw(monday thursday friday) ],
       members  => [
           { name => "fred",    role => "lead", age  => 36, },
           { name => "wilma",   role => "wife", age  => 31, },
           { name => "pebbles", role => "kid",  age  =>  4, },
       ],
   },

   jetsons     => {
       series   => "jetsons",
       nights   => [ qw(wednesday saturday) ],
       members  => [
           { name => "george",  role => "lead", age  => 41, },
           { name => "jane",    role => "wife", age  => 39, },
           { name => "elroy",   role => "kid",  age  =>  9, },
       ],
    },
   simpsons    => {
       series   => "simpsons",
       nights   => [ qw(monday) ],
       members  => [
           { name => "homer", role => "lead", age  => 34, },
           { name => "marge", role => "wife", age => 37, },
           { name => "bart",  role => "kid",  age  =>  11, },
       ],
    },
 );
```

4.12.3 Generation of a HASH OF COMPLEX RECORDS

```
# reading from file
# this is most easily done by having the file itself be
# in the raw data format as shown above.  perl is happy
# to parse complex data structures if declared as data, so
# sometimes it's easiest to do that

# here's a piece by piece build up
$rec = {};
$rec->{series} = "flintstones";
$rec->{nights} = [ find_days() ];

@members = ();
# assume this file in field=value syntax
while (<>) {
    %fields = split /[\s=]+/;
    push @members, { %fields };
}
$rec->{members} = [ @members ];

# now remember the whole thing
$TV{ $rec->{series} } = $rec;

###########################################################
# now, you might want to make interesting extra fields that
# include pointers back into the same data structure so if
# change one piece, it changes everywhere, like for example
# if you wanted a {kids} field that was a reference
# to an array of the kids' records without having duplicate
# records and thus update problems.
###########################################################
foreach $family (keys %TV) {
    $rec = $TV{$family}; # temp pointer
    @kids = ();
    for $person ( @{ $rec->{members} } ) {
        if ($person->{role} =~ /kid|son|daughter/) {
            push @kids, $person;
        }
    }
    # REMEMBER: $rec and $TV{$family} point to same data!!
    $rec->{kids} = [ @kids ];
}
```

```
    # you copied the array, but the array itself contains pointers
    # to uncopied objects. this means that if you make bart get
    # older via

    $TV{simpsons}{kids}[0]{age}++;

    # then this would also change in
    print $TV{simpsons}{members}[2]{age};

    # because $TV{simpsons}{kids}[0] and $TV{simpsons}{members}[2]
    # both point to the same underlying anonymous hash table

    # print the whole thing
    foreach $family ( keys %TV ) {
        print "the $family";
        print " is on during @{ $TV{$family}{nights} }\n";
        print "its members are:\n";
        for $who ( @{ $TV{$family}{members} } ) {
            print " $who->{name} ($who->{role}), age $who->{age}\n";
        }
        print "it turns out that $TV{$family}{lead} has ";
        print scalar ( @{ $TV{$family}{kids} } ), " kids named ";
        print join (", ", map { $_->{name} } @{ $TV{$family}{kids} } );
        print "\n";
    }
```

4.13 Database Ties

You cannot easily tie a multilevel data structure (such as a hash of hashes) to a dbm file. The first problem is that all but GDBM and Berkeley DB have size limitations, but beyond that, you also have problems with how references are to be represented on disk. One experimental module that does partially attempt to address this need is the MLDBM module. Check your nearest CPAN site as described in *perlmodlib* for source code to MLDBM.

Manipulating Arrays of Arrays in Perl

5.1 DESCRIPTION

5.1.1 Declaration and Access of Arrays of Arrays

The simplest thing to build is an array of arrays (sometimes imprecisely called a list of lists). It's reasonably easy to understand, and almost everything that applies here will also be applicable later on with the fancier data structures.

An array of an array is just a regular old array @AoA that you can get at with two subscripts, like `$AoA[3][2]`. Here's a declaration of the array:

```
    # assign to our array, an array of array references
    @AoA = (
           [ "fred", "barney" ],
           [ "george", "jane", "elroy" ],
           [ "homer", "marge", "bart" ],
    );

    print $AoA[2][2];
  bart
```

Now you should be very careful that the outer bracket type is a round one, that is, a parenthesis. That's because you're assigning to an @array, so you need parentheses. If you wanted there *not* to be an @AoA, but rather just a reference to it, you could do something more like this:

```
    # assign a reference to array of array references
    $ref_to_AoA = [
        [ "fred", "barney", "pebbles", "bambam", "dino", ],
        [ "homer", "bart", "marge", "maggie", ],
        [ "george", "jane", "elroy", "judy", ],
    ];

    print $ref_to_AoA->[2][2];
```

Notice that the outer bracket type has changed, and so our access syntax has also changed. That's because unlike C, in perl you can't freely interchange arrays and references thereto. $ref_to_AoA is a reference to an array, whereas @AoA is an array proper. Likewise, `$AoA[2]` is not an array, but an array ref. So how come you can write these:

```
$AoA[2][2]
$ref_to_AoA->[2][2]
```

instead of having to write these:

```
$AoA[2]->[2]
$ref_to_AoA->[2]->[2]
```

Well, that's because the rule is that on adjacent brackets only (whether square or curly), you are free to omit the pointer dereferencing arrow. But you cannot do so for the very first one if it's a scalar containing a reference, which means that $ref_to_AoA always needs it.

5.1.2 Growing Your Own

That's all well and good for declaration of a fixed data structure, but what if you wanted to add new elements on the fly, or build it up entirely from scratch?

First, let's look at reading it in from a file. This is something like adding a row at a time. We'll assume that there's a flat file in which each line is a row and each word an element. If you're trying to develop an @AoA array containing all these, here's the right way to do that:

```
while (<>) {
    @tmp = split;
    push @AoA, [ @tmp ];
}
```

You might also have loaded that from a function:

```
for $i ( 1 .. 10 ) {
    $AoA[$i] = [ somefunc($i) ];
}
```

Or you might have had a temporary variable sitting around with the array in it.

```
for $i ( 1 .. 10 ) {
    @tmp = somefunc($i);
    $AoA[$i] = [ @tmp ];
}
```

It's very important that you make sure to use the `[]` array reference constructor. That's because this will be very wrong:

```
$AoA[$i] = @tmp;
```

You see, assigning a named array like that to a scalar just counts the number of elements in @tmp, which probably isn't what you want.

If you are running under `use strict`, you'll have to add some declarations to make it happy:

```
use strict;
my(@AoA, @tmp);
while (<>) {
    @tmp = split;
    push @AoA, [ @tmp ];
}
```

Of course, you don't need the temporary array to have a name at all:

```
    while (<>) {
        push @AoA, [ split ];
    }
```

You also don't have to use push(). You could just make a direct assignment if you knew where you wanted to put it:

```
    my (@AoA, $i, $line);
    for $i ( 0 .. 10 ) {
        $line = <>;
        $AoA[$i] = [ split ' ', $line ];
    }
```

or even just

```
    my (@AoA, $i);
    for $i ( 0 .. 10 ) {
        $AoA[$i] = [ split ' ', <> ];
    }
```

You should in general be leery of using functions that could potentially return lists in scalar context without explicitly stating such. This would be clearer to the casual reader:

```
    my (@AoA, $i);
    for $i ( 0 .. 10 ) {
        $AoA[$i] = [ split ' ', scalar(<>) ];
    }
```

If you wanted to have a $ref_to_AoA variable as a reference to an array, you'd have to do something like this:

```
    while (<>) {
        push @$ref_to_AoA, [ split ];
    }
```

Now you can add new rows. What about adding new columns? If you're dealing with just matrices, it's often easiest to use simple assignment:

```
    for $x (1 .. 10) {
        for $y (1 .. 10) {
            $AoA[$x][$y] = func($x, $y);
        }
    }

    for $x ( 3, 7, 9 ) {
        $AoA[$x][20] += func2($x);
    }
```

It doesn't matter whether those elements are already there or not: it'll gladly create them for you, setting intervening elements to `undef` as need be.

If you wanted just to append to a row, you'd have to do something a bit funnier looking:

```
    # add new columns to an existing row
    push @{ $AoA[0] }, "wilma", "betty";
```

Notice that I *couldn't* say just:

```
    push $AoA[0], "wilma", "betty";  # WRONG!
```

In fact, that wouldn't even compile. How come? Because the argument to push() must be a real array, not just a reference to such.

5.1.3 Access and Printing

Now it's time to print your data structure out. How are you going to do that? Well, if you want only one of the elements, it's trivial:

```
    print $AoA[0][0];
```

If you want to print the whole thing, though, you can't say

```
    print @AoA;         # WRONG
```

because you'll get just references listed, and perl will never automatically dereference things for you. Instead, you have to roll yourself a loop or two. This prints the whole structure, using the shell-style for() construct to loop across the outer set of subscripts.

```
    for $aref ( @AoA ) {
        print "\t [ @$aref ],\n";
    }
```

If you wanted to keep track of subscripts, you might do this:

```
    for $i ( 0 .. $#AoA ) {
        print "\t elt $i is [ @{$AoA[$i]} ],\n";
    }
```

or maybe even this. Notice the inner loop.

```
    for $i ( 0 .. $#AoA ) {
        for $j ( 0 .. $#{$AoA[$i]} ) {
            print "elt $i $j is $AoA[$i][$j]\n";
        }
    }
```

As you can see, it's getting a bit complicated. That's why sometimes is easier to take a temporary on your way through:

```
    for $i ( 0 .. $#AoA ) {
        $aref = $AoA[$i];
        for $j ( 0 .. $#{$aref} ) {
            print "elt $i $j is $AoA[$i][$j]\n";
        }
    }
```

Hmm... that's still a bit ugly. How about this:

```
    for $i ( 0 .. $#AoA ) {
        $aref = $AoA[$i];
        $n = @$aref - 1;
        for $j ( 0 .. $n ) {
            print "elt $i $j is $AoA[$i][$j]\n";
        }
    }
```

5.1.4 Slices

If you want to get at a slice (part of a row) in a multidimensional array, you're going to have to do some fancy subscripting. That's because while we have a nice synonym for single elements via the pointer arrow for dereferencing, no such convenience exists for slices. (Remember, of course, that you can always write a loop to do a slice operation.)

Here's how to do one operation using a loop. We'll assume an @AoA variable as before.

```
@part = ();
$x = 4;
for ($y = 7; $y < 13; $y++) {
    push @part, $AoA[$x][$y];
}
```

That same loop could be replaced with a slice operation:

```
@part = @{ $AoA[4] } [ 7..12 ];
```

but as you might well imagine, this is pretty rough on the reader.

Ah, but what if you wanted a *two-dimensional slice*, such as having $x run from 4..8 and $y run from 7 to 12? Hmm... here's the simple way:

```
@newAoA = ();
for ($startx = $x = 4; $x <= 8; $x++) {
    for ($starty = $y = 7; $y <= 12; $y++) {
        $newAoA[$x - $startx][$y - $starty] = $AoA[$x][$y];
    }
}
```

We can reduce some of the looping through slices

```
for ($x = 4; $x <= 8; $x++) {
    push @newAoA, [ @{ $AoA[$x] } [ 7..12 ] ];
}
```

If you were into Schwartzian Transforms, you would probably have selected map for that

```
@newAoA = map { [ @{ $AoA[$_] } [ 7..12 ] ] } 4 .. 8;
```

Although if your manager accused of seeking job security (or rapid insecurity) through inscrutable code, it would be hard to argue. :-) If I were you, I'd put that in a function:

```
@newAoA = splice_2D( \@AoA, 4 => 8, 7 => 12 );
sub splice_2D {
    my $lrr = shift;        # ref to array of array refs!
    my ($x_lo, $x_hi,
        $y_lo, $y_hi) = @_;

    return map {
        [ @{ $lrr->[$_] } [ $y_lo .. $y_hi ] ]
    } $x_lo .. $x_hi;
}
```

Perl regular expressions quick start

6.1 DESCRIPTION

This page covers the very basics of understanding, creating and using regular expressions ('regexes') in Perl.

6.2 The Guide

6.2.1 Simple word matching

The simplest regex is simply a word, or more generally, a string of characters. A regex consisting of a word matches any string that contains that word:

```
    "Hello World" =~ /World/;  # matches
```

In this statement, `World` is a regex and the `//` enclosing `/World/` tells perl to search a string for a match. The operator =~ associates the string with the regex match and produces a true value if the regex matched, or false if the regex did not match. In our case, `World` matches the second word in `"Hello World"`, so the expression is true. This idea has several variations.

Expressions like this are useful in conditionals:

```
    print "It matches\n" if "Hello World" =~ /World/;
```

The sense of the match can be reversed by using `!~` operator:

```
    print "It doesn't match\n" if "Hello World" !~ /World/;
```

The literal string in the regex can be replaced by a variable:

```
    $greeting = "World";
    print "It matches\n" if "Hello World" =~ /$greeting/;
```

If you're matching against `$_`, the `$_ =~` part can be omitted:

```
    $_ = "Hello World";
    print "It matches\n" if /World/;
```

Finally, the `//` default delimiters for a match can be changed to arbitrary delimiters by putting an `'m'` out front:

```
    "Hello World" =~ m!World!;   # matches, delimited by '!'
    "Hello World" =~ m{World};   # matches, note the matching '{}'
    "/usr/bin/perl" =~ m"/perl"; # matches after '/usr/bin',
                                 # '/' becomes an ordinary char
```

Regexes must match a part of the string *exactly* in order for the statement to be true:

```
    "Hello World" =~ /world/;  # doesn't match, case sensitive
    "Hello World" =~ /o W/;    # matches, ' ' is an ordinary char
    "Hello World" =~ /World /; # doesn't match, no ' ' at end
```

perl will always match at the earliest possible point in the string:

```
    "Hello World" =~ /o/;       # matches 'o' in 'Hello'
    "That hat is red" =~ /hat/; # matches 'hat' in 'That'
```

Not all characters can be used 'as is' in a match. Some characters, called **metacharacters**, are reserved for use in regex notation. The metacharacters are

```
    {}[]()^$.|*+?\
```

A metacharacter can be matched by putting a backslash before it:

```
    "2+2=4" =~ /2+2/;    # doesn't match, + is a metacharacter
    "2+2=4" =~ /2\+2/;   # matches, \+ is treated like an ordinary +
    'C:\WIN32' =~ /C:\\WIN/;                       # matches
    "/usr/bin/perl" =~ /\/usr\/bin\/perl/;  # matches
```

In the last regex, the forward slash `'/'` is also backslashed, because it is used to delimit the regex.

Non-printable ASCII characters are represented by **escape sequences**. Common examples are `\t` for a tab, `\n` for a newline, and `\r` for a carriage return. Arbitrary bytes are represented by octal escape sequences, e.g., `\033`, or hexadecimal escape sequences, e.g., `\x1B`:

```
    "1000\t2000" =~ m(0\t2)        # matches
    "cat"        =~ /\143\x61\x74/ # matches, but a weird way to spell cat
```

Regexes are treated mostly as double quoted strings, so variable substitution works:

```
    $foo = 'house';
    'cathouse' =~ /cat$foo/;   # matches
    'housecat' =~ /${foo}cat/; # matches
```

With all of the regexes above, if the regex matched anywhere in the string, it was considered a match. To specify *where* it should match, we would use the **anchor** metacharacters ^ and `$`. The anchor ^ means match at the beginning of the string and the anchor `$` means match at the end of the string, or before a newline at the end of the string. Some examples:

```
    "housekeeper" =~ /keeper/;         # matches
    "housekeeper" =~ /^keeper/;        # doesn't match
    "housekeeper" =~ /keeper$/;        # matches
    "housekeeper\n" =~ /keeper$/;      # matches
    "housekeeper" =~ /^housekeeper$/;  # matches
```

6.2.2 Using character classes

A **character class** allows a set of possible characters, rather than just a single character, to match at a particular point in a regex. Character classes are denoted by brackets `[...]`, with the set of characters to be possibly matched inside. Here are some examples:

```
    /cat/;            # matches 'cat'
    /[bcr]at/;        # matches 'bat', 'cat', or 'rat'
    "abc" =~ /[cab]/; # matches 'a'
```

In the last statement, even though `'c'` is the first character in the class, the earliest point at which the regex can match is `'a'`.

```
    /[yY][eE][sS]/; # match 'yes' in a case-insensitive way
                    # 'yes', 'Yes', 'YES', etc.
    /yes/i;         # also match 'yes' in a case-insensitive way
```

The last example shows a match with an `'i'` **modifier**, which makes the match case-insensitive.

Character classes also have ordinary and special characters, but the sets of ordinary and special characters inside a character class are different than those outside a character class. The special characters for a character class are `-]\^$` and are matched using an escape:

```
   /[\]c]def/; # matches ']def' or 'cdef'
   $x = 'bcr';
   /[$x]at/;   # matches 'bat, 'cat', or 'rat'
   /[\$x]at/;  # matches '$at' or 'xat'
   /[\\$x]at/; # matches '\at', 'bat, 'cat', or 'rat'
```

The special character `'-'` acts as a range operator within character classes, so that the unwieldy `[0123456789]` and `[abc...xyz]` become the svelte `[0-9]` and `[a-z]`:

```
    /item[0-9]/;  # matches 'item0' or ... or 'item9'
    /[0-9a-fA-F]/;  # matches a hexadecimal digit
```

If `'-'` is the first or last character in a character class, it is treated as an ordinary character.

The special character ˆ in the first position of a character class denotes a **negated character class**, which matches any character but those in the brackets. Both `[...]` and `[ˆ...]` must match a character, or the match fails. Then

```
    /[^a]at/;  # doesn't match 'aat' or 'at', but matches
               # all other 'bat', 'cat, '0at', '%at', etc.
    /[^0-9]/;  # matches a non-numeric character
    /[a^]at/;  # matches 'aat' or '^at'; here '^' is ordinary
```

Perl has several abbreviations for common character classes:

- \d is a digit and represents

  ```
  [0-9]
  ```

- \s is a whitespace character and represents

  ```
  [\ \t\r\n\f]
  ```

- \w is a word character (alphanumeric or _) and represents

```
[0-9a-zA-Z_]
```

- \D is a negated \d; it represents any character but a digit

```
[^0-9]
```

- \S is a negated \s; it represents any non-whitespace character

```
[^\s]
```

- \W is a negated \w; it represents any non-word character

```
[^\w]
```

- The period '.' matches any character but "\n"

The `\d\s\w\D\S\W` abbreviations can be used both inside and outside of character classes. Here are some in use:

```
/\d\d:\d\d:\d\d/; # matches a hh:mm:ss time format
/[\d\s]/;         # matches any digit or whitespace character
/\w\W\w/;         # matches a word char, followed by a
                  # non-word char, followed by a word char
/..rt/;           # matches any two chars, followed by 'rt'
/end\./;          # matches 'end.'
/end[.]/;         # same thing, matches 'end.'
```

The **word anchor** `\b` matches a boundary between a word character and a non-word character `\w\W` or `\W\w`:

```
$x = "Housecat catenates house and cat";
$x =~ /\bcat/;  # matches cat in 'catenates'
$x =~ /cat\b/;  # matches cat in 'housecat'
$x =~ /\bcat\b/;  # matches 'cat' at end of string
```

In the last example, the end of the string is considered a word boundary.

6.2.3 Matching this or that

We can match different character strings with the **alternation** metacharacter `'|'`. To match `dog` or `cat`, we form the regex `dog|cat`. As before, perl will try to match the regex at the earliest possible point in the string. At each character position, perl will first try to match the first alternative, `dog`. If `dog` doesn't match, perl will then try the next alternative, `cat`. If `cat` doesn't match either, then the match fails and perl moves to the next position in the string. Some examples:

```
"cats and dogs" =~ /cat|dog|bird/;  # matches "cat"
"cats and dogs" =~ /dog|cat|bird/;  # matches "cat"
```

Even though `dog` is the first alternative in the second regex, `cat` is able to match earlier in the string.

```
"cats"          =~ /c|ca|cat|cats/; # matches "c"
"cats"          =~ /cats|cat|ca|c/; # matches "cats"
```

At a given character position, the first alternative that allows the regex match to succeed will be the one that matches. Here, all the alternatives match at the first string position, so the first matches.

6.2.4 Grouping things and hierarchical matching

The **grouping** metacharacters `()` allow a part of a regex to be treated as a single unit. Parts of a regex are grouped by enclosing them in parentheses. The regex `house(cat|keeper)` means match `house` followed by either `cat` or `keeper`. Some more examples are

```
/(a|b)b/;    # matches 'ab' or 'bb'
/(^a|b)c/;   # matches 'ac' at start of string or 'bc' anywhere

/house(cat|)/;  # matches either 'housecat' or 'house'
/house(cat(s|)|)/;  # matches either 'housecats' or 'housecat' or
                    # 'house'.  Note groups can be nested.

"20" =~ /(19|20|)\d\d/;  # matches the null alternative '()\d\d',
                         # because '20\d\d' can't match
```

6.2.5 Extracting matches

The grouping metacharacters `()` also allow the extraction of the parts of a string that matched. For each grouping, the part that matched inside goes into the special variables `$1`, `$2`, etc. They can be used just as ordinary variables:

```
# extract hours, minutes, seconds
$time =~ /(\d\d):(\d\d):(\d\d)/;  # match hh:mm:ss format
$hours = $1;
$minutes = $2;
$seconds = $3;
```

In list context, a match `/regex/` with groupings will return the list of matched values `($1,$2,...)`. So we could rewrite it as

```
($hours, $minutes, $second) = ($time =~ /(\d\d):(\d\d):(\d\d)/);
```

If the groupings in a regex are nested, `$1` gets the group with the leftmost opening parenthesis, `$2` the next opening parenthesis, etc. For example, here is a complex regex and the matching variables indicated below it:

```
/(ab(cd|ef)((gi)|j))/;
 1  2      34
```

Associated with the matching variables `$1`, `$2`, ... are the **backreferences** `\1`, `\2`, ... Backreferences are matching variables that can be used *inside* a regex:

```
/(\w\w\w)\s\1/; # find sequences like 'the the' in string
```

`$1`, `$2`, ... should only be used outside of a regex, and `\1`, `\2`, ... only inside a regex.

6.2.6 Matching repetitions

The **quantifier** metacharacters `?`, `*`, `+`, and `{}` allow us to determine the number of repeats of a portion of a regex we consider to be a match. Quantifiers are put immediately after the character, character class, or grouping that we want to specify. They have the following meanings:

- `a?` = match 'a' 1 or 0 times
- `a*` = match 'a' 0 or more times, i.e., any number of times

- `a+` = match 'a' 1 or more times, i.e., at least once
- `a{n,m}` = match at least `n` times, but not more than `m` times.
- `a{n,}` = match at least `n` or more times
- `a{n}` = match exactly `n` times

Here are some examples:

```
    /[a-z]+\s+\d*/;  # match a lowercase word, at least some space, and
                     # any number of digits
    /(\w+)\s+\1/;    # match doubled words of arbitrary length
    $year =~ /\d{2,4}/;  # make sure year is at least 2 but not more
                         # than 4 digits
    $year =~ /\d{4}|\d{2}/;    # better match; throw out 3 digit dates
```

These quantifiers will try to match as much of the string as possible, while still allowing the regex to match. So we have

```
    $x = 'the cat in the hat';
    $x =~ /^(.*)(at)(.*)$/; # matches,
                            # $1 = 'the cat in the h'
                            # $2 = 'at'
                            # $3 = ''   (0 matches)
```

The first quantifier `.*` grabs as much of the string as possible while still having the regex match. The second quantifier `.*` has no string left to it, so it matches 0 times.

6.2.7 More matching

There are a few more things you might want to know about matching operators. In the code

```
    $pattern = 'Seuss';
    while (<>) {
        print if /$pattern/;
    }
```

perl has to re-evaluate `$pattern` each time through the loop. If `$pattern` won't be changing, use the `//o` modifier, to only perform variable substitutions once. If you don't want any substitutions at all, use the special delimiter `m''`:

```
    @pattern = ('Seuss');
    m/@pattern/; # matches 'Seuss'
    m'@pattern'; # matches the literal string '@pattern'
```

The global modifier `//g` allows the matching operator to match within a string as many times as possible. In scalar context, successive matches against a string will have `//g` jump from match to match, keeping track of position in the string as it goes along. You can get or set the position with the `pos()` function. For example,

```
    $x = "cat dog house"; # 3 words
    while ($x =~ /(\w+)/g) {
        print "Word is $1, ends at position ", pos $x, "\n";
    }
```

prints

```
    Word is cat, ends at position 3
    Word is dog, ends at position 7
    Word is house, ends at position 13
```

A failed match or changing the target string resets the position. If you don't want the position reset after failure to match, add the `//c`, as in `/regex/gc`.

In list context, `//g` returns a list of matched groupings, or if there are no groupings, a list of matches to the whole regex. So

```
    @words = ($x =~ /(\w+)/g);  # matches,
                                # $word[0] = 'cat'
                                # $word[1] = 'dog'
                                # $word[2] = 'house'
```

6.2.8 Search and replace

Search and replace is performed using `s/regex/replacement/modifiers`. The `replacement` is a Perl double quoted string that replaces in the string whatever is matched with the `regex`. The operator `=~` is also used here to associate a string with `s///`. If matching against `$_`, the `$_ =~` can be dropped. If there is a match, `s///` returns the number of substitutions made, otherwise it returns false. Here are a few examples:

```
    $x = "Time to feed the cat!";
    $x =~ s/cat/hacker/;   # $x contains "Time to feed the hacker!"
    $y = "'quoted words'";
    $y =~ s/^'(.*)'$/$1/;  # strip single quotes,
                           # $y contains "quoted words"
```

With the `s///` operator, the matched variables `$1`, `$2`, etc. are immediately available for use in the replacement expression. With the global modifier, `s///g` will search and replace all occurrences of the regex in the string:

```
    $x = "I batted 4 for 4";
    $x =~ s/4/four/;   # $x contains "I batted four for 4"
    $x = "I batted 4 for 4";
    $x =~ s/4/four/g;  # $x contains "I batted four for four"
```

The evaluation modifier `s///e` wraps an `eval{...}` around the replacement string and the evaluated result is substituted for the matched substring. Some examples:

```
    # reverse all the words in a string
    $x = "the cat in the hat";
    $x =~ s/(\w+)/reverse $1/ge;   # $x contains "eht tac ni eht tah"

    # convert percentage to decimal
    $x = "A 39% hit rate";
    $x =~ s!(\d+)%!$1/100!e;       # $x contains "A 0.39 hit rate"
```

The last example shows that `s///` can use other delimiters, such as `s!!!` and `s{}{}`, and even `s{}//`. If single quotes are used `s'''`, then the regex and replacement are treated as single quoted strings.

6.2.9 The split operator

`split /regex/, string` splits `string` into a list of substrings and returns that list. The regex determines the character sequence that `string` is split with respect to. For example, to split a string into words, use

```
$x = "Calvin and Hobbes";
@word = split /\s+/, $x;  # $word[0] = 'Calvin'
                          # $word[1] = 'and'
                          # $word[2] = 'Hobbes'
```

To extract a comma-delimited list of numbers, use

```
$x = "1.618,2.718,   3.142";
@const = split /,\s*/, $x;  # $const[0] = '1.618'
                            # $const[1] = '2.718'
                            # $const[2] = '3.142'
```

If the empty regex `//` is used, the string is split into individual characters. If the regex has groupings, then the list produced contains the matched substrings from the groupings as well:

```
$x = "/usr/bin";
@parts = split m!(/)!, $x;  # $parts[0] = ''
                            # $parts[1] = '/'
                            # $parts[2] = 'usr'
                            # $parts[3] = '/'
                            # $parts[4] = 'bin'
```

Since the first character of $x matched the regex, `split` prepended an empty initial element to the list.

6.3 BUGS

None.

perlretut

Perl regular expressions tutorial

7.1 DESCRIPTION

This page provides a basic tutorial on understanding, creating and using regular expressions in Perl. It serves as a complement to the reference page on regular expressions *perlre*. Regular expressions are an integral part of the `m//`, `s///`, `qr//` and `split` operators and so this tutorial also overlaps with Regexp Quote-Like Operators in *perlop* and split in *perlfunc*.

Perl is widely renowned for excellence in text processing, and regular expressions are one of the big factors behind this fame. Perl regular expressions display an efficiency and flexibility unknown in most other computer languages. Mastering even the basics of regular expressions will allow you to manipulate text with surprising ease.

What is a regular expression? A regular expression is simply a string that describes a pattern. Patterns are in common use these days; examples are the patterns typed into a search engine to find web pages and the patterns used to list files in a directory, e.g., `ls *.txt` or `dir *.*`. In Perl, the patterns described by regular expressions are used to search strings, extract desired parts of strings, and to do search and replace operations.

Regular expressions have the undeserved reputation of being abstract and difficult to understand. Regular expressions are constructed using simple concepts like conditionals and loops and are no more difficult to understand than the corresponding `if` conditionals and `while` loops in the Perl language itself. In fact, the main challenge in learning regular expressions is just getting used to the terse notation used to express these concepts.

This tutorial flattens the learning curve by discussing regular expression concepts, along with their notation, one at a time and with many examples. The first part of the tutorial will progress from the simplest word searches to the basic regular expression concepts. If you master the first part, you will have all the tools needed to solve about 98% of your needs. The second part of the tutorial is for those comfortable with the basics and hungry for more power tools. It discusses the more advanced regular expression operators and introduces the latest cutting edge innovations in 5.6.0.

A note: to save time, ’regular expression’ is often abbreviated as regexp or regex. Regexp is a more natural abbreviation than regex, but is harder to pronounce. The Perl pod documentation is evenly split on regexp vs regex; in Perl, there is more than one way to abbreviate it. We’ll use regexp in this tutorial.

7.2 Part 1: The basics

7.2.1 Simple word matching

The simplest regexp is simply a word, or more generally, a string of characters. A regexp consisting of a word matches any string that contains that word:

```
    "Hello World" =~ /World/;  # matches
```

What is this perl statement all about? `"Hello World"` is a simple double quoted string. `World` is the regular expression and the `//` enclosing `/World/` tells perl to search a string for a match. The operator `=~` associates the string with the regexp match and produces a true value if the regexp matched, or false if the regexp did not match. In our case, `World` matches the second word in `"Hello World"`, so the expression is true. Expressions like this are useful in conditionals:

```
if ("Hello World" =~ /World/) {
    print "It matches\n";
}
else {
    print "It doesn't match\n";
}
```

There are useful variations on this theme. The sense of the match can be reversed by using `!~` operator:

```
if ("Hello World" !~ /World/) {
    print "It doesn't match\n";
}
else {
    print "It matches\n";
}
```

The literal string in the regexp can be replaced by a variable:

```
$greeting = "World";
if ("Hello World" =~ /$greeting/) {
    print "It matches\n";
}
else {
    print "It doesn't match\n";
}
```

If you're matching against the special default variable `$_`, the `$_ =~` part can be omitted:

```
$_ = "Hello World";
if (/World/) {
    print "It matches\n";
}
else {
    print "It doesn't match\n";
}
```

And finally, the `//` default delimiters for a match can be changed to arbitrary delimiters by putting an `'m'` out front:

```
"Hello World" =~ m!World!;   # matches, delimited by '!'
"Hello World" =~ m{World};   # matches, note the matching '{}'
"/usr/bin/perl" =~ m"/perl"; # matches after '/usr/bin',
                             # '/' becomes an ordinary char
```

`/World/`, `m!World!`, and `m{World}` all represent the same thing. When, e.g., `""` is used as a delimiter, the forward slash `'/'` becomes an ordinary character and can be used in a regexp without trouble.

Let's consider how different regexps would match `"Hello World"`:

```
"Hello World" =~ /world/;  # doesn't match
"Hello World" =~ /o W/;    # matches
"Hello World" =~ /oW/;     # doesn't match
"Hello World" =~ /World /; # doesn't match
```

The first regexp `world` doesn't match because regexps are case-sensitive. The second regexp matches because the substring `'o W'` occurs in the string `"Hello World"`. The space character ' ' is treated like any other character in a regexp and is needed to match in this case. The lack of a space character is the reason the third regexp `'oW'` doesn't match. The fourth regexp `'World '` doesn't match because there is a space at the end of the regexp, but not at the end of the string. The lesson here is that regexps must match a part of the string *exactly* in order for the statement to be true.

If a regexp matches in more than one place in the string, perl will always match at the earliest possible point in the string:

```
    "Hello World" =~ /o/;       # matches 'o' in 'Hello'
    "That hat is red" =~ /hat/; # matches 'hat' in 'That'
```

With respect to character matching, there are a few more points you need to know about. First of all, not all characters can be used 'as is' in a match. Some characters, called **metacharacters**, are reserved for use in regexp notation. The metacharacters are

```
    {}[]()^$.|*+?\
```

The significance of each of these will be explained in the rest of the tutorial, but for now, it is important only to know that a metacharacter can be matched by putting a backslash before it:

```
    "2+2=4" =~ /2+2/;    # doesn't match, + is a metacharacter
    "2+2=4" =~ /2\+2/;   # matches, \+ is treated like an ordinary +
    "The interval is [0,1)." =~ /[0,1)./     # is a syntax error!
    "The interval is [0,1)." =~ /\[0,1\)\./  # matches
    "/usr/bin/perl" =~ /\/usr\/bin\/perl/;  # matches
```

In the last regexp, the forward slash `'/'` is also backslashed, because it is used to delimit the regexp. This can lead to LTS (leaning toothpick syndrome), however, and it is often more readable to change delimiters.

```
    "/usr/bin/perl" =~ m!/usr/bin/perl!;    # easier to read
```

The backslash character `'\'` is a metacharacter itself and needs to be backslashed:

```
    'C:\WIN32' =~ /C:\\WIN/;   # matches
```

In addition to the metacharacters, there are some ASCII characters which don't have printable character equivalents and are instead represented by **escape sequences**. Common examples are `\t` for a tab, `\n` for a newline, `\r` for a carriage return and `\a` for a bell. If your string is better thought of as a sequence of arbitrary bytes, the octal escape sequence, e.g., `\033`, or hexadecimal escape sequence, e.g., `\x1B` may be a more natural representation for your bytes. Here are some examples of escapes:

```
    "1000\t2000" =~ m(0\t2)   # matches
    "1000\n2000" =~ /0\n20/   # matches
    "1000\t2000" =~ /\000\t2/ # doesn't match, "0" ne "\000"
    "cat"        =~ /\143\x61\x74/ # matches, but a weird way to spell cat
```

If you've been around Perl a while, all this talk of escape sequences may seem familiar. Similar escape sequences are used in double-quoted strings and in fact the regexps in Perl are mostly treated as double-quoted strings. This means that variables can be used in regexps as well. Just like double-quoted strings, the values of the variables in the regexp will be substituted in before the regexp is evaluated for matching purposes. So we have:

```
    $foo = 'house';
    'housecat' =~ /$foo/;      # matches
    'cathouse' =~ /cat$foo/;   # matches
    'housecat' =~ /${foo}cat/; # matches
```

So far, so good. With the knowledge above you can already perform searches with just about any literal string regexp you can dream up. Here is a *very simple* emulation of the Unix grep program:

```
    % cat > simple_grep
    #!/usr/bin/perl
    $regexp = shift;
    while (<>) {
        print if /$regexp/;
    }
    ^D

    % chmod +x simple_grep

    % simple_grep abba /usr/dict/words
    Babbage
    cabbage
    cabbages
    sabbath
    Sabbathize
    Sabbathizes
    sabbatical
    scabbard
    scabbards
```

This program is easy to understand. `#!/usr/bin/perl` is the standard way to invoke a perl program from the shell. `$regexp = shift;` saves the first command line argument as the regexp to be used, leaving the rest of the command line arguments to be treated as files. `while (<>)` loops over all the lines in all the files. For each line, `print if /$regexp/;` prints the line if the regexp matches the line. In this line, both `print` and `/$regexp/` use the default variable `$_` implicitly.

With all of the regexps above, if the regexp matched anywhere in the string, it was considered a match. Sometimes, however, we'd like to specify *where* in the string the regexp should try to match. To do this, we would use the **anchor** metacharacters ˆ and `$`. The anchor ˆ means match at the beginning of the string and the anchor `$` means match at the end of the string, or before a newline at the end of the string. Here is how they are used:

```
    "housekeeper" =~ /keeper/;    # matches
    "housekeeper" =~ /^keeper/;   # doesn't match
    "housekeeper" =~ /keeper$/;   # matches
    "housekeeper\n" =~ /keeper$/; # matches
```

The second regexp doesn't match because ˆ constrains `keeper` to match only at the beginning of the string, but `"housekeeper"` has keeper starting in the middle. The third regexp does match, since the `$` constrains `keeper` to match only at the end of the string.

When both ˆ and `$` are used at the same time, the regexp has to match both the beginning and the end of the string, i.e., the regexp matches the whole string. Consider

```
    "keeper" =~ /^keep$/;      # doesn't match
    "keeper" =~ /^keeper$/;    # matches
    ""       =~ /^$/;          # ^$ matches an empty string
```

The first regexp doesn't match because the string has more to it than `keep`. Since the second regexp is exactly the string, it matches. Using both ˆ and `$` in a regexp forces the complete string to match, so it gives you complete control over which strings match and which don't. Suppose you are looking for a fellow named bert, off in a string by himself:

```
    "dogbert" =~ /bert/;   # matches, but not what you want
    "dilbert" =~ /^bert/;  # doesn't match, but ..
    "bertram" =~ /^bert/;  # matches, so still not good enough

    "bertram" =~ /^bert$/; # doesn't match, good
    "dilbert" =~ /^bert$/; # doesn't match, good
    "bert"    =~ /^bert$/; # matches, perfect
```

Of course, in the case of a literal string, one could just as easily use the string equivalence `$string eq 'bert'` and it would be more efficient. The `^...$` regexp really becomes useful when we add in the more powerful regexp tools below.

7.2.2 Using character classes

Although one can already do quite a lot with the literal string regexps above, we've only scratched the surface of regular expression technology. In this and subsequent sections we will introduce regexp concepts (and associated metacharacter notations) that will allow a regexp to not just represent a single character sequence, but a *whole class* of them.

One such concept is that of a **character class**. A character class allows a set of possible characters, rather than just a single character, to match at a particular point in a regexp. Character classes are denoted by brackets `[...]`, with the set of characters to be possibly matched inside. Here are some examples:

```
    /cat/;       # matches 'cat'
    /[bcr]at/;   # matches 'bat, 'cat', or 'rat'
    /item[0123456789]/;  # matches 'item0' or ... or 'item9'
    "abc" =~ /[cab]/;    # matches 'a'
```

In the last statement, even though `'c'` is the first character in the class, `'a'` matches because the first character position in the string is the earliest point at which the regexp can match.

```
    /[yY][eE][sS]/;      # match 'yes' in a case-insensitive way
                         # 'yes', 'Yes', 'YES', etc.
```

This regexp displays a common task: perform a case-insensitive match. Perl provides away of avoiding all those brackets by simply appending an `'i'` to the end of the match. Then `/[yY][eE][sS]/;` can be rewritten as `/yes/i;`. The `'i'` stands for case-insensitive and is an example of a **modifier** of the matching operation. We will meet other modifiers later in the tutorial.

We saw in the section above that there were ordinary characters, which represented themselves, and special characters, which needed a backslash \ to represent themselves. The same is true in a character class, but the sets of ordinary and special characters inside a character class are different than those outside a character class. The special characters for a character class are `-]\^$`. `]` is special because it denotes the end of a character class. `$` is special because it denotes a scalar variable. `\` is special because it is used in escape sequences, just like above. Here is how the special characters `]$\` are handled:

```
   /[\]c]def/; # matches ']def' or 'cdef'
   $x = 'bcr';
   /[$x]at/;   # matches 'bat', 'cat', or 'rat'
   /[\$x]at/;  # matches '$at' or 'xat'
   /[\\$x]at/; # matches '\at', 'bat, 'cat', or 'rat'
```

The last two are a little tricky. in `[\$x]`, the backslash protects the dollar sign, so the character class has two members `$` and `x`. In `[\\$x]`, the backslash is protected, so `$x` is treated as a variable and substituted in double quote fashion.

The special character `'-'` acts as a range operator within character classes, so that a contiguous set of characters can be written as a range. With ranges, the unwieldy `[0123456789]` and `[abc...xyz]` become the svelte `[0-9]` and `[a-z]`. Some examples are

```
/item[0-9]/;  # matches 'item0' or ... or 'item9'
/[0-9bx-z]aa/;  # matches '0aa', ..., '9aa',
                # 'baa', 'xaa', 'yaa', or 'zaa'
/[0-9a-fA-F]/;  # matches a hexadecimal digit
/[0-9a-zA-Z_]/; # matches a "word" character,
                # like those in a perl variable name
```

If `'-'` is the first or last character in a character class, it is treated as an ordinary character; `[-ab]`, `[ab-]` and `[a\-b]` are all equivalent.

The special character ˆ in the first position of a character class denotes a **negated character class**, which matches any character but those in the brackets. Both `[...]` and `[ˆ...]` must match a character, or the match fails. Then

```
/[^a]at/;  # doesn't match 'aat' or 'at', but matches
           # all other 'bat', 'cat, '0at', '%at', etc.
/[^0-9]/;  # matches a non-numeric character
/[a^]at/;  # matches 'aat' or '^at'; here '^' is ordinary
```

Now, even `[0-9]` can be a bother the write multiple times, so in the interest of saving keystrokes and making regexps more readable, Perl has several abbreviations for common character classes:

- \d is a digit and represents [0-9]
- \s is a whitespace character and represents [\ \t\r\n\f]
- \w is a word character (alphanumeric or _) and represents [0-9a-zA-Z_]
- \D is a negated \d; it represents any character but a digit [ˆ0-9]
- \S is a negated \s; it represents any non-whitespace character [ˆ\s]
- \W is a negated \w; it represents any non-word character [ˆ\w]
- The period '.' matches any character but "\n"

The `\d\s\w\D\S\W` abbreviations can be used both inside and outside of character classes. Here are some in use:

```
/\d\d:\d\d:\d\d/; # matches a hh:mm:ss time format
/[\d\s]/;         # matches any digit or whitespace character
/\w\W\w/;         # matches a word char, followed by a
                  # non-word char, followed by a word char
/..rt/;           # matches any two chars, followed by 'rt'
/end\./;          # matches 'end.'
/end[.]/;         # same thing, matches 'end.'
```

Because a period is a metacharacter, it needs to be escaped to match as an ordinary period. Because, for example, `\d` and `\w` are sets of characters, it is incorrect to think of `[ˆ\d\w]` as `[\D\W]`; in fact `[ˆ\d\w]` is the same as `[ˆ\w]`, which is the same as `[\W]`. Think DeMorgan's laws.

An anchor useful in basic regexps is the **word anchor** `\b`. This matches a boundary between a word character and a non-word character `\w\W` or `\W\w`:

```
$x = "Housecat catenates house and cat";
$x =~ /cat/;    # matches cat in 'housecat'
$x =~ /\bcat/;  # matches cat in 'catenates'
$x =~ /cat\b/;  # matches cat in 'housecat'
$x =~ /\bcat\b/;  # matches 'cat' at end of string
```

Note in the last example, the end of the string is considered a word boundary.

You might wonder why `'.'` matches everything but `"\n"` - why not every character? The reason is that often one is matching against lines and would like to ignore the newline characters. For instance, while the string `"\n"` represents one line, we would like to think of as empty. Then

```
""   =~ /^$/;    # matches
"\n" =~ /^$/;    # matches, "\n" is ignored

""   =~ /./;      # doesn't match; it needs a char
""   =~ /^.$/;    # doesn't match; it needs a char
"\n" =~ /^.$/;    # doesn't match; it needs a char other than "\n"
"a"  =~ /^.$/;    # matches
"a\n"  =~ /^.$/;  # matches, ignores the "\n"
```

This behavior is convenient, because we usually want to ignore newlines when we count and match characters in a line. Sometimes, however, we want to keep track of newlines. We might even want ˆ and `$` to anchor at the beginning and end of lines within the string, rather than just the beginning and end of the string. Perl allows us to choose between ignoring and paying attention to newlines by using the `//s` and `//m` modifiers. `//s` and `//m` stand for single line and multi-line and they determine whether a string is to be treated as one continuous string, or as a set of lines. The two modifiers affect two aspects of how the regexp is interpreted: 1) how the `'.'` character class is defined, and 2) where the anchors ˆ and `$` are able to match. Here are the four possible combinations:

- no modifiers (//): Default behavior. `'.'` matches any character except `"\n"`. ˆ matches only at the beginning of the string and `$` matches only at the end or before a newline at the end.
- s modifier (//s): Treat string as a single long line. `'.'` matches any character, even `"\n"`. ˆ matches only at the beginning of the string and `$` matches only at the end or before a newline at the end.
- m modifier (//m): Treat string as a set of multiple lines. `'.'` matches any character except `"\n"`. ˆ and `$` are able to match at the start or end of *any* line within the string.
- both s and m modifiers (//sm): Treat string as a single long line, but detect multiple lines. `'.'` matches any character, even `"\n"`. ˆ and `$`, however, are able to match at the start or end of *any* line within the string.

Here are examples of `//s` and `//m` in action:

```
$x = "There once was a girl\nWho programmed in Perl\n";

$x =~ /^Who/;   # doesn't match, "Who" not at start of string
$x =~ /^Who/s;  # doesn't match, "Who" not at start of string
$x =~ /^Who/m;  # matches, "Who" at start of second line
$x =~ /^Who/sm; # matches, "Who" at start of second line

$x =~ /girl.Who/;   # doesn't match, "." doesn't match "\n"
$x =~ /girl.Who/s;  # matches, "." matches "\n"
$x =~ /girl.Who/m;  # doesn't match, "." doesn't match "\n"
$x =~ /girl.Who/sm; # matches, "." matches "\n"
```

Most of the time, the default behavior is what is want, but `//s` and `//m` are occasionally very useful. If `//m` is being used, the start of the string can still be matched with `\A` and the end of string can still be matched with the anchors `\Z` (matches both the end and the newline before, like `$`), and `\z` (matches only the end):

```
$x =~ /^Who/m;   # matches, "Who" at start of second line
$x =~ /\AWho/m;  # doesn't match, "Who" is not at start of string

$x =~ /girl$/m;  # matches, "girl" at end of first line
$x =~ /girl\Z/m; # doesn't match, "girl" is not at end of string

$x =~ /Perl\Z/m; # matches, "Perl" is at newline before end
$x =~ /Perl\z/m; # doesn't match, "Perl" is not at end of string
```

We now know how to create choices among classes of characters in a regexp. What about choices among words or character strings? Such choices are described in the next section.

7.2.3 Matching this or that

Sometimes we would like to our regexp to be able to match different possible words or character strings. This is accomplished by using the **alternation** metacharacter |. To match `dog` or `cat`, we form the regexp `dog|cat`. As before, perl will try to match the regexp at the earliest possible point in the string. At each character position, perl will first try to match the first alternative, `dog`. If `dog` doesn't match, perl will then try the next alternative, `cat`. If `cat` doesn't match either, then the match fails and perl moves to the next position in the string. Some examples:

```
    "cats and dogs" =~ /cat|dog|bird/;  # matches "cat"
    "cats and dogs" =~ /dog|cat|bird/;  # matches "cat"
```

Even though `dog` is the first alternative in the second regexp, `cat` is able to match earlier in the string.

```
    "cats"          =~ /c|ca|cat|cats/; # matches "c"
    "cats"          =~ /cats|cat|ca|c/; # matches "cats"
```

Here, all the alternatives match at the first string position, so the first alternative is the one that matches. If some of the alternatives are truncations of the others, put the longest ones first to give them a chance to match.

```
    "cab" =~ /a|b|c/ # matches "c"
                     # /a|b|c/ == /[abc]/
```

The last example points out that character classes are like alternations of characters. At a given character position, the first alternative that allows the regexp match to succeed will be the one that matches.

7.2.4 Grouping things and hierarchical matching

Alternation allows a regexp to choose among alternatives, but by itself it unsatisfying. The reason is that each alternative is a whole regexp, but sometime we want alternatives for just part of a regexp. For instance, suppose we want to search for housecats or housekeepers. The regexp `housecat|housekeeper` fits the bill, but is inefficient because we had to type `house` twice. It would be nice to have parts of the regexp be constant, like `house`, and some parts have alternatives, like `cat|keeper`.

The **grouping** metacharacters `()` solve this problem. Grouping allows parts of a regexp to be treated as a single unit. Parts of a regexp are grouped by enclosing them in parentheses. Thus we could solve the `housecat|housekeeper` by forming the regexp as `house(cat|keeper)`. The regexp `house(cat|keeper)` means match `house` followed by either `cat` or `keeper`. Some more examples are

```
    /(a|b)b/;    # matches 'ab' or 'bb'
    /(ac|b)b/;   # matches 'acb' or 'bb'
    /(^a|b)c/;   # matches 'ac' at start of string or 'bc' anywhere
    /(a|[bc])d/; # matches 'ad', 'bd', or 'cd'

    /house(cat|)/;  # matches either 'housecat' or 'house'
    /house(cat(s|)|)/;  # matches either 'housecats' or 'housecat' or
                        # 'house'.  Note groups can be nested.

    /(19|20|)\d\d/;  # match years 19xx, 20xx, or the Y2K problem, xx
    "20" =~ /(19|20|)\d\d/;  # matches the null alternative '()\d\d',
                             # because '20\d\d' can't match
```

Alternations behave the same way in groups as out of them: at a given string position, the leftmost alternative that allows the regexp to match is taken. So in the last example at the first string position, `"20"` matches the second alternative, but there is nothing left over to match the next two digits `\d\d`. So perl moves on to the next alternative, which is the null alternative and that works, since `"20"` is two digits.

The process of trying one alternative, seeing if it matches, and moving on to the next alternative if it doesn't, is called **backtracking**. The term 'backtracking' comes from the idea that matching a regexp is like a walk in the woods. Successfully matching a regexp is like arriving at a destination. There are many possible trailheads, one for each string position, and each one is tried in order, left to right. From each trailhead there may be many paths, some of which get you there, and some which are dead ends. When you walk along a trail and hit a dead end, you have to backtrack along the trail to an earlier point to try another trail. If you hit your destination, you stop immediately and forget about trying all the other trails. You are persistent, and only if you have tried all the trails from all the trailheads and not arrived at your destination, do you declare failure. To be concrete, here is a step-by-step analysis of what perl does when it tries to match the regexp

```
    "abcde" =~ /(abd|abc)(df|d|de)/;
```

1. Start with the first letter in the string 'a'.
2. Try the first alternative in the first group 'abd'.
3. Match 'a' followed by 'b'. So far so good.
4. 'd' in the regexp doesn't match 'c' in the string - a dead end. So backtrack two characters and pick the second alternative in the first group 'abc'.
5. Match 'a' followed by 'b' followed by 'c'. We are on a roll and have satisfied the first group. Set $1 to 'abc'.
6. Move on to the second group and pick the first alternative 'df'.
7. Match the 'd'.
8. 'f' in the regexp doesn't match 'e' in the string, so a dead end. Backtrack one character and pick the second alternative in the second group 'd'.
9. 'd' matches. The second grouping is satisfied, so set $2 to 'd'.
10. We are at the end of the regexp, so we are done! We have matched 'abcd' out of the string "abcde".

There are a couple of things to note about this analysis. First, the third alternative in the second group 'de' also allows a match, but we stopped before we got to it - at a given character position, leftmost wins. Second, we were able to get a match at the first character position of the string 'a'. If there were no matches at the first position, perl would move to the second character position 'b' and attempt the match all over again. Only when all possible paths at all possible character positions have been exhausted does perl give up and declare `$string =˜ /(abd|abc)(df|d|de)/;` to be false.

Even with all this work, regexp matching happens remarkably fast. To speed things up, during compilation stage, perl compiles the regexp into a compact sequence of opcodes that can often fit inside a processor cache. When the code is executed, these opcodes can then run at full throttle and search very quickly.

7.2.5 Extracting matches

The grouping metacharacters `()` also serve another completely different function: they allow the extraction of the parts of a string that matched. This is very useful to find out what matched and for text processing in general. For each grouping, the part that matched inside goes into the special variables `$1`, `$2`, etc. They can be used just as ordinary variables:

```
    # extract hours, minutes, seconds
    if ($time =~ /(\d\d):(\d\d):(\d\d)/) {    # match hh:mm:ss format
        $hours = $1;
        $minutes = $2;
        $seconds = $3;
    }
```

Now, we know that in scalar context, `$time =˜ /(\d\d):(\d\d):(\d\d)/` returns a true or false value. In list context, however, it returns the list of matched values `($1,$2,$3)`. So we could write the code more compactly as

```
    # extract hours, minutes, seconds
    ($hours, $minutes, $second) = ($time =~ /(\d\d):(\d\d):(\d\d)/);
```

If the groupings in a regexp are nested, `$1` gets the group with the leftmost opening parenthesis, `$2` the next opening parenthesis, etc. For example, here is a complex regexp and the matching variables indicated below it:

```
    /(ab(cd|ef)((gi)|j))/;
     1  2      34
```

so that if the regexp matched, e.g., `$2` would contain 'cd' or 'ef'. For convenience, perl sets `$+` to the string held by the highest numbered `$1`, `$2`, ... that got assigned (and, somewhat related, `$^N` to the value of the `$1`, `$2`, ... most-recently assigned; i.e. the `$1`, `$2`, ... associated with the rightmost closing parenthesis used in the match).

Closely associated with the matching variables `$1`, `$2`, ... are the **backreferences** `\1`, `\2`, ... Backreferences are simply matching variables that can be used *inside* a regexp. This is a really nice feature - what matches later in a regexp can depend on what matched earlier in the regexp. Suppose we wanted to look for doubled words in text, like 'the the'. The following regexp finds all 3-letter doubles with a space in between:

```
    /(\w\w\w)\s\1/;
```

The grouping assigns a value to \1, so that the same 3 letter sequence is used for both parts. Here are some words with repeated parts:

```
    % simple_grep '^(\w\w\w\w|\w\w\w|\w\w|\w)\1$' /usr/dict/words
    beriberi
    booboo
    coco
    mama
    murmur
    papa
```

The regexp has a single grouping which considers 4-letter combinations, then 3-letter combinations, etc. and uses `\1` to look for a repeat. Although `$1` and `\1` represent the same thing, care should be taken to use matched variables `$1`, `$2`, ... only outside a regexp and backreferences `\1`, `\2`, ... only inside a regexp; not doing so may lead to surprising and/or undefined results.

In addition to what was matched, Perl 5.6.0 also provides the positions of what was matched with the `@-` and `@+` arrays. `$-[0]` is the position of the start of the entire match and `$+[0]` is the position of the end. Similarly, `$-[n]` is the position of the start of the `$n` match and `$+[n]` is the position of the end. If `$n` is undefined, so are `$-[n]` and `$+[n]`. Then this code

```
    $x = "Mmm...donut, thought Homer";
    $x =~ /^(Mmm|Yech)\.\.\.(donut|peas)/; # matches
    foreach $expr (1..$#-) {
        print "Match $expr: '${$expr}' at position ($-[$expr],$+[$expr])\n";
    }
```

prints

```
    Match 1: 'Mmm' at position (0,3)
    Match 2: 'donut' at position (6,11)
```

Even if there are no groupings in a regexp, it is still possible to find out what exactly matched in a string. If you use them, perl will set `` $` `` to the part of the string before the match, will set `$&` to the part of the string that matched, and will set `$'` to the part of the string after the match. An example:

```
$x = "the cat caught the mouse";
$x =~ /cat/;  # $` = 'the ', $& = 'cat', $' = ' caught the mouse'
$x =~ /the/;  # $` = '', $& = 'the', $' = ' cat caught the mouse'
```

In the second match, `` $` = '' `` because the regexp matched at the first character position in the string and stopped, it never saw the second 'the'. It is important to note that using `` $` `` and `$'` slows down regexp matching quite a bit, and `$&` slows it down to a lesser extent, because if they are used in one regexp in a program, they are generated for <all> regexps in the program. So if raw performance is a goal of your application, they should be avoided. If you need them, use `@-` and `@+` instead:

```
$` is the same as substr( $x, 0, $-[0] )
$& is the same as substr( $x, $-[0], $+[0]-$-[0] )
$' is the same as substr( $x, $+[0] )
```

7.2.6 Matching repetitions

The examples in the previous section display an annoying weakness. We were only matching 3-letter words, or syllables of 4 letters or less. We'd like to be able to match words or syllables of any length, without writing out tedious alternatives like `\w\w\w\w|\w\w\w|\w\w|\w`.

This is exactly the problem the **quantifier** metacharacters `?`, `*`, `+`, and `{}` were created for. They allow us to determine the number of repeats of a portion of a regexp we consider to be a match. Quantifiers are put immediately after the character, character class, or grouping that we want to specify. They have the following meanings:

- `a?` = match 'a' 1 or 0 times
- `a*` = match 'a' 0 or more times, i.e., any number of times
- `a+` = match 'a' 1 or more times, i.e., at least once
- `a{n,m}` = match at least `n` times, but not more than `m` times.
- `a{n,}` = match at least `n` or more times
- `a{n}` = match exactly `n` times

Here are some examples:

```
/[a-z]+\s+\d*/;  # match a lowercase word, at least some space, and
                 # any number of digits
/(\w+)\s+\1/;    # match doubled words of arbitrary length
/y(es)?/i;       # matches 'y', 'Y', or a case-insensitive 'yes'
$year =~ /\d{2,4}/;  # make sure year is at least 2 but not more
                     # than 4 digits
$year =~ /\d{4}|\d{2}/;    # better match; throw out 3 digit dates
$year =~ /\d{2}(\d{2})?/;  # same thing written differently. However,
                           # this produces $1 and the other does not.

% simple_grep '^(\w+)\1$' /usr/dict/words   # isn't this easier?
beriberi
booboo
coco
mama
murmur
papa
```

For all of these quantifiers, perl will try to match as much of the string as possible, while still allowing the regexp to succeed. Thus with `/a?.../`, perl will first try to match the regexp with the `a` present; if that fails, perl will try to match the regexp without the `a` present. For the quantifier `*`, we get the following:

```
$x = "the cat in the hat";
$x =~ /^(.*)(cat)(.*)$/; # matches,
                         # $1 = 'the '
                         # $2 = 'cat'
                         # $3 = ' in the hat'
```

Which is what we might expect, the match finds the only `cat` in the string and locks onto it. Consider, however, this regexp:

```
$x =~ /^(.*)(at)(.*)$/; # matches,
                        # $1 = 'the cat in the h'
                        # $2 = 'at'
                        # $3 = ''   (0 matches)
```

One might initially guess that perl would find the `at` in `cat` and stop there, but that wouldn't give the longest possible string to the first quantifier `.*`. Instead, the first quantifier `.*` grabs as much of the string as possible while still having the regexp match. In this example, that means having the `at` sequence with the final `at` in the string. The other important principle illustrated here is that when there are two or more elements in a regexp, the *leftmost* quantifier, if there is one, gets to grab as much the string as possible, leaving the rest of the regexp to fight over scraps. Thus in our example, the first quantifier `.*` grabs most of the string, while the second quantifier `.*` gets the empty string. Quantifiers that grab as much of the string as possible are called **maximal match** or **greedy** quantifiers.

When a regexp can match a string in several different ways, we can use the principles above to predict which way the regexp will match:

- Principle 0: Taken as a whole, any regexp will be matched at the earliest possible position in the string.
- Principle 1: In an alternation a|b|`c...`, the leftmost alternative that allows a match for the whole regexp will be the one used.
- Principle 2: The maximal matching quantifiers ?, *, + and `{n,m}` will in general match as much of the string as possible while still allowing the whole regexp to match.
- Principle 3: If there are two or more elements in a regexp, the leftmost greedy quantifier, if any, will match as much of the string as possible while still allowing the whole regexp to match. The next leftmost greedy quantifier, if any, will try to match as much of the string remaining available to it as possible, while still allowing the whole regexp to match. And so on, until all the regexp elements are satisfied.

As we have seen above, Principle 0 overrides the others - the regexp will be matched as early as possible, with the other principles determining how the regexp matches at that earliest character position.

Here is an example of these principles in action:

```
$x = "The programming republic of Perl";
$x =~ /^(.+)(e|r)(.*)$/;  # matches,
                          # $1 = 'The programming republic of Pe'
                          # $2 = 'r'
                          # $3 = 'l'
```

This regexp matches at the earliest string position, `'T'`. One might think that `e`, being leftmost in the alternation, would be matched, but `r` produces the longest string in the first quantifier.

```
$x =~ /(m{1,2})(.*)$/;  # matches,
                        # $1 = 'mm'
                        # $2 = 'ing republic of Perl'
```

Here, The earliest possible match is at the first `'m'` in `programming`. `m{1,2}` is the first quantifier, so it gets to match a maximal `mm`.

```
    $x =~ /.*(m{1,2})(.*)$/;  # matches,
                              # $1 = 'm'
                              # $2 = 'ing republic of Perl'
```

Here, the regexp matches at the start of the string. The first quantifier `.*` grabs as much as possible, leaving just a single `'m'` for the second quantifier `m{1,2}`.

```
    $x =~ /(.?)(m{1,2})(.*)$/;  # matches,
                                # $1 = 'a'
                                # $2 = 'mm'
                                # $3 = 'ing republic of Perl'
```

Here, `.?` eats its maximal one character at the earliest possible position in the string, `'a'` in `programming`, leaving `m{1,2}` the opportunity to match both `m`'s. Finally,

```
    "aXXXb" =~ /(X*)/; # matches with $1 = ''
```

because it can match zero copies of `'X'` at the beginning of the string. If you definitely want to match at least one `'X'`, use `X+`, not `X*`.

Sometimes greed is not good. At times, we would like quantifiers to match a *minimal* piece of string, rather than a maximal piece. For this purpose, Larry Wall created the **minimal match** or **non-greedy** quantifiers `??`,`*?`, `+?`, and `{}?`. These are the usual quantifiers with a `?` appended to them. They have the following meanings:

- `a??` = match 'a' 0 or 1 times. Try 0 first, then 1.
- `a*?` = match 'a' 0 or more times, i.e., any number of times, but as few times as possible
- `a+?` = match 'a' 1 or more times, i.e., at least once, but as few times as possible
- `a{n,m}?` = match at least `n` times, not more than `m` times, as few times as possible
- `a{n,}?` = match at least `n` times, but as few times as possible
- `a{n}?` = match exactly `n` times. Because we match exactly `n` times, `a{n}?` is equivalent to `a{n}` and is just there for notational consistency.

Let's look at the example above, but with minimal quantifiers:

```
    $x = "The programming republic of Perl";
    $x =~ /^(.+?)(e|r)(.*)$/; # matches,
                              # $1 = 'Th'
                              # $2 = 'e'
                              # $3 = ' programming republic of Perl'
```

The minimal string that will allow both the start of the string `^` and the alternation to match is `Th`, with the alternation `e|r` matching `e`. The second quantifier `.*` is free to gobble up the rest of the string.

```
    $x =~ /(m{1,2}?)(.*?)$/;  # matches,
                              # $1 = 'm'
                              # $2 = 'ming republic of Perl'
```

The first string position that this regexp can match is at the first `'m'` in `programming`. At this position, the minimal `m{1,2}?` matches just one `'m'`. Although the second quantifier `.*?` would prefer to match no characters, it is constrained by the end-of-string anchor `$` to match the rest of the string.

```
$x =~ /(.*?)(m{1,2}?)(.*)$/;  # matches,
                              # $1 = 'The progra'
                              # $2 = 'm'
                              # $3 = 'ming republic of Perl'
```

In this regexp, you might expect the first minimal quantifier `.*?` to match the empty string, because it is not constrained by a ˆ anchor to match the beginning of the word. Principle 0 applies here, however. Because it is possible for the whole regexp to match at the start of the string, it *will* match at the start of the string. Thus the first quantifier has to match everything up to the first `m`. The second minimal quantifier matches just one `m` and the third quantifier matches the rest of the string.

```
$x =~ /(.??)(m{1,2})(.*)$/;  # matches,
                             # $1 = 'a'
                             # $2 = 'mm'
                             # $3 = 'ing republic of Perl'
```

Just as in the previous regexp, the first quantifier `.??` can match earliest at position `'a'`, so it does. The second quantifier is greedy, so it matches `mm`, and the third matches the rest of the string.

We can modify principle 3 above to take into account non-greedy quantifiers:

- Principle 3: If there are two or more elements in a regexp, the leftmost greedy (non-greedy) quantifier, if any, will match as much (little) of the string as possible while still allowing the whole regexp to match. The next leftmost greedy (non-greedy) quantifier, if any, will try to match as much (little) of the string remaining available to it as possible, while still allowing the whole regexp to match. And so on, until all the regexp elements are satisfied.

Just like alternation, quantifiers are also susceptible to backtracking. Here is a step-by-step analysis of the example

```
$x = "the cat in the hat";
$x =~ /^(.*)(at)(.*)$/; # matches,
                        # $1 = 'the cat in the h'
                        # $2 = 'at'
                        # $3 = ''   (0 matches)
```

1. Start with the first letter in the string 't'.
2. The first quantifier '.*' starts out by matching the whole string 'the cat in the hat'.
3. 'a' in the regexp element 'at' doesn't match the end of the string. Backtrack one character.
4. 'a' in the regexp element 'at' still doesn't match the last letter of the string 't', so backtrack one more character.
5. Now we can match the 'a' and the 't'.
6. Move on to the third element '.*'. Since we are at the end of the string and '.*' can match 0 times, assign it the empty string.
7. We are done!

Most of the time, all this moving forward and backtracking happens quickly and searching is fast. There are some pathological regexps, however, whose execution time exponentially grows with the size of the string. A typical structure that blows up in your face is of the form

```
/(a|b+)*/;
```

The problem is the nested indeterminate quantifiers. There are many different ways of partitioning a string of length n between the + and *: one repetition with `b+` of length n, two repetitions with the first `b+` length k and the second with length n-k, m repetitions whose bits add up to length n, etc. In fact there are an exponential number of ways to partition a string as a function of length. A regexp may get lucky and match early in the process, but if there is no match, perl will try *every* possibility before giving up. So be careful with nested `*`'s, `{n,m}`'s, and +'s. The book *Mastering regular expressions* by Jeffrey Friedl gives a wonderful discussion of this and other efficiency issues.

7.2.7 Building a regexp

At this point, we have all the basic regexp concepts covered, so let's give a more involved example of a regular expression. We will build a regexp that matches numbers.

The first task in building a regexp is to decide what we want to match and what we want to exclude. In our case, we want to match both integers and floating point numbers and we want to reject any string that isn't a number.

The next task is to break the problem down into smaller problems that are easily converted into a regexp.

The simplest case is integers. These consist of a sequence of digits, with an optional sign in front. The digits we can represent with `\d+` and the sign can be matched with `[+-]`. Thus the integer regexp is

```
 /[+-]?\d+/;  # matches integers
```

A floating point number potentially has a sign, an integral part, a decimal point, a fractional part, and an exponent. One or more of these parts is optional, so we need to check out the different possibilities. Floating point numbers which are in proper form include 123., 0.345, .34, -1e6, and 25.4E-72. As with integers, the sign out front is completely optional and can be matched by `[+-]?`. We can see that if there is no exponent, floating point numbers must have a decimal point, otherwise they are integers. We might be tempted to model these with `\d*\.\d*`, but this would also match just a single decimal point, which is not a number. So the three cases of floating point number sans exponent are

```
/[+-]?\d+\./;  # 1., 321., etc.
/[+-]?\.\d+/;  # .1, .234, etc.
/[+-]?\d+\.\d+/;  # 1.0, 30.56, etc.
```

These can be combined into a single regexp with a three-way alternation:

```
/[+-]?(\d+\.\d+|\d+\.|\.\d+)/;  # floating point, no exponent
```

In this alternation, it is important to put `'\d+\.\d+'` before `'\d+\.'`. If `'\d+\.'` were first, the regexp would happily match that and ignore the fractional part of the number.

Now consider floating point numbers with exponents. The key observation here is that *both* integers and numbers with decimal points are allowed in front of an exponent. Then exponents, like the overall sign, are independent of whether we are matching numbers with or without decimal points, and can be 'decoupled' from the mantissa. The overall form of the regexp now becomes clear:

```
 /^(optional sign)(integer | f.p. mantissa)(optional exponent)$/;
```

The exponent is an `e` or `E`, followed by an integer. So the exponent regexp is

```
/[eE][+-]?\d+/;  # exponent
```

Putting all the parts together, we get a regexp that matches numbers:

```
/^[+-]?(\d+\.\d+|\d+\.|\.\d+|\d+)([eE][+-]?\d+)?$/;  # Ta da!
```

Long regexps like this may impress your friends, but can be hard to decipher. In complex situations like this, the `//x` modifier for a match is invaluable. It allows one to put nearly arbitrary whitespace and comments into a regexp without affecting their meaning. Using it, we can rewrite our 'extended' regexp in the more pleasing form

```
/^
   [+-]?         # first, match an optional sign
   (             # then match integers or f.p. mantissas:
       \d+\.\d+  # mantissa of the form a.b
      |\d+\.     # mantissa of the form a.
      |\.\d+     # mantissa of the form .b
      |\d+       # integer of the form a
   )
   ([eE][+-]?\d+)?  # finally, optionally match an exponent
$/x;
```

If whitespace is mostly irrelevant, how does one include space characters in an extended regexp? The answer is to backslash it `'\ '` or put it in a character class `[ ]`. The same thing goes for pound signs, use `\#` or `[#]`. For instance, Perl allows a space between the sign and the mantissa/integer, and we could add this to our regexp as follows:

```
/^
   [+-]?\ *      # first, match an optional sign *and space*
   (             # then match integers or f.p. mantissas:
       \d+\.\d+  # mantissa of the form a.b
      |\d+\.     # mantissa of the form a.
      |\.\d+     # mantissa of the form .b
      |\d+       # integer of the form a
   )
   ([eE][+-]?\d+)?  # finally, optionally match an exponent
$/x;
```

In this form, it is easier to see a way to simplify the alternation. Alternatives 1, 2, and 4 all start with `\d+`, so it could be factored out:

```
/^
   [+-]?\ *      # first, match an optional sign
   (             # then match integers or f.p. mantissas:
       \d+       # start out with a ...
       (
           \.\d* # mantissa of the form a.b or a.
       )?        # ? takes care of integers of the form a
      |\.\d+     # mantissa of the form .b
   )
   ([eE][+-]?\d+)?  # finally, optionally match an exponent
$/x;
```

or written in the compact form,

```
/^[+-]?\ *(\d+(\.\d*)?|\.\d+)([eE][+-]?\d+)?$/;
```

This is our final regexp. To recap, we built a regexp by

- specifying the task in detail,
- breaking down the problem into smaller parts,
- translating the small parts into regexps,
- combining the regexps,
- and optimizing the final combined regexp.

These are also the typical steps involved in writing a computer program. This makes perfect sense, because regular expressions are essentially programs written a little computer language that specifies patterns.

7.2.8 Using regular expressions in Perl

The last topic of Part 1 briefly covers how regexps are used in Perl programs. Where do they fit into Perl syntax?

We have already introduced the matching operator in its default `/regexp/` and arbitrary delimiter `m!regexp!` forms. We have used the binding operator `=~` and its negation `!~` to test for string matches. Associated with the matching operator, we have discussed the single line `//s`, multi-line `//m`, case-insensitive `//i` and extended `//x` modifiers.

There are a few more things you might want to know about matching operators. First, we pointed out earlier that variables in regexps are substituted before the regexp is evaluated:

```
    $pattern = 'Seuss';
    while (<>) {
        print if /$pattern/;
    }
```

This will print any lines containing the word `Seuss`. It is not as efficient as it could be, however, because perl has to re-evaluate `$pattern` each time through the loop. If `$pattern` won't be changing over the lifetime of the script, we can add the `//o` modifier, which directs perl to only perform variable substitutions once:

```
    #!/usr/bin/perl
    #    Improved simple_grep
    $regexp = shift;
    while (<>) {
        print if /$regexp/o;  # a good deal faster
    }
```

If you change `$pattern` after the first substitution happens, perl will ignore it. If you don't want any substitutions at all, use the special delimiter `m''`:

```
    @pattern = ('Seuss');
    while (<>) {
        print if m'@pattern';  # matches literal '@pattern', not 'Seuss'
    }
```

`m''` acts like single quotes on a regexp; all other `m` delimiters act like double quotes. If the regexp evaluates to the empty string, the regexp in the *last successful match* is used instead. So we have

```
    "dog" =~ /d/;  # 'd' matches
    "dogbert =~ //;  # this matches the 'd' regexp used before
```

The final two modifiers `//g` and `//c` concern multiple matches. The modifier `//g` stands for global matching and allows the matching operator to match within a string as many times as possible. In scalar context, successive invocations against a string will have '`//g` jump from match to match, keeping track of position in the string as it goes along. You can get or set the position with the `pos()` function.

The use of `//g` is shown in the following example. Suppose we have a string that consists of words separated by spaces. If we know how many words there are in advance, we could extract the words using groupings:

```
    $x = "cat dog house"; # 3 words
    $x =~ /^\s*(\w+)\s+(\w+)\s+(\w+)\s*$/; # matches,
                                           # $1 = 'cat'
                                           # $2 = 'dog'
                                           # $3 = 'house'
```

But what if we had an indeterminate number of words? This is the sort of task `//g` was made for. To extract all words, form the simple regexp `(\w+)` and loop over all matches with `/(\w+)/g`:

```
    while ($x =~ /(\w+)/g) {
        print "Word is $1, ends at position ", pos $x, "\n";
    }
```

prints

```
    Word is cat, ends at position 3
    Word is dog, ends at position 7
    Word is house, ends at position 13
```

A failed match or changing the target string resets the position. If you don't want the position reset after failure to match, add the `//c`, as in `/regexp/gc`. The current position in the string is associated with the string, not the regexp. This means that different strings have different positions and their respective positions can be set or read independently.

In list context, `//g` returns a list of matched groupings, or if there are no groupings, a list of matches to the whole regexp. So if we wanted just the words, we could use

```
@words = ($x =~ /(\w+)/g);  # matches,
                            # $word[0] = 'cat'
                            # $word[1] = 'dog'
                            # $word[2] = 'house'
```

Closely associated with the `//g` modifier is the `\G` anchor. The `\G` anchor matches at the point where the previous `//g` match left off. `\G` allows us to easily do context-sensitive matching:

```
$metric = 1;  # use metric units
...
$x = <FILE>;  # read in measurement
$x =~ /^([+-]?\d+)\s*/g;  # get magnitude
$weight = $1;
if ($metric) { # error checking
    print "Units error!" unless $x =~ /\Gkg\./g;
}
else {
    print "Units error!" unless $x =~ /\Glbs\./g;
}
$x =~ /\G\s+(widget|sprocket)/g;  # continue processing
```

The combination of `//g` and `\G` allows us to process the string a bit at a time and use arbitrary Perl logic to decide what to do next. Currently, the `\G` anchor is only fully supported when used to anchor to the start of the pattern.

`\G` is also invaluable in processing fixed length records with regexps. Suppose we have a snippet of coding region DNA, encoded as base pair letters `ATCGTTGAAT...` and we want to find all the stop codons `TGA`. In a coding region, codons are 3-letter sequences, so we can think of the DNA snippet as a sequence of 3-letter records. The naive regexp

```
# expanded, this is "ATC GTT GAA TGC AAA TGA CAT GAC"
$dna = "ATCGTTGAATGCAAATGACATGAC";
$dna =~ /TGA/;
```

doesn't work; it may match a `TGA`, but there is no guarantee that the match is aligned with codon boundaries, e.g., the substring `GTT GAA` gives a match. A better solution is

```
while ($dna =~ /(\w\w\w)*?TGA/g) {  # note the minimal *?
    print "Got a TGA stop codon at position ", pos $dna, "\n";
}
```

which prints

```
Got a TGA stop codon at position 18
Got a TGA stop codon at position 23
```

Position 18 is good, but position 23 is bogus. What happened?

The answer is that our regexp works well until we get past the last real match. Then the regexp will fail to match a synchronized `TGA` and start stepping ahead one character position at a time, not what we want. The solution is to use `\G` to anchor the match to the codon alignment:

```
    while ($dna =~ /\G(\w\w\w)*?TGA/g) {
        print "Got a TGA stop codon at position ", pos $dna, "\n";
    }
```

This prints

```
    Got a TGA stop codon at position 18
```

which is the correct answer. This example illustrates that it is important not only to match what is desired, but to reject what is not desired.

search and replace

Regular expressions also play a big role in **search and replace** operations in Perl. Search and replace is accomplished with the `s///` operator. The general form is `s/regexp/replacement/modifiers`, with everything we know about regexps and modifiers applying in this case as well. The `replacement` is a Perl double quoted string that replaces in the string whatever is matched with the `regexp`. The operator `=~` is also used here to associate a string with `s///`. If matching against `$_`, the `$_ =~` can be dropped. If there is a match, `s///` returns the number of substitutions made, otherwise it returns false. Here are a few examples:

```
    $x = "Time to feed the cat!";
    $x =~ s/cat/hacker/;   # $x contains "Time to feed the hacker!"
    if ($x =~ s/^(Time.*hacker)!$/$1 now!/) {
        $more_insistent = 1;
    }
    $y = "'quoted words'";
    $y =~ s/^'(.*)'$/$1/;  # strip single quotes,
                           # $y contains "quoted words"
```

In the last example, the whole string was matched, but only the part inside the single quotes was grouped. With the `s///` operator, the matched variables `$1`, `$2`, etc. are immediately available for use in the replacement expression, so we use `$1` to replace the quoted string with just what was quoted. With the global modifier, `s///g` will search and replace all occurrences of the regexp in the string:

```
    $x = "I batted 4 for 4";
    $x =~ s/4/four/;   # doesn't do it all:
                       # $x contains "I batted four for 4"
    $x = "I batted 4 for 4";
    $x =~ s/4/four/g;  # does it all:
                       # $x contains "I batted four for four"
```

If you prefer 'regex' over 'regexp' in this tutorial, you could use the following program to replace it:

```
    % cat > simple_replace
    #!/usr/bin/perl
    $regexp = shift;
    $replacement = shift;
    while (<>) {
        s/$regexp/$replacement/go;
        print;
    }
    ^D

    % simple_replace regexp regex perlretut.pod
```

In `simple_replace` we used the `s///g` modifier to replace all occurrences of the regexp on each line and the `s///o` modifier to compile the regexp only once. As with `simple_grep`, both the `print` and the `s/$regexp/$replacement/go` use `$_` implicitly.

A modifier available specifically to search and replace is the `s///e` evaluation modifier. `s///e` wraps an `eval{...}` around the replacement string and the evaluated result is substituted for the matched substring. `s///e` is useful if you need to do a bit of computation in the process of replacing text. This example counts character frequencies in a line:

```
$x = "Bill the cat";
$x =~ s/(.)/$chars{$1}++;$1/eg;  # final $1 replaces char with itself
print "frequency of '$_' is $chars{$_}\n"
    foreach (sort {$chars{$b} <=> $chars{$a}} keys %chars);
```

This prints

```
frequency of ' ' is 2
frequency of 't' is 2
frequency of 'l' is 2
frequency of 'B' is 1
frequency of 'c' is 1
frequency of 'e' is 1
frequency of 'h' is 1
frequency of 'i' is 1
frequency of 'a' is 1
```

As with the match `m//` operator, `s///` can use other delimiters, such as `s!!!` and `s{}{}`, and even `s{}//`. If single quotes are used `s'''`, then the regexp and replacement are treated as single quoted strings and there are no substitutions. `s///` in list context returns the same thing as in scalar context, i.e., the number of matches.

The split operator

The **`split`** function can also optionally use a matching operator `m//` to split a string. `split /regexp/, string, limit` splits `string` into a list of substrings and returns that list. The regexp is used to match the character sequence that the `string` is split with respect to. The `limit`, if present, constrains splitting into no more than `limit` number of strings. For example, to split a string into words, use

```
$x = "Calvin and Hobbes";
@words = split /\s+/, $x;  # $word[0] = 'Calvin'
                           # $word[1] = 'and'
                           # $word[2] = 'Hobbes'
```

If the empty regexp `//` is used, the regexp always matches and the string is split into individual characters. If the regexp has groupings, then list produced contains the matched substrings from the groupings as well. For instance,

```
$x = "/usr/bin/perl";
@dirs = split m!/!, $x;  # $dirs[0] = ''
                         # $dirs[1] = 'usr'
                         # $dirs[2] = 'bin'
                         # $dirs[3] = 'perl'
@parts = split m!(/)!, $x;  # $parts[0] = ''
                            # $parts[1] = '/'
                            # $parts[2] = 'usr'
                            # $parts[3] = '/'
                            # $parts[4] = 'bin'
                            # $parts[5] = '/'
                            # $parts[6] = 'perl'
```

Since the first character of $x matched the regexp, `split` prepended an empty initial element to the list.

If you have read this far, congratulations! You now have all the basic tools needed to use regular expressions to solve a wide range of text processing problems. If this is your first time through the tutorial, why not stop here and play around with regexps a while... Part 2 concerns the more esoteric aspects of regular expressions and those concepts certainly aren't needed right at the start.

7.3 Part 2: Power tools

OK, you know the basics of regexps and you want to know more. If matching regular expressions is analogous to a walk in the woods, then the tools discussed in Part 1 are analogous to topo maps and a compass, basic tools we use all the time. Most of the tools in part 2 are analogous to flare guns and satellite phones. They aren't used too often on a hike, but when we are stuck, they can be invaluable.

What follows are the more advanced, less used, or sometimes esoteric capabilities of perl regexps. In Part 2, we will assume you are comfortable with the basics and concentrate on the new features.

7.3.1 More on characters, strings, and character classes

There are a number of escape sequences and character classes that we haven't covered yet.

There are several escape sequences that convert characters or strings between upper and lower case. `\l` and `\u` convert the next character to lower or upper case, respectively:

```
    $x = "perl";
    $string =~ /\u$x/;  # matches 'Perl' in $string
    $x = "M(rs?|s)\\."; # note the double backslash
    $string =~ /\l$x/;  # matches 'mr.', 'mrs.', and 'ms.',
```

`\L` and `\U` converts a whole substring, delimited by `\L` or `\U` and `\E`, to lower or upper case:

```
    $x = "This word is in lower case:\L SHOUT\E";
    $x =~ /shout/;       # matches
    $x = "I STILL KEYPUNCH CARDS FOR MY 360"
    $x =~ /\Ukeypunch/;  # matches punch card string
```

If there is no `\E`, case is converted until the end of the string. The regexps `\L\u$word` or `\u\L$word` convert the first character of `$word` to uppercase and the rest of the characters to lowercase.

Control characters can be escaped with `\c`, so that a control-Z character would be matched with `\cZ`. The escape sequence `\Q`...`\E` quotes, or protects most non-alphabetic characters. For instance,

```
    $x = "\QThat !^*&%~& cat!";
    $x =~ /\Q!^*&%~&\E/;  # check for rough language
```

It does not protect `$` or `@`, so that variables can still be substituted.

With the advent of 5.6.0, perl regexps can handle more than just the standard ASCII character set. Perl now supports **Unicode**, a standard for encoding the character sets from many of the world's written languages. Unicode does this by allowing characters to be more than one byte wide. Perl uses the UTF-8 encoding, in which ASCII characters are still encoded as one byte, but characters greater than `chr(127)` may be stored as two or more bytes.

What does this mean for regexps? Well, regexp users don't need to know much about perl's internal representation of strings. But they do need to know 1) how to represent Unicode characters in a regexp and 2) when a matching operation will treat the string to be searched as a sequence of bytes (the old way) or as a sequence of Unicode characters (the new way). The answer to 1) is that Unicode characters greater than `chr(127)` may be represented using the `\x{hex}` notation, with `hex` a hexadecimal integer:

```
    /\x{263a}/;  # match a Unicode smiley face :)
```

Unicode characters in the range of 128-255 use two hexadecimal digits with braces: `\x{ab}`. Note that this is different than `\xab`, which is just a hexadecimal byte with no Unicode significance.

NOTE: in Perl 5.6.0 it used to be that one needed to say `use utf8` to use any Unicode features. This is no more the case: for almost all Unicode processing, the explicit `utf8` pragma is not needed. (The only case where it matters is if your Perl script is in Unicode and encoded in UTF-8, then an explicit `use utf8` is needed.)

Figuring out the hexadecimal sequence of a Unicode character you want or deciphering someone else's hexadecimal Unicode regexp is about as much fun as programming in machine code. So another way to specify Unicode characters is to use the **named character** escape sequence `\N{name}`. `name` is a name for the Unicode character, as specified in the Unicode standard. For instance, if we wanted to represent or match the astrological sign for the planet Mercury, we could use

```
    use charnames ":full"; # use named chars with Unicode full names
    $x = "abc\N{MERCURY}def";
    $x =~ /\N{MERCURY}/;   # matches
```

One can also use short names or restrict names to a certain alphabet:

```
    use charnames ':full';
    print "\N{GREEK SMALL LETTER SIGMA} is called sigma.\n";

    use charnames ":short";
    print "\N{greek:Sigma} is an upper-case sigma.\n";

    use charnames qw(greek);
    print "\N{sigma} is Greek sigma\n";
```

A list of full names is found in the file Names.txt in the lib/perl5/5.X.X/unicore directory.

The answer to requirement 2), as of 5.6.0, is that if a regexp contains Unicode characters, the string is searched as a sequence of Unicode characters. Otherwise, the string is searched as a sequence of bytes. If the string is being searched as a sequence of Unicode characters, but matching a single byte is required, we can use the `\C` escape sequence. `\C` is a character class akin to `.` except that it matches *any* byte 0-255. So

```
    use charnames ":full"; # use named chars with Unicode full names
    $x = "a";
    $x =~ /\C/;  # matches 'a', eats one byte
    $x = "";
    $x =~ /\C/;  # doesn't match, no bytes to match
    $x = "\N{MERCURY}";  # two-byte Unicode character
    $x =~ /\C/;  # matches, but dangerous!
```

The last regexp matches, but is dangerous because the string *character* position is no longer synchronized to the string *byte* position. This generates the warning 'Malformed UTF-8 character'. The `\C` is best used for matching the binary data in strings with binary data intermixed with Unicode characters.

Let us now discuss the rest of the character classes. Just as with Unicode characters, there are named Unicode character classes represented by the `\p{name}` escape sequence. Closely associated is the `\P{name}` character class, which is the negation of the `\p{name}` class. For example, to match lower and uppercase characters,

```
    use charnames ":full"; # use named chars with Unicode full names
    $x = "BOB";
    $x =~ /^\p{IsUpper}/;   # matches, uppercase char class
    $x =~ /^\P{IsUpper}/;   # doesn't match, char class sans uppercase
    $x =~ /^\p{IsLower}/;   # doesn't match, lowercase char class
    $x =~ /^\P{IsLower}/;   # matches, char class sans lowercase
```

Here is the association between some Perl named classes and the traditional Unicode classes:

```
    Perl class name  Unicode class name or regular expression

    IsAlpha          /^[LM]/
    IsAlnum          /^[LMN]/
    IsASCII          $code <= 127
    IsCntrl          /^C/
    IsBlank          $code =~ /^(0020|0009)$/ || /^Z[^lp]/
    IsDigit          Nd
    IsGraph          /^([LMNPS]|Co)/
    IsLower          Ll
    IsPrint         /^([LMNPS]|Co|Zs)/
    IsPunct         /^P/
    IsSpace         /^Z/ || ($code =~ /^(0009|000A|000B|000C|000D)$/
    IsSpacePerl     /^Z/ || ($code =~ /^(0009|000A|000C|000D|0085|2028|2029)$/
    IsUpper         /^L[ut]/
    IsWord          /^[LMN]/ || $code eq "005F"
    IsXDigit        $code =~ /^00(3[0-9]|[46][1-6])$/
```

You can also use the official Unicode class names with the `\p` and `\P`, like `\p{L}` for Unicode 'letters', or `\p{Lu}` for uppercase letters, or `\P{Nd}` for non-digits. If a `name` is just one letter, the braces can be dropped. For instance, `\pM` is the character class of Unicode 'marks', for example accent marks. For the full list see *perlunicode*.

The Unicode has also been separated into various sets of charaters which you can test with `\p{In...}` (in) and `\P{In...}` (not in), for example `\p{Latin}`, `\p{Greek}`, or `\P{Katakana}`. For the full list see *perlunicode*.

`\X` is an abbreviation for a character class sequence that includes the Unicode 'combining character sequences'. A 'combining character sequence' is a base character followed by any number of combining characters. An example of a combining character is an accent. Using the Unicode full names, e.g., `A + COMBINING RING` is a combining character sequence with base character `A` and combining character `COMBINING RING` , which translates in Danish to A with the circle atop it, as in the word Angstrom. `\X` is equivalent to `\PM\pM*}`, i.e., a non-mark followed by one or more marks.

For the full and latest information about Unicode see the latest Unicode standard, or the Unicode Consortium's website http://www.unicode.org/

As if all those classes weren't enough, Perl also defines POSIX style character classes. These have the form `[:name:]`, with `name` the name of the POSIX class. The POSIX classes are `alpha`, `alnum`, `ascii`, `cntrl`, `digit`, `graph`, `lower`, `print`, `punct`, `space`, `upper`, and `xdigit`, and two extensions, `word` (a Perl extension to match `\w`), and `blank` (a GNU extension). If `utf8` is being used, then these classes are defined the same as their corresponding perl Unicode classes: `[:upper:]` is the same as `\p{IsUpper}`, etc. The POSIX character classes, however, don't require using `utf8`. The `[:digit:]`, `[:word:]`, and `[:space:]` correspond to the familiar `\d`, `\w`, and `\s` character classes. To negate a POSIX class, put a ˆ in front of the name, so that, e.g., `[:ˆdigit:]` corresponds to `\D` and under `utf8`, `\P{IsDigit}`. The Unicode and POSIX character classes can be used just like `\d`, with the exception that POSIX character classes can only be used inside of a character class:

```
    /\s+[abc[:digit:]xyz]\s*/;  # match a,b,c,x,y,z, or a digit
    /^=item\s[[:digit:]]/;      # match '=item',
                                # followed by a space and a digit
    use charnames ":full";
    /\s+[abc\p{IsDigit}xyz]\s+/;  # match a,b,c,x,y,z, or a digit
    /^=item\s\p{IsDigit}/;        # match '=item',
                                  # followed by a space and a digit
```

Whew! That is all the rest of the characters and character classes.

7.3.2 Compiling and saving regular expressions

In Part 1 we discussed the `//o` modifier, which compiles a regexp just once. This suggests that a compiled regexp is some data structure that can be stored once and used again and again. The regexp quote `qr//` does exactly that: `qr/string/` compiles the `string` as a regexp and transforms the result into a form that can be assigned to a variable:

```
    $reg = qr/foo+bar?/;  # reg contains a compiled regexp
```

Then `$reg` can be used as a regexp:

```
    $x = "fooooba";
    $x =~ $reg;     # matches, just like /foo+bar?/
    $x =~ /$reg/;   # same thing, alternate form
```

`$reg` can also be interpolated into a larger regexp:

```
    $x =~ /(abc)?$reg/;  # still matches
```

As with the matching operator, the regexp quote can use different delimiters, e.g., `qr!!`, `qr{}` and `qr˜˜`. The single quote delimiters `qr”` prevent any interpolation from taking place.

Pre-compiled regexps are useful for creating dynamic matches that don’t need to be recompiled each time they are encountered. Using pre-compiled regexps, `simple_grep` program can be expanded into a program that matches multiple patterns:

```
    % cat > multi_grep
    #!/usr/bin/perl
    # multi_grep - match any of <number> regexps
    # usage: multi_grep <number> regexp1 regexp2 ... file1 file2 ...

    $number = shift;
    $regexp[$_] = shift foreach (0..$number-1);
    @compiled = map qr/$_/, @regexp;
    while ($line = <>) {
        foreach $pattern (@compiled) {
            if ($line =~ /$pattern/) {
                print $line;
                last;  # we matched, so move onto the next line
            }
        }
    }
    ^D

    % multi_grep 2 last for multi_grep
        $regexp[$_] = shift foreach (0..$number-1);
            foreach $pattern (@compiled) {
                    last;
```

Storing pre-compiled regexps in an array `@compiled` allows us to simply loop through the regexps without any recompilation, thus gaining flexibility without sacrificing speed.

7.3.3 Embedding comments and modifiers in a regular expression

Starting with this section, we will be discussing Perl’s set of **extended patterns**. These are extensions to the traditional regular expression syntax that provide powerful new tools for pattern matching. We have already seen extensions in the form of the minimal matching constructs `??`, `*?`, `+?`, `{n,m}?`, and `{n,}?`. The rest of the extensions below have the form `(?char...)`, where the `char` is a character that determines the type of extension.

The first extension is an embedded comment `(?#text)`. This embeds a comment into the regular expression without affecting its meaning. The comment should not have any closing parentheses in the text. An example is

```
    /(?# Match an integer:)[+-]?\d+/;
```

This style of commenting has been largely superseded by the raw, freeform commenting that is allowed with the `//x` modifier.

The modifiers `//i`, `//m`, `//s`, and `//x` can also embedded in a regexp using `(?i)`, `(?m)`, `(?s)`, and `(?x)`. For instance,

```
    /(?i)yes/;  # match 'yes' case insensitively
    /yes/i;     # same thing
    /(?x)(          # freeform version of an integer regexp
             [+-]?  # match an optional sign
             \d+    # match a sequence of digits
         )
    /x;
```

Embedded modifiers can have two important advantages over the usual modifiers. Embedded modifiers allow a custom set of modifiers to *each* regexp pattern. This is great for matching an array of regexps that must have different modifiers:

```
    $pattern[0] = '(?i)doctor';
    $pattern[1] = 'Johnson';
    ...
    while (<>) {
        foreach $patt (@pattern) {
            print if /$patt/;
        }
    }
```

The second advantage is that embedded modifiers only affect the regexp inside the group the embedded modifier is contained in. So grouping can be used to localize the modifier's effects:

```
    /Answer: ((?i)yes)/;  # matches 'Answer: yes', 'Answer: YES', etc.
```

Embedded modifiers can also turn off any modifiers already present by using, e.g., `(?-i)`. Modifiers can also be combined into a single expression, e.g., `(?s-i)` turns on single line mode and turns off case insensitivity.

7.3.4 Non-capturing groupings

We noted in Part 1 that groupings `()` had two distinct functions: 1) group regexp elements together as a single unit, and 2) extract, or capture, substrings that matched the regexp in the grouping. Non-capturing groupings, denoted by `(?:regexp)`, allow the regexp to be treated as a single unit, but don't extract substrings or set matching variables `$1`, etc. Both capturing and non-capturing groupings are allowed to co-exist in the same regexp. Because there is no extraction, non-capturing groupings are faster than capturing groupings. Non-capturing groupings are also handy for choosing exactly which parts of a regexp are to be extracted to matching variables:

```
    # match a number, $1-$4 are set, but we only want $1
    /([+-]?\ *(\d+(\.\d*)?|\.\d+)([eE][+-]?\d+)?)/;

    # match a number faster , only $1 is set
    /([+-]?\ *(?:\d+(?:\.\d*)?|\.\d+)(?:[eE][+-]?\d+)?)/;

    # match a number, get $1 = whole number, $2 = exponent
    /([+-]?\ *(?:\d+(?:\.\d*)?|\.\d+)(?:[eE]([+-]?\d+))?)/;
```

Non-capturing groupings are also useful for removing nuisance elements gathered from a split operation:

```
    $x = '12a34b5';
    @num = split /(a|b)/, $x;    # @num = ('12','a','34','b','5')
    @num = split /(?:a|b)/, $x;  # @num = ('12','34','5')
```

Non-capturing groupings may also have embedded modifiers: `(?i-m:regexp)` is a non-capturing grouping that matches `regexp` case insensitively and turns off multi-line mode.

7.3.5 Looking ahead and looking behind

This section concerns the lookahead and lookbehind assertions. First, a little background.

In Perl regular expressions, most regexp elements 'eat up' a certain amount of string when they match. For instance, the regexp element `[abc}]` eats up one character of the string when it matches, in the sense that perl moves to the next character position in the string after the match. There are some elements, however, that don't eat up characters (advance the character position) if they match. The examples we have seen so far are the anchors. The anchor ˆ matches the beginning of the line, but doesn't eat any characters. Similarly, the word boundary anchor `\b` matches, e.g., if the character to the left is a word character and the character to the right is a non-word character, but it doesn't eat up any characters itself. Anchors are examples of 'zero-width assertions'. Zero-width, because they consume no characters, and assertions, because they test some property of the string. In the context of our walk in the woods analogy to regexp matching, most regexp elements move us along a trail, but anchors have us stop a moment and check our surroundings. If the local environment checks out, we can proceed forward. But if the local environment doesn't satisfy us, we must backtrack.

Checking the environment entails either looking ahead on the trail, looking behind, or both. ˆ looks behind, to see that there are no characters before. `$` looks ahead, to see that there are no characters after. `\b` looks both ahead and behind, to see if the characters on either side differ in their 'word'-ness.

The lookahead and lookbehind assertions are generalizations of the anchor concept. Lookahead and lookbehind are zero-width assertions that let us specify which characters we want to test for. The lookahead assertion is denoted by `(?=regexp)` and the lookbehind assertion is denoted by `(?<=fixed-regexp)`. Some examples are

```
    $x = "I catch the housecat 'Tom-cat' with catnip";
    $x =~ /cat(?=\s+)/;  # matches 'cat' in 'housecat'
    @catwords = ($x =~ /(?<=\s)cat\w+/g);  # matches,
                                           # $catwords[0] = 'catch'
                                           # $catwords[1] = 'catnip'
    $x =~ /\bcat\b/;  # matches 'cat' in 'Tom-cat'
    $x =~ /(?<=\s)cat(?=\s)/; # doesn't match; no isolated 'cat' in
                              # middle of $x
```

Note that the parentheses in `(?=regexp)` and `(?<=regexp)` are non-capturing, since these are zero-width assertions. Thus in the second regexp, the substrings captured are those of the whole regexp itself. Lookahead `(?=regexp)` can match arbitrary regexps, but lookbehind `(?<=fixed-regexp)` only works for regexps of fixed width, i.e., a fixed number of characters long. Thus `(?<=(ab|bc))` is fine, but `(?<=(ab)*)` is not. The negated versions of the lookahead and lookbehind assertions are denoted by `(?!regexp)` and `(?<!fixed-regexp)` respectively. They evaluate true if the regexps do *not* match:

```
    $x = "foobar";
    $x =~ /foo(?!bar)/;  # doesn't match, 'bar' follows 'foo'
    $x =~ /foo(?!baz)/;  # matches, 'baz' doesn't follow 'foo'
    $x =~ /(?<!\s)foo/;  # matches, there is no \s before 'foo'
```

The `\C` is unsupported in lookbehind, because the already treacherous definition of `\C` would become even more so when going backwards.

7.3.6 Using independent subexpressions to prevent backtracking

The last few extended patterns in this tutorial are experimental as of 5.6.0. Play with them, use them in some code, but don't rely on them just yet for production code.

Independent subexpressions are regular expressions, in the context of a larger regular expression, that function independently of the larger regular expression. That is, they consume as much or as little of the string as they wish without regard for the ability of the larger regexp to match. Independent subexpressions are represented by `(?>regexp)`. We can illustrate their behavior by first considering an ordinary regexp:

```
    $x = "ab";
    $x =~ /a*ab/;  # matches
```

This obviously matches, but in the process of matching, the subexpression `a*` first grabbed the `a`. Doing so, however, wouldn't allow the whole regexp to match, so after backtracking, `a*` eventually gave back the `a` and matched the empty string. Here, what `a*` matched was *dependent* on what the rest of the regexp matched.

Contrast that with an independent subexpression:

```
    $x =~ /(?>a*)ab/;  # doesn't match!
```

The independent subexpression `(?>a*)` doesn't care about the rest of the regexp, so it sees an `a` and grabs it. Then the rest of the regexp `ab` cannot match. Because `(?>a*)` is independent, there is no backtracking and the independent subexpression does not give up its `a`. Thus the match of the regexp as a whole fails. A similar behavior occurs with completely independent regexps:

```
    $x = "ab";
    $x =~ /a*/g;   # matches, eats an 'a'
    $x =~ /\Gab/g; # doesn't match, no 'a' available
```

Here `//g` and `\G` create a 'tag team' handoff of the string from one regexp to the other. Regexps with an independent subexpression are much like this, with a handoff of the string to the independent subexpression, and a handoff of the string back to the enclosing regexp.

The ability of an independent subexpression to prevent backtracking can be quite useful. Suppose we want to match a non-empty string enclosed in parentheses up to two levels deep. Then the following regexp matches:

```
    $x = "abc(de(fg)h";  # unbalanced parentheses
    $x =~ /\( ( [^()]+ | \([^()]*\) )+ \)/x;
```

The regexp matches an open parenthesis, one or more copies of an alternation, and a close parenthesis. The alternation is two-way, with the first alternative `[^()]+` matching a substring with no parentheses and the second alternative `\([^()]*\)` matching a substring delimited by parentheses. The problem with this regexp is that it is pathological: it has nested indeterminate quantifiers of the form `(a+|b)+`. We discussed in Part 1 how nested quantifiers like this could take an exponentially long time to execute if there was no match possible. To prevent the exponential blowup, we need to prevent useless backtracking at some point. This can be done by enclosing the inner quantifier as an independent subexpression:

```
    $x =~ /\( ( (?>[^()]+) | \([^()]*\) )+ \)/x;
```

Here, `(?>[^()]+)` breaks the degeneracy of string partitioning by gobbling up as much of the string as possible and keeping it. Then match failures fail much more quickly.

7.3.7 Conditional expressions

A **conditional expression** is a form of if-then-else statement that allows one to choose which patterns are to be matched, based on some condition. There are two types of conditional expression: `(?(condition)yes-regexp)` and `(?(condition)yes-regexp|no-regexp)`. `(?(condition)yes-regexp)` is like an `'if () {}'` statement in Perl. If the `condition` is true, the `yes-regexp` will be matched. If the `condition` is false, the `yes-regexp` will be skipped and perl will move onto the next regexp element. The second form is like an `'if () {} else {}'` statement in Perl. If the `condition` is true, the `yes-regexp` will be matched, otherwise the `no-regexp` will be matched.

The `condition` can have two forms. The first form is simply an integer in parentheses `(integer)`. It is true if the corresponding backreference `\integer` matched earlier in the regexp. The second form is a bare zero width assertion `(?...)`, either a lookahead, a lookbehind, or a code assertion (discussed in the next section).

The integer form of the `condition` allows us to choose, with more flexibility, what to match based on what matched earlier in the regexp. This searches for words of the form `"$x$x"` or `"$x$y$y$x"`:

```
% simple_grep '^(\w+)(\w+)?(?(2)\2\1|\1)$' /usr/dict/words
beriberi
coco
couscous
deed
...
toot
toto
tutu
```

The lookbehind `condition` allows, along with backreferences, an earlier part of the match to influence a later part of the match. For instance,

```
/[ATGC]+(?(?<=AA)G|C)$/;
```

matches a DNA sequence such that it either ends in `AAG`, or some other base pair combination and `C`. Note that the form is `(?(?<=AA)G|C)` and not `(?((?<=AA))G|C)`; for the lookahead, lookbehind or code assertions, the parentheses around the conditional are not needed.

7.3.8 A bit of magic: executing Perl code in a regular expression

Normally, regexps are a part of Perl expressions. **Code evaluation** expressions turn that around by allowing arbitrary Perl code to be a part of a regexp. A code evaluation expression is denoted `(?{code})`, with `code` a string of Perl statements.

Code expressions are zero-width assertions, and the value they return depends on their environment. There are two possibilities: either the code expression is used as a conditional in a conditional expression `(?(condition)...)`, or it is not. If the code expression is a conditional, the code is evaluated and the result (i.e., the result of the last statement) is used to determine truth or falsehood. If the code expression is not used as a conditional, the assertion always evaluates true and the result is put into the special variable `$^R`. The variable `$^R` can then be used in code expressions later in the regexp. Here are some silly examples:

```
$x = "abcdef";
$x =~ /abc(?{print "Hi Mom!";})def/; # matches,
                                     # prints 'Hi Mom!'
$x =~ /aaa(?{print "Hi Mom!";})def/; # doesn't match,
                                     # no 'Hi Mom!'
```

Pay careful attention to the next example:

```
$x =~ /abc(?{print "Hi Mom!";})ddd/; # doesn't match,
                                     # no 'Hi Mom!'
                                     # but why not?
```

At first glance, you'd think that it shouldn't print, because obviously the `ddd` isn't going to match the target string. But look at this example:

```
$x =~ /abc(?{print "Hi Mom!";})[d]dd/; # doesn't match,
                                       # but _does_ print
```

Hmm. What happened here? If you've been following along, you know that the above pattern should be effectively the same as the last one – enclosing the d in a character class isn't going to change what it matches. So why does the first not print while the second one does?

The answer lies in the optimizations the REx engine makes. In the first case, all the engine sees are plain old characters (aside from the `?{}` construct). It's smart enough to realize that the string 'ddd' doesn't occur in our target string before actually running the pattern through. But in the second case, we've tricked it into thinking that our pattern is more complicated than it is. It takes a look, sees our character class, and decides that it will have to actually run the pattern to determine whether or not it matches, and in the process of running it hits the print statement before it discovers that we don't have a match.

To take a closer look at how the engine does optimizations, see the section §7.3.9 below.

More fun with `?{}`:

```
    $x =~ /(?{print "Hi Mom!";})/;       # matches,
                                         # prints 'Hi Mom!'
    $x =~ /(?{$c = 1;})(?{print "$c";})/;  # matches,
                                           # prints '1'
    $x =~ /(?{$c = 1;})(?{print "$^R";})/; # matches,
                                           # prints '1'
```

The bit of magic mentioned in the section title occurs when the regexp backtracks in the process of searching for a match. If the regexp backtracks over a code expression and if the variables used within are localized using `local`, the changes in the variables produced by the code expression are undone! Thus, if we wanted to count how many times a character got matched inside a group, we could use, e.g.,

```
    $x = "aaaa";
    $count = 0;  # initialize 'a' count
    $c = "bob";  # test if $c gets clobbered
    $x =~ /(?{local $c = 0;})         # initialize count
           ( a                        # match 'a'
             (?{local $c = $c + 1;})  # increment count
           )*                         # do this any number of times,
           aa                         # but match 'aa' at the end
           (?{$count = $c;})          # copy local $c var into $count
          /x;
    print "'a' count is $count, \$c variable is '$c'\n";
```

This prints

```
    'a' count is 2, $c variable is 'bob'
```

If we replace the `(?{local $c = $c + 1;})` with `(?{$c = $c + 1;})`, the variable changes are *not* undone during backtracking, and we get

```
    'a' count is 4, $c variable is 'bob'
```

Note that only localized variable changes are undone. Other side effects of code expression execution are permanent. Thus

```
    $x = "aaaa";
    $x =~ /(a(?{print "Yow\n";}))*aa/;
```

produces

```
   Yow
   Yow
   Yow
   Yow
```

The result `$^R` is automatically localized, so that it will behave properly in the presence of backtracking.

This example uses a code expression in a conditional to match the article 'the' in either English or German:

```
    $lang = 'DE';  # use German
    ...
    $text = "das";
    print "matched\n"
        if $text =~ /(?(?{
                          $lang eq 'EN'; # is the language English?
                         })
                       the |             # if so, then match 'the'
                       (die|das|der)     # else, match 'die|das|der'
                    )
                   /xi;
```

Note that the syntax here is `(?(?{...})yes-regexp|no-regexp)`, not `(?((?{...}))yes-regexp|no-regexp)`. In other words, in the case of a code expression, we don't need the extra parentheses around the conditional.

If you try to use code expressions with interpolating variables, perl may surprise you:

```
    $bar = 5;
    $pat = '(?{ 1 })';
    /foo(?{ $bar })bar/; # compiles ok, $bar not interpolated
    /foo(?{ 1 })$bar/;   # compile error!
    /foo${pat}bar/;      # compile error!

    $pat = qr/(?{ $foo = 1 })/;  # precompile code regexp
    /foo${pat}bar/;      # compiles ok
```

If a regexp has (1) code expressions and interpolating variables,or (2) a variable that interpolates a code expression, perl treats the regexp as an error. If the code expression is precompiled into a variable, however, interpolating is ok. The question is, why is this an error?

The reason is that variable interpolation and code expressions together pose a security risk. The combination is dangerous because many programmers who write search engines often take user input and plug it directly into a regexp:

```
    $regexp = <>;       # read user-supplied regexp
    $chomp $regexp;     # get rid of possible newline
    $text =~ /$regexp/; # search $text for the $regexp
```

If the `$regexp` variable contains a code expression, the user could then execute arbitrary Perl code. For instance, some joker could search for `system('rm -rf *');` to erase your files. In this sense, the combination of interpolation and code expressions **taints** your regexp. So by default, using both interpolation and code expressions in the same regexp is not allowed. If you're not concerned about malicious users, it is possible to bypass this security check by invoking `use re 'eval'`:

```
    use re 'eval';       # throw caution out the door
    $bar = 5;
    $pat = '(?{ 1 })';
    /foo(?{ 1 })$bar/;   # compiles ok
    /foo${pat}bar/;      # compiles ok
```

Another form of code expression is the **pattern code expression** . The pattern code expression is like a regular code expression, except that the result of the code evaluation is treated as a regular expression and matched immediately. A simple example is

```
    $length = 5;
    $char = 'a';
    $x = 'aaaaabb';
    $x =~ /(??{$char x $length})/x; # matches, there are 5 of 'a'
```

This final example contains both ordinary and pattern code expressions. It detects if a binary string `1101010010001...` has a Fibonacci spacing 0,1,1,2,3,5,... of the 1's:

```
    $s0 = 0; $s1 = 1; # initial conditions
    $x = "1101010010001000001";
    print "It is a Fibonacci sequence\n"
        if $x =~ /^1         # match an initial '1'
                    (
                       (??{'0' x $s0}) # match $s0 of '0'
                       1               # and then a '1'
                       (?{
                          $largest = $s0;   # largest seq so far
                          $s2 = $s1 + $s0;  # compute next term
                          $s0 = $s1;        # in Fibonacci sequence
                          $s1 = $s2;
                         })
                    )+   # repeat as needed
                  $      # that is all there is
                 /x;
    print "Largest sequence matched was $largest\n";
```

This prints

```
    It is a Fibonacci sequence
    Largest sequence matched was 5
```

Ha! Try that with your garden variety regexp package...

Note that the variables `$s0` and `$s1` are not substituted when the regexp is compiled, as happens for ordinary variables outside a code expression. Rather, the code expressions are evaluated when perl encounters them during the search for a match.

The regexp without the `//x` modifier is

```
    /^1((??{'0'x$s0})1(?{$largest=$s0;$s2=$s1+$s0$s0=$s1;$s1=$s2;}))+$/;
```

and is a great start on an Obfuscated Perl entry :-) When working with code and conditional expressions, the extended form of regexps is almost necessary in creating and debugging regexps.

7.3.9 Pragmas and debugging

Speaking of debugging, there are several pragmas available to control and debug regexps in Perl. We have already encountered one pragma in the previous section, `use re 'eval';` , that allows variable interpolation and code expressions to coexist in a regexp. The other pragmas are

```
    use re 'taint';
    $tainted = <>;
    @parts = ($tainted =~ /(\w+)\s+(\w+)/; # @parts is now tainted
```

The `taint` pragma causes any substrings from a match with a tainted variable to be tainted as well. This is not normally the case, as regexps are often used to extract the safe bits from a tainted variable. Use `taint` when you are not extracting safe bits, but are performing some other processing. Both `taint` and `eval` pragmas are lexically scoped, which means they are in effect only until the end of the block enclosing the pragmas.

```
    use re 'debug';
    /^(.*)$/s;       # output debugging info
    use re 'debugcolor';
    /^(.*)$/s;       # output debugging info in living color
```

The global debug and debugcolor pragmas allow one to get detailed debugging info about regexp compilation and execution. debugcolor is the same as debug, except the debugging information is displayed in color on terminals that can display termcap color sequences. Here is example output:

```
    % perl -e 'use re "debug"; "abc" =~ /a*b+c/;'
    Compiling REx `a*b+c'
    size 9 first at 1
       1: STAR(4)
       2:   EXACT <a>(0)
       4: PLUS(7)
       5:   EXACT <b>(0)
       7: EXACT <c>(9)
       9: END(0)
    floating `bc' at 0..2147483647 (checking floating) minlen 2
    Guessing start of match, REx `a*b+c' against `abc'...
    Found floating substr `bc' at offset 1...
    Guessed: match at offset 0
    Matching REx `a*b+c' against `abc'
      Setting an EVAL scope, savestack=3
       0 <> <abc>           |  1:  STAR
                             EXACT <a> can match 1 times out of 32767...
      Setting an EVAL scope, savestack=3
       1 <a> <bc>           |  4:    PLUS
                             EXACT <b> can match 1 times out of 32767...
      Setting an EVAL scope, savestack=3
       2 <ab> <c>           |  7:      EXACT <c>
       3 <abc> <>           |  9:      END
    Match successful!
    Freeing REx: `a*b+c'
```

If you have gotten this far into the tutorial, you can probably guess what the different parts of the debugging output tell you. The first part

```
    Compiling REx `a*b+c'
    size 9 first at 1
       1: STAR(4)
       2:   EXACT <a>(0)
       4: PLUS(7)
       5:   EXACT <b>(0)
       7: EXACT <c>(9)
       9: END(0)
```

describes the compilation stage. STAR(4) means that there is a starred object, in this case 'a', and if it matches, goto line 4, i.e., PLUS(7). The middle lines describe some heuristics and optimizations performed before a match:

```
    floating `bc' at 0..2147483647 (checking floating) minlen 2
    Guessing start of match, REx `a*b+c' against `abc'...
    Found floating substr `bc' at offset 1...
    Guessed: match at offset 0
```

Then the match is executed and the remaining lines describe the process:

```
    Matching REx ‘a*b+c’ against ‘abc’
      Setting an EVAL scope, savestack=3
       0 <> <abc>            |  1:  STAR
                              EXACT <a> can match 1 times out of 32767...
      Setting an EVAL scope, savestack=3
       1 <a> <bc>            |  4:    PLUS
                              EXACT <b> can match 1 times out of 32767...
      Setting an EVAL scope, savestack=3
       2 <ab> <c>            |  7:      EXACT <c>
       3 <abc> <>            |  9:      END
    Match successful!
    Freeing REx: ‘a*b+c’
```

Each step is of the form `n <x> <y>` , with `<x>` the part of the string matched and `<y>` the part not yet matched. The `| 1: STAR` says that perl is at line number 1 n the compilation list above. See Debugging regular expressions in *perldebguts* for much more detail.

An alternative method of debugging regexps is to embed `print` statements within the regexp. This provides a blow-by-blow account of the backtracking in an alternation:

```
    "that this" =~ m@(?{print "Start at position ", pos, "\n";})
                     t(?{print "t1\n";})
                     h(?{print "h1\n";})
                     i(?{print "i1\n";})
                     s(?{print "s1\n";})
                         |
                     t(?{print "t2\n";})
                     h(?{print "h2\n";})
                     a(?{print "a2\n";})
                     t(?{print "t2\n";})
                     (?{print "Done at position ", pos, "\n";})
                    @x;
```

prints

```
    Start at position 0
    t1
    h1
    t2
    h2
    a2
    t2
    Done at position 4
```

7.4 BUGS

Code expressions, conditional expressions, and independent expressions are **experimental**. Don’t use them in production code. Yet.

7.5 SEE ALSO

This is just a tutorial. For the full story on perl regular expressions, see the *perlre* regular expressions reference page.

For more information on the matching `m//` and substitution `s///` operators, see Regexp Quote-Like Operators in *perlop*. For information on the `split` operation, see split in *perlfunc*.

For an excellent all-around resource on the care and feeding of regular expressions, see the book *Mastering Regular Expressions* by Jeffrey Friedl (published by O’Reilly, ISBN 1556592-257-3).

Chapter 8

perlboot

Beginner's Object-Oriented Tutorial

8.1 DESCRIPTION

If you're not familiar with objects from other languages, some of the other Perl object documentation may be a little daunting, such as *perlobj*, a basic reference in using objects, and *perltoot*, which introduces readers to the peculiarities of Perl's object system in a tutorial way.

So, let's take a different approach, presuming no prior object experience. It helps if you know about subroutines (*perlsub*), references (*perlref* et. seq.), and packages (*perlmod*), so become familiar with those first if you haven't already.

8.1.1 If we could talk to the animals...

Let's let the animals talk for a moment:

```
    sub Cow::speak {
      print "a Cow goes moooo!\n";
    }
    sub Horse::speak {
      print "a Horse goes neigh!\n";
    }
    sub Sheep::speak {
      print "a Sheep goes baaaah!\n"
    }

    Cow::speak;
    Horse::speak;
    Sheep::speak;
```

This results in:

```
    a Cow goes moooo!
    a Horse goes neigh!
    a Sheep goes baaaah!
```

Nothing spectacular here. Simple subroutines, albeit from separate packages, and called using the full package name. So let's create an entire pasture:

```
# Cow::speak, Horse::speak, Sheep::speak as before
@pasture = qw(Cow Cow Horse Sheep Sheep);
foreach $animal (@pasture) {
  &{$animal."::speak"};
}
```

This results in:

```
a Cow goes moooo!
a Cow goes moooo!
a Horse goes neigh!
a Sheep goes baaaah!
a Sheep goes baaaah!
```

Wow. That symbolic coderef de-referencing there is pretty nasty. We're counting on `no strict subs` mode, certainly not recommended for larger programs. And why was that necessary? Because the name of the package seems to be inseparable from the name of the subroutine we want to invoke within that package.

Or is it?

8.1.2 Introducing the method invocation arrow

For now, let's say that `Class->method` invokes subroutine `method` in package `Class`. (Here, "Class" is used in its "category" meaning, not its "scholastic" meaning.) That's not completely accurate, but we'll do this one step at a time. Now let's use it like so:

```
# Cow::speak, Horse::speak, Sheep::speak as before
Cow->speak;
Horse->speak;
Sheep->speak;
```

And once again, this results in:

```
a Cow goes moooo!
a Horse goes neigh!
a Sheep goes baaaah!
```

That's not fun yet. Same number of characters, all constant, no variables. But yet, the parts are separable now. Watch:

```
$a = "Cow";
$a->speak; # invokes Cow->speak
```

Ahh! Now that the package name has been parted from the subroutine name, we can use a variable package name. And this time, we've got something that works even when `use strict refs` is enabled.

8.1.3 Invoking a barnyard

Let's take that new arrow invocation and put it back in the barnyard example:

```
sub Cow::speak {
  print "a Cow goes moooo!\n";
}
sub Horse::speak {
  print "a Horse goes neigh!\n";
}
sub Sheep::speak {
  print "a Sheep goes baaaah!\n"
}
```

```
@pasture = qw(Cow Cow Horse Sheep Sheep);
foreach $animal (@pasture) {
  $animal->speak;
}
```

There! Now we have the animals all talking, and safely at that, without the use of symbolic coderefs.

But look at all that common code. Each of the `speak` routines has a similar structure: a `print` operator and a string that contains common text, except for two of the words. It'd be nice if we could factor out the commonality, in case we decide later to change it all to `says` instead of `goes`.

And we actually have a way of doing that without much fuss, but we have to hear a bit more about what the method invocation arrow is actually doing for us.

8.1.4 The extra parameter of method invocation

The invocation of:

```
Class->method(@args)
```

attempts to invoke subroutine `Class::method` as:

```
Class::method("Class", @args);
```

(If the subroutine can't be found, "inheritance" kicks in, but we'll get to that later.) This means that we get the class name as the first parameter (the only parameter, if no arguments are given). So we can rewrite the `Sheep` speaking subroutine as:

```
sub Sheep::speak {
  my $class = shift;
  print "a $class goes baaaah!\n";
}
```

And the other two animals come out similarly:

```
sub Cow::speak {
  my $class = shift;
  print "a $class goes moooo!\n";
}
sub Horse::speak {
  my $class = shift;
  print "a $class goes neigh!\n";
}
```

In each case, `$class` will get the value appropriate for that subroutine. But once again, we have a lot of similar structure. Can we factor that out even further? Yes, by calling another method in the same class.

8.1.5 Calling a second method to simplify things

Let's call out from `speak` to a helper method called `sound`. This method provides the constant text for the sound itself.

```
{ package Cow;
  sub sound { "moooo" }
  sub speak {
    my $class = shift;
    print "a $class goes ", $class->sound, "!\n"
  }
}
```

Now, when we call `Cow->speak`, we get a `$class` of `Cow` in `speak`. This in turn selects the `Cow->sound` method, which returns `moooo`. But how different would this be for the `Horse`?

```
    { package Horse;
      sub sound { "neigh" }
      sub speak {
        my $class = shift;
        print "a $class goes ", $class->sound, "!\n"
      }
    }
```

Only the name of the package and the specific sound change. So can we somehow share the definition for `speak` between the Cow and the Horse? Yes, with inheritance!

8.1.6 Inheriting the windpipes

We'll define a common subroutine package called `Animal`, with the definition for `speak`:

```
    { package Animal;
      sub speak {
        my $class = shift;
        print "a $class goes ", $class->sound, "!\n"
      }
    }
```

Then, for each animal, we say it "inherits" from `Animal`, along with the animal-specific sound:

```
    { package Cow;
      @ISA = qw(Animal);
      sub sound { "moooo" }
    }
```

Note the added `@ISA` array. We'll get to that in a minute.

But what happens when we invoke `Cow->speak` now?

First, Perl constructs the argument list. In this case, it's just `Cow`. Then Perl looks for `Cow::speak`. But that's not there, so Perl checks for the inheritance array `@Cow::ISA`. It's there, and contains the single name `Animal`.

Perl next checks for `speak` inside `Animal` instead, as in `Animal::speak`. And that's found, so Perl invokes that subroutine with the already frozen argument list.

Inside the `Animal::speak` subroutine, `$class` becomes `Cow` (the first argument). So when we get to the step of invoking `$class->sound`, it'll be looking for `Cow->sound`, which gets it on the first try without looking at `@ISA`. Success!

8.1.7 A few notes about @ISA

This magical `@ISA` variable (pronounced "is a" not "ice-uh"), has declared that `Cow` "is a" `Animal`. Note that it's an array, not a simple single value, because on rare occasions, it makes sense to have more than one parent class searched for the missing methods.

If `Animal` also had an `@ISA`, then we'd check there too. The search is recursive, depth-first, left-to-right in each `@ISA`. Typically, each `@ISA` has only one element (multiple elements means multiple inheritance and multiple headaches), so we get a nice tree of inheritance.

When we turn on `use strict`, we'll get complaints on `@ISA`, since it's not a variable containing an explicit package name, nor is it a lexical ("my") variable. We can't make it a lexical variable though (it has to belong to the package to be found by the inheritance mechanism), so there's a couple of straightforward ways to handle that.

The easiest is to just spell the package name out:

```
    @Cow::ISA = qw(Animal);
```

Or allow it as an implicitly named package variable:

```
    package Cow;
    use vars qw(@ISA);
    @ISA = qw(Animal);
```

If you're bringing in the class from outside, via an object-oriented module, you change:

```
    package Cow;
    use Animal;
    use vars qw(@ISA);
    @ISA = qw(Animal);
```

into just:

```
    package Cow;
    use base qw(Animal);
```

And that's pretty darn compact.

8.1.8 Overriding the methods

Let's add a mouse, which can barely be heard:

```
    # Animal package from before
    { package Mouse;
      @ISA = qw(Animal);
      sub sound { "squeak" }
      sub speak {
        my $class = shift;
        print "a $class goes ", $class->sound, "!\n";
        print "[but you can barely hear it!]\n";
      }
    }

    Mouse->speak;
```

which results in:

```
    a Mouse goes squeak!
    [but you can barely hear it!]
```

Here, `Mouse` has its own speaking routine, so `Mouse->speak` doesn't immediately invoke `Animal->speak`. This is known as "overriding". In fact, we didn't even need to say that a `Mouse` was an `Animal` at all, since all of the methods needed for `speak` are completely defined with `Mouse`.

But we've now duplicated some of the code from `Animal->speak`, and this can once again be a maintenance headache. So, can we avoid that? Can we say somehow that a `Mouse` does everything any other `Animal` does, but add in the extra comment? Sure!

First, we can invoke the `Animal::speak` method directly:

```
# Animal package from before
{ package Mouse;
  @ISA = qw(Animal);
  sub sound { "squeak" }
  sub speak {
    my $class = shift;
    Animal::speak($class);
    print "[but you can barely hear it!]\n";
  }
}
```

Note that we have to include the `$class` parameter (almost surely the value of `"Mouse"`) as the first parameter to `Animal::speak`, since we've stopped using the method arrow. Why did we stop? Well, if we invoke `Animal->speak` there, the first parameter to the method will be `"Animal"` not `"Mouse"`, and when time comes for it to call for the `sound`, it won't have the right class to come back to this package.

Invoking `Animal::speak` directly is a mess, however. What if `Animal::speak` didn't exist before, and was being inherited from a class mentioned in `@Animal::ISA`? Because we are no longer using the method arrow, we get one and only one chance to hit the right subroutine.

Also note that the `Animal` classname is now hardwired into the subroutine selection. This is a mess if someone maintains the code, changing `@ISA` for <Mouse> and didn't notice `Animal` there in `speak`. So, this is probably not the right way to go.

8.1.9 Starting the search from a different place

A better solution is to tell Perl to search from a higher place in the inheritance chain:

```
# same Animal as before
{ package Mouse;
  # same @ISA, &sound as before
  sub speak {
    my $class = shift;
    $class->Animal::speak;
    print "[but you can barely hear it!]\n";
  }
}
```

Ahh. This works. Using this syntax, we start with `Animal` to find `speak`, and use all of `Animal`'s inheritance chain if not found immediately. And yet the first parameter will be `$class`, so the found `speak` method will get `Mouse` as its first entry, and eventually work its way back to `Mouse::sound` for the details.

But this isn't the best solution. We still have to keep the `@ISA` and the initial search package coordinated. Worse, if `Mouse` had multiple entries in `@ISA`, we wouldn't necessarily know which one had actually defined `speak`. So, is there an even better way?

8.1.10 The SUPER way of doing things

By changing the `Animal` class to the `SUPER` class in that invocation, we get a search of all of our super classes (classes listed in `@ISA`) automatically:

```
# same Animal as before
{ package Mouse;
  # same @ISA, &sound as before
  sub speak {
    my $class = shift;
    $class->SUPER::speak;
    print "[but you can barely hear it!]\n";
  }
}
```

So, `SUPER::speak` means look in the current package's `@ISA` for `speak`, invoking the first one found. Note that it does *not* look in the `@ISA` of `$class`.

8.1.11 Where we're at so far...

So far, we've seen the method arrow syntax:

```
  Class->method(@args);
```

or the equivalent:

```
  $a = "Class";
  $a->method(@args);
```

which constructs an argument list of:

```
  ("Class", @args)
```

and attempts to invoke

```
  Class::method("Class", @Args);
```

However, if `Class::method` is not found, then `@Class::ISA` is examined (recursively) to locate a package that does indeed contain `method`, and that subroutine is invoked instead.

Using this simple syntax, we have class methods, (multiple) inheritance, overriding, and extending. Using just what we've seen so far, we've been able to factor out common code, and provide a nice way to reuse implementations with variations. This is at the core of what objects provide, but objects also provide instance data, which we haven't even begun to cover.

8.1.12 A horse is a horse, of course of course – or is it?

Let's start with the code for the `Animal` class and the `Horse` class:

```
  { package Animal;
    sub speak {
      my $class = shift;
      print "a $class goes ", $class->sound, "!\n"
    }
  }
  { package Horse;
    @ISA = qw(Animal);
    sub sound { "neigh" }
  }
```

This lets us invoke `Horse->speak` to ripple upward to `Animal::speak`, calling back to `Horse::sound` to get the specific sound, and the output of:

```
  a Horse goes neigh!
```

But all of our Horse objects would have to be absolutely identical. If I add a subroutine, all horses automatically share it. That's great for making horses the same, but how do we capture the distinctions about an individual horse? For example, suppose I want to give my first horse a name. There's got to be a way to keep its name separate from the other horses.

We can do that by drawing a new distinction, called an "instance". An "instance" is generally created by a class. In Perl, any reference can be an instance, so let's start with the simplest reference that can hold a horse's name: a scalar reference.

```
my $name = "Mr. Ed";
my $talking = \$name;
```

So now `$talking` is a reference to what will be the instance-specific data (the name). The final step in turning this into a real instance is with a special operator called `bless`:

```
bless $talking, Horse;
```

This operator stores information about the package named `Horse` into the thing pointed at by the reference. At this point, we say `$talking` is an instance of `Horse`. That is, it's a specific horse. The reference is otherwise unchanged, and can still be used with traditional dereferencing operators.

8.1.13 Invoking an instance method

The method arrow can be used on instances, as well as names of packages (classes). So, let's get the sound that `$talking` makes:

```
my $noise = $talking->sound;
```

To invoke `sound`, Perl first notes that `$talking` is a blessed reference (and thus an instance). It then constructs an argument list, in this case from just `($talking)`. (Later we'll see that arguments will take their place following the instance variable, just like with classes.)

Now for the fun part: Perl takes the class in which the instance was blessed, in this case `Horse`, and uses that to locate the subroutine to invoke the method. In this case, `Horse::sound` is found directly (without using inheritance), yielding the final subroutine invocation:

```
Horse::sound($talking)
```

Note that the first parameter here is still the instance, not the name of the class as before. We'll get `neigh` as the return value, and that'll end up as the `$noise` variable above.

If Horse::sound had not been found, we'd be wandering up the `@Horse::ISA` list to try to find the method in one of the superclasses, just as for a class method. The only difference between a class method and an instance method is whether the first parameter is an instance (a blessed reference) or a class name (a string).

8.1.14 Accessing the instance data

Because we get the instance as the first parameter, we can now access the instance-specific data. In this case, let's add a way to get at the name:

```
{ package Horse;
  @ISA = qw(Animal);
  sub sound { "neigh" }
  sub name {
    my $self = shift;
    $$self;
  }
}
```

Now we call for the name:

```
print $talking->name, " says ", $talking->sound, "\n";
```

Inside `Horse::name`, the `@_` array contains just `$talking`, which the `shift` stores into `$self`. (It's traditional to shift the first parameter off into a variable named `$self` for instance methods, so stay with that unless you have strong reasons otherwise.) Then, `$self` gets de-referenced as a scalar ref, yielding `Mr.  Ed`, and we're done with that. The result is:

```
Mr. Ed says neigh.
```

8.1.15 How to build a horse

Of course, if we constructed all of our horses by hand, we'd most likely make mistakes from time to time. We're also violating one of the properties of object-oriented programming, in that the "inside guts" of a Horse are visible. That's good if you're a veterinarian, but not if you just like to own horses. So, let's let the Horse class build a new horse:

```
{ package Horse;
  @ISA = qw(Animal);
  sub sound { "neigh" }
  sub name {
    my $self = shift;
    $$self;
  }
  sub named {
    my $class = shift;
    my $name = shift;
    bless \$name, $class;
  }
}
```

Now with the new `named` method, we can build a horse:

```
my $talking = Horse->named("Mr. Ed");
```

Notice we're back to a class method, so the two arguments to `Horse::named` are `Horse` and `Mr. Ed`. The `bless` operator not only blesses `$name`, it also returns the reference to `$name`, so that's fine as a return value. And that's how to build a horse.

We've called the constructor `named` here, so that it quickly denotes the constructor's argument as the name for this particular `Horse`. You can use different constructors with different names for different ways of "giving birth" to the object (like maybe recording its pedigree or date of birth). However, you'll find that most people coming to Perl from more limited languages use a single constructor named `new`, with various ways of interpreting the arguments to `new`. Either style is fine, as long as you document your particular way of giving birth to an object. (And you *were* going to do that, right?)

8.1.16 Inheriting the constructor

But was there anything specific to `Horse` in that method? No. Therefore, it's also the same recipe for building anything else that inherited from `Animal`, so let's put it there:

```
{ package Animal;
  sub speak {
    my $class = shift;
    print "a $class goes ", $class->sound, "!\n"
  }
  sub name {
    my $self = shift;
    $$self;
  }
  sub named {
    my $class = shift;
    my $name = shift;
    bless \$name, $class;
  }
}
{ package Horse;
  @ISA = qw(Animal);
  sub sound { "neigh" }
}
```

Ahh, but what happens if we invoke `speak` on an instance?

```
  my $talking = Horse->named("Mr. Ed");
  $talking->speak;
```

We get a debugging value:

```
  a Horse=SCALAR(0xaca42ac) goes neigh!
```

Why? Because the `Animal::speak` routine is expecting a classname as its first parameter, not an instance. When the instance is passed in, we'll end up using a blessed scalar reference as a string, and that shows up as we saw it just now.

8.1.17 Making a method work with either classes or instances

All we need is for a method to detect if it is being called on a class or called on an instance. The most straightforward way is with the `ref` operator. This returns a string (the classname) when used on a blessed reference, and `undef` when used on a string (like a classname). Let's modify the `name` method first to notice the change:

```
  sub name {
    my $either = shift;
    ref $either
      ? $$either # it's an instance, return name
      : "an unnamed $either"; # it's a class, return generic
  }
```

Here, the `?:` operator comes in handy to select either the dereference or a derived string. Now we can use this with either an instance or a class. Note that I've changed the first parameter holder to `$either` to show that this is intended:

```
  my $talking = Horse->named("Mr. Ed");
  print Horse->name, "\n"; # prints "an unnamed Horse\n"
  print $talking->name, "\n"; # prints "Mr Ed.\n"
```

and now we'll fix `speak` to use this:

```
  sub speak {
    my $either = shift;
    print $either->name, " goes ", $either->sound, "\n";
  }
```

And since `sound` already worked with either a class or an instance, we're done!

8.1.18 Adding parameters to a method

Let's train our animals to eat:

```
  { package Animal;
    sub named {
      my $class = shift;
      my $name = shift;
      bless \$name, $class;
    }
    sub name {
      my $either = shift;
      ref $either
```

```
        ? $$either # it’s an instance, return name
        : "an unnamed $either"; # it’s a class, return generic
    }
    sub speak {
      my $either = shift;
      print $either->name, " goes ", $either->sound, "\n";
    }
    sub eat {
      my $either = shift;
      my $food = shift;
      print $either->name, " eats $food.\n";
    }
  }
  { package Horse;
    @ISA = qw(Animal);
    sub sound { "neigh" }
  }
  { package Sheep;
    @ISA = qw(Animal);
    sub sound { "baaaah" }
  }
```

And now try it out:

```
  my $talking = Horse->named("Mr. Ed");
  $talking->eat("hay");
  Sheep->eat("grass");
```

which prints:

```
  Mr. Ed eats hay.
  an unnamed Sheep eats grass.
```

An instance method with parameters gets invoked with the instance, and then the list of parameters. So that first invocation is like:

```
  Animal::eat($talking, "hay");
```

8.1.19 More interesting instances

What if an instance needs more data? Most interesting instances are made of many items, each of which can in turn be a reference or even another object. The easiest way to store these is often in a hash. The keys of the hash serve as the names of parts of the object (often called "instance variables" or "member variables"), and the corresponding values are, well, the values.

But how do we turn the horse into a hash? Recall that an object was any blessed reference. We can just as easily make it a blessed hash reference as a blessed scalar reference, as long as everything that looks at the reference is changed accordingly.

Let’s make a sheep that has a name and a color:

```
  my $bad = bless { Name => "Evil", Color => "black" }, Sheep;
```

so `$bad->{Name}` has `Evil`, and `$bad->{Color}` has `black`. But we want to make `$bad->name` access the name, and that’s now messed up because it’s expecting a scalar reference. Not to worry, because that’s pretty easy to fix up:

```
## in Animal
sub name {
  my $either = shift;
  ref $either ?
    $either->{Name} :
    "an unnamed $either";
}
```

And of course `named` still builds a scalar sheep, so let's fix that as well:

```
## in Animal
sub named {
  my $class = shift;
  my $name = shift;
  my $self = { Name => $name, Color => $class->default_color };
  bless $self, $class;
}
```

What's this `default_color`? Well, if `named` has only the name, we still need to set a color, so we'll have a class-specific initial color. For a sheep, we might define it as white:

```
## in Sheep
sub default_color { "white" }
```

And then to keep from having to define one for each additional class, we'll define a "backstop" method that serves as the "default default", directly in `Animal`:

```
## in Animal
sub default_color { "brown" }
```

Now, because `name` and `named` were the only methods that referenced the "structure" of the object, the rest of the methods can remain the same, so `speak` still works as before.

8.1.20 A horse of a different color

But having all our horses be brown would be boring. So let's add a method or two to get and set the color.

```
## in Animal
sub color {
  $_[0]->{Color}
}
sub set_color {
  $_[0]->{Color} = $_[1];
}
```

Note the alternate way of accessing the arguments: `$_[0]` is used in-place, rather than with a `shift`. (This saves us a bit of time for something that may be invoked frequently.) And now we can fix that color for Mr. Ed:

```
my $talking = Horse->named("Mr. Ed");
$talking->set_color("black-and-white");
print $talking->name, " is colored ", $talking->color, "\n";
```

which results in:

```
Mr. Ed is colored black-and-white
```

8.1.21 Summary

So, now we have class methods, constructors, instance methods, instance data, and even accessors. But that's still just the beginning of what Perl has to offer. We haven't even begun to talk about accessors that double as getters and setters, destructors, indirect object notation, subclasses that add instance data, per-class data, overloading, "isa" and "can" tests, `UNIVERSAL` class, and so on. That's for the rest of the Perl documentation to cover. Hopefully, this gets you started, though.

Chapter 9

perltoot

Tom’s object-oriented tutorial for perl

9.1 DESCRIPTION

Object-oriented programming is a big seller these days. Some managers would rather have objects than sliced bread. Why is that? What’s so special about an object? Just what *is* an object anyway?

An object is nothing but a way of tucking away complex behaviours into a neat little easy-to-use bundle. (This is what professors call abstraction.) Smart people who have nothing to do but sit around for weeks on end figuring out really hard problems make these nifty objects that even regular people can use. (This is what professors call software reuse.) Users (well, programmers) can play with this little bundle all they want, but they aren’t to open it up and mess with the insides. Just like an expensive piece of hardware, the contract says that you void the warranty if you muck with the cover. So don’t do that.

The heart of objects is the class, a protected little private namespace full of data and functions. A class is a set of related routines that addresses some problem area. You can think of it as a user-defined type. The Perl package mechanism, also used for more traditional modules, is used for class modules as well. Objects "live" in a class, meaning that they belong to some package.

More often than not, the class provides the user with little bundles. These bundles are objects. They know whose class they belong to, and how to behave. Users ask the class to do something, like "give me an object." Or they can ask one of these objects to do something. Asking a class to do something for you is calling a *class method*. Asking an object to do something for you is calling an *object method*. Asking either a class (usually) or an object (sometimes) to give you back an object is calling a *constructor*, which is just a kind of method.

That’s all well and good, but how is an object different from any other Perl data type? Just what is an object *really*; that is, what’s its fundamental type? The answer to the first question is easy. An object is different from any other data type in Perl in one and only one way: you may dereference it using not merely string or numeric subscripts as with simple arrays and hashes, but with named subroutine calls. In a word, with *methods*.

The answer to the second question is that it’s a reference, and not just any reference, mind you, but one whose referent has been *bless*()ed into a particular class (read: package). What kind of reference? Well, the answer to that one is a bit less concrete. That’s because in Perl the designer of the class can employ any sort of reference they’d like as the underlying intrinsic data type. It could be a scalar, an array, or a hash reference. It could even be a code reference. But because of its inherent flexibility, an object is usually a hash reference.

9.2 Creating a Class

Before you create a class, you need to decide what to name it. That’s because the class (package) name governs the name of the file used to house it, just as with regular modules. Then, that class (package) should provide one or more ways to generate objects. Finally, it should provide mechanisms to allow users of its objects to indirectly manipulate these objects from a distance.

For example, let's make a simple Person class module. It gets stored in the file Person.pm. If it were called a Happy::Person class, it would be stored in the file Happy/Person.pm, and its package would become Happy::Person instead of just Person. (On a personal computer not running Unix or Plan 9, but something like Mac OS or VMS, the directory separator may be different, but the principle is the same.) Do not assume any formal relationship between modules based on their directory names. This is merely a grouping convenience, and has no effect on inheritance, variable accessibility, or anything else.

For this module we aren't going to use Exporter, because we're a well-behaved class module that doesn't export anything at all. In order to manufacture objects, a class needs to have a *constructor method*. A constructor gives you back not just a regular data type, but a brand-new object in that class. This magic is taken care of by the bless() function, whose sole purpose is to enable its referent to be used as an object. Remember: being an object really means nothing more than that methods may now be called against it.

While a constructor may be named anything you'd like, most Perl programmers seem to like to call theirs new(). However, new() is not a reserved word, and a class is under no obligation to supply such. Some programmers have also been known to use a function with the same name as the class as the constructor.

9.2.1 Object Representation

By far the most common mechanism used in Perl to represent a Pascal record, a C struct, or a C++ class is an anonymous hash. That's because a hash has an arbitrary number of data fields, each conveniently accessed by an arbitrary name of your own devising.

If you were just doing a simple struct-like emulation, you would likely go about it something like this:

```
$rec = {
    name  => "Jason",
    age   => 23,
    peers => [ "Norbert", "Rhys", "Phineas"],
};
```

If you felt like it, you could add a bit of visual distinction by up-casing the hash keys:

```
$rec = {
    NAME  => "Jason",
    AGE   => 23,
    PEERS => [ "Norbert", "Rhys", "Phineas"],
};
```

And so you could get at `$rec->{NAME}` to find "Jason", or `@{ $rec->{PEERS} }` to get at "Norbert", "Rhys", and "Phineas". (Have you ever noticed how many 23-year-old programmers seem to be named "Jason" these days? :-)

This same model is often used for classes, although it is not considered the pinnacle of programming propriety for folks from outside the class to come waltzing into an object, brazenly accessing its data members directly. Generally speaking, an object should be considered an opaque cookie that you use *object methods* to access. Visually, methods look like you're dereffing a reference using a function name instead of brackets or braces.

9.2.2 Class Interface

Some languages provide a formal syntactic interface to a class's methods, but Perl does not. It relies on you to read the documentation of each class. If you try to call an undefined method on an object, Perl won't complain, but the program will trigger an exception while it's running. Likewise, if you call a method expecting a prime number as its argument with a non-prime one instead, you can't expect the compiler to catch this. (Well, you can expect it all you like, but it's not going to happen.)

Let's suppose you have a well-educated user of your Person class, someone who has read the docs that explain the prescribed interface. Here's how they might use the Person class:

```
use Person;
```

```
    $him = Person->new();
    $him->name("Jason");
    $him->age(23);
    $him->peers( "Norbert", "Rhys", "Phineas" );

    push @All_Recs, $him;  # save object in array for later

    printf "%s is %d years old.\n", $him->name, $him->age;
    print "His peers are: ", join(", ", $him->peers), "\n";

    printf "Last rec's name is %s\n", $All_Recs[-1]->name;
```

As you can see, the user of the class doesn't know (or at least, has no business paying attention to the fact) that the object has one particular implementation or another. The interface to the class and its objects is exclusively via methods, and that's all the user of the class should ever play with.

9.2.3 Constructors and Instance Methods

Still, *someone* has to know what's in the object. And that someone is the class. It implements methods that the programmer uses to access the object. Here's how to implement the Person class using the standard hash-ref-as-an-object idiom. We'll make a class method called new() to act as the constructor, and three object methods called name(), age(), and peers() to get at per-object data hidden away in our anonymous hash.

```
    package Person;
    use strict;

    ##################################################
    ## the object constructor (simplistic version)  ##
    ##################################################
    sub new {
        my $self  = {};
        $self->{NAME}   = undef;
        $self->{AGE}    = undef;
        $self->{PEERS}  = [];
        bless($self);           # but see below
        return $self;
    }

    ##############################################
    ## methods to access per-object data        ##
    ##                                          ##
    ## With args, they set the value.  Without  ##
    ## any, they only retrieve it/them.         ##
    ##############################################

    sub name {
        my $self = shift;
        if (@_) { $self->{NAME} = shift }
        return $self->{NAME};
    }

    sub age {
        my $self = shift;
        if (@_) { $self->{AGE} = shift }
        return $self->{AGE};
    }
    sub peers {
        my $self = shift;
        if (@_) { @{ $self->{PEERS} } = @_ }
        return @{ $self->{PEERS} };
    }

    1;  # so the require or use succeeds
```

We've created three methods to access an object's data, name(), age(), and peers(). These are all substantially similar. If called with an argument, they set the appropriate field; otherwise they return the value held by that field, meaning the value of that hash key.

9.2.4 Planning for the Future: Better Constructors

Even though at this point you may not even know what it means, someday you're going to worry about inheritance. (You can safely ignore this for now and worry about it later if you'd like.) To ensure that this all works out smoothly, you must use the double-argument form of bless(). The second argument is the class into which the referent will be blessed. By not assuming our own class as the default second argument and instead using the class passed into us, we make our constructor inheritable.

```
    sub new {
        my $class = shift;
        my $self  = {};
        $self->{NAME}   = undef;
        $self->{AGE}    = undef;
        $self->{PEERS}  = [];
        bless ($self, $class);
        return $self;
    }
```

That's about all there is for constructors. These methods bring objects to life, returning neat little opaque bundles to the user to be used in subsequent method calls.

9.2.5 Destructors

Every story has a beginning and an end. The beginning of the object's story is its constructor, explicitly called when the object comes into existence. But the ending of its story is the *destructor*, a method implicitly called when an object leaves this life. Any per-object clean-up code is placed in the destructor, which must (in Perl) be called DESTROY.

If constructors can have arbitrary names, then why not destructors? Because while a constructor is explicitly called, a destructor is not. Destruction happens automatically via Perl's garbage collection (GC) system, which is a quick but somewhat lazy reference-based GC system. To know what to call, Perl insists that the destructor be named DESTROY. Perl's notion of the right time to call a destructor is not well-defined currently, which is why your destructors should not rely on when they are called.

Why is DESTROY in all caps? Perl on occasion uses purely uppercase function names as a convention to indicate that the function will be automatically called by Perl in some way. Others that are called implicitly include BEGIN, END, AUTOLOAD, plus all methods used by tied objects, described in *perltie*.

In really good object-oriented programming languages, the user doesn't care when the destructor is called. It just happens when it's supposed to. In low-level languages without any GC at all, there's no way to depend on this happening at the right time, so the programmer must explicitly call the destructor to clean up memory and state, crossing their fingers that it's the right time to do so. Unlike C++, an object destructor is nearly never needed in Perl, and even when it is, explicit invocation is uncalled for. In the case of our Person class, we don't need a destructor because Perl takes care of simple matters like memory deallocation.

The only situation where Perl's reference-based GC won't work is when there's a circularity in the data structure, such as:

```
    $this->{WHATEVER} = $this;
```

In that case, you must delete the self-reference manually if you expect your program not to leak memory. While admittedly error-prone, this is the best we can do right now. Nonetheless, rest assured that when your program is finished, its objects' destructors are all duly called. So you are guaranteed that an object *eventually* gets properly destroyed, except in the unique case of a program that never exits. (If you're running Perl embedded in another application, this full GC pass happens a bit more frequently–whenever a thread shuts down.)

9.2.6 Other Object Methods

The methods we've talked about so far have either been constructors or else simple "data methods", interfaces to data stored in the object. These are a bit like an object's data members in the C++ world, except that strangers don't access them as data. Instead, they should only access the object's data indirectly via its methods. This is an important rule: in Perl, access to an object's data should *only* be made through methods.

Perl doesn't impose restrictions on who gets to use which methods. The public-versus-private distinction is by convention, not syntax. (Well, unless you use the Alias module described below in Data Members as Variables.) Occasionally you'll see method names beginning or ending with an underscore or two. This marking is a convention indicating that the methods are private to that class alone and sometimes to its closest acquaintances, its immediate subclasses. But this distinction is not enforced by Perl itself. It's up to the programmer to behave.

There's no reason to limit methods to those that simply access data. Methods can do anything at all. The key point is that they're invoked against an object or a class. Let's say we'd like object methods that do more than fetch or set one particular field.

```
    sub exclaim {
        my $self = shift;
        return sprintf "Hi, I'm %s, age %d, working with %s",
            $self->{NAME}, $self->{AGE}, join(", ", @{$self->{PEERS}});
    }
```

Or maybe even one like this:

```
    sub happy_birthday {
        my $self = shift;
        return ++$self->{AGE};
    }
```

Some might argue that one should go at these this way:

```
    sub exclaim {
        my $self = shift;
        return sprintf "Hi, I'm %s, age %d, working with %s",
            $self->name, $self->age, join(", ", $self->peers);
    }

    sub happy_birthday {
        my $self = shift;
        return $self->age( $self->age() + 1 );
    }
```

But since these methods are all executing in the class itself, this may not be critical. There are tradeoffs to be made. Using direct hash access is faster (about an order of magnitude faster, in fact), and it's more convenient when you want to interpolate in strings. But using methods (the external interface) internally shields not just the users of your class but even you yourself from changes in your data representation.

9.3 Class Data

What about "class data", data items common to each object in a class? What would you want that for? Well, in your Person class, you might like to keep track of the total people alive. How do you implement that?

You *could* make it a global variable called $Person::Census. But about only reason you'd do that would be if you *wanted* people to be able to get at your class data directly. They could just say $Person::Census and play around with it. Maybe this is ok in your design scheme. You might even conceivably want to make it an exported variable. To be exportable, a variable must be a (package) global. If this were a traditional module rather than an object-oriented one, you might do that.

While this approach is expected in most traditional modules, it's generally considered rather poor form in most object modules. In an object module, you should set up a protective veil to separate interface from implementation. So provide a class method to access class data just as you provide object methods to access object data.

So, you *could* still keep $Census as a package global and rely upon others to honor the contract of the module and therefore not play around with its implementation. You could even be supertricky and make $Census a tied object as described in *perltie*, thereby intercepting all accesses.

But more often than not, you just want to make your class data a file-scoped lexical. To do so, simply put this at the top of the file:

```
    my $Census = 0;
```

Even though the scope of a my() normally expires when the block in which it was declared is done (in this case the whole file being required or used), Perl's deep binding of lexical variables guarantees that the variable will not be deallocated, remaining accessible to functions declared within that scope. This doesn't work with global variables given temporary values via local(), though.

Irrespective of whether you leave $Census a package global or make it instead a file-scoped lexical, you should make these changes to your Person::new() constructor:

```
    sub new {
        my $class = shift;
        my $self  = {};
        $Census++;
        $self->{NAME}   = undef;
        $self->{AGE}    = undef;
        $self->{PEERS}  = [];
        bless ($self, $class);
        return $self;
    }

    sub population {
        return $Census;
    }
```

Now that we've done this, we certainly do need a destructor so that when Person is destroyed, the $Census goes down. Here's how this could be done:

```
    sub DESTROY { --$Census }
```

Notice how there's no memory to deallocate in the destructor? That's something that Perl takes care of for you all by itself.

Alternatively, you could use the Class::Data::Inheritable module from CPAN.

9.3.1 Accessing Class Data

It turns out that this is not really a good way to go about handling class data. A good scalable rule is that *you must never reference class data directly from an object method*. Otherwise you aren't building a scalable, inheritable class. The object must be the rendezvous point for all operations, especially from an object method. The globals (class data) would in some sense be in the "wrong" package in your derived classes. In Perl, methods execute in the context of the class they were defined in, *not* that of the object that triggered them. Therefore, namespace visibility of package globals in methods is unrelated to inheritance.

Got that? Maybe not. Ok, let's say that some other class "borrowed" (well, inherited) the DESTROY method as it was defined above. When those objects are destroyed, the original $Census variable will be altered, not the one in the new class's package namespace. Perhaps this is what you want, but probably it isn't.

Here's how to fix this. We'll store a reference to the data in the value accessed by the hash key "_CENSUS". Why the underscore? Well, mostly because an initial underscore already conveys strong feelings of magicalness to a C programmer. It's really just a mnemonic device to remind ourselves that this field is special and not to be used as a public data member in the same way that NAME, AGE, and PEERS are. (Because we've been developing this code under the strict pragma, prior to perl version 5.004 we'll have to quote the field name.)

```
    sub new {
        my $class = shift;
        my $self  = {};
        $self->{NAME}     = undef;
        $self->{AGE}      = undef;
        $self->{PEERS}    = [];
        # "private" data
        $self->{"_CENSUS"} = \$Census;
        bless ($self, $class);
        ++ ${ $self->{"_CENSUS"} };
        return $self;
    }

    sub population {
        my $self = shift;
        if (ref $self) {
            return ${ $self->{"_CENSUS"} };
        } else {
            return $Census;
        }
    }

    sub DESTROY {
        my $self = shift;
        -- ${ $self->{"_CENSUS"} };
    }
```

9.3.2 Debugging Methods

It's common for a class to have a debugging mechanism. For example, you might want to see when objects are created or destroyed. To do that, add a debugging variable as a file-scoped lexical. For this, we'll pull in the standard Carp module to emit our warnings and fatal messages. That way messages will come out with the caller's filename and line number instead of our own; if we wanted them to be from our own perspective, we'd just use die() and warn() directly instead of croak() and carp() respectively.

```
    use Carp;
    my $Debugging = 0;
```

Now add a new class method to access the variable.

```
    sub debug {
        my $class = shift;
        if (ref $class)  { confess "Class method called as object method" }
        unless (@_ == 1) { confess "usage: CLASSNAME->debug(level)" }
        $Debugging = shift;
    }
```

Now fix up DESTROY to murmur a bit as the moribund object expires:

```
    sub DESTROY {
        my $self = shift;
        if ($Debugging) { carp "Destroying $self " . $self->name }
        -- ${ $self->{"_CENSUS"} };
    }
```

One could conceivably make a per-object debug state. That way you could call both of these:

```
    Person->debug(1);   # entire class
    $him->debug(1);     # just this object
```

To do so, we need our debugging method to be a "bimodal" one, one that works on both classes *and* objects. Therefore, adjust the debug() and DESTROY methods as follows:

```
    sub debug {
        my $self = shift;
        confess "usage: thing->debug(level)"    unless @_ == 1;
        my $level = shift;
        if (ref($self))  {
            $self->{"_DEBUG"} = $level;         # just myself
        } else {
            $Debugging        = $level;         # whole class
        }
    }

    sub DESTROY {
        my $self = shift;
        if ($Debugging || $self->{"_DEBUG"}) {
            carp "Destroying $self " . $self->name;
        }
        -- ${ $self->{"_CENSUS"} };
    }
```

What happens if a derived class (which we'll call Employee) inherits methods from this Person base class? Then `Employee->debug()`, when called as a class method, manipulates $Person::Debugging not $Employee::Debugging.

9.3.3 Class Destructors

The object destructor handles the death of each distinct object. But sometimes you want a bit of cleanup when the entire class is shut down, which currently only happens when the program exits. To make such a *class destructor*, create a function in that class's package named END. This works just like the END function in traditional modules, meaning that it gets called whenever your program exits unless it execs or dies of an uncaught signal. For example,

```
    sub END {
        if ($Debugging) {
            print "All persons are going away now.\n";
        }
    }
```

When the program exits, all the class destructors (END functions) are be called in the opposite order that they were loaded in (LIFO order).

9.3.4 Documenting the Interface

And there you have it: we've just shown you the *implementation* of this Person class. Its *interface* would be its documentation. Usually this means putting it in pod ("plain old documentation") format right there in the same file. In our Person example, we would place the following docs anywhere in the Person.pm file. Even though it looks mostly like code, it's not. It's embedded documentation such as would be used by the pod2man, pod2html, or pod2text programs. The Perl compiler ignores pods entirely, just as the translators ignore code. Here's an example of some pods describing the informal interface:

```
    =head1 NAME

    Person - class to implement people

    =head1 SYNOPSIS

     use Person;

     #################
     # class methods #
     #################
     $ob    = Person->new;
     $count = Person->population;

     #######################
     # object data methods #
     #######################

     ### get versions ###
         $who   = $ob->name;
         $years = $ob->age;
         @pals  = $ob->peers;

     ### set versions ###
         $ob->name("Jason");
         $ob->age(23);
         $ob->peers( "Norbert", "Rhys", "Phineas" );

     ########################
     # other object methods #
     ########################

     $phrase = $ob->exclaim;
     $ob->happy_birthday;

    =head1 DESCRIPTION

    The Person class implements dah dee dah dee dah....
```

That's all there is to the matter of interface versus implementation. A programmer who opens up the module and plays around with all the private little shiny bits that were safely locked up behind the interface contract has voided the warranty, and you shouldn't worry about their fate.

9.4 Aggregation

Suppose you later want to change the class to implement better names. Perhaps you'd like to support both given names (called Christian names, irrespective of one's religion) and family names (called surnames), plus nicknames and titles. If users of your Person class have been properly accessing it through its documented interface, then you can easily change the underlying implementation. If they haven't, then they lose and it's their fault for breaking the contract and voiding their warranty.

To do this, we'll make another class, this one called Fullname. What's the Fullname class look like? To answer that question, you have to first figure out how you want to use it. How about we use it this way:

```
    $him = Person->new();
    $him->fullname->title("St");
    $him->fullname->christian("Thomas");
    $him->fullname->surname("Aquinas");
    $him->fullname->nickname("Tommy");
    printf "His normal name is %s\n", $him->name;
    printf "But his real name is %s\n", $him->fullname->as_string;
```

Ok. To do this, we'll change Person::new() so that it supports a full name field this way:

```
    sub new {
        my $class = shift;
        my $self  = {};
        $self->{FULLNAME} = Fullname->new();
        $self->{AGE}      = undef;
        $self->{PEERS}    = [];
        $self->{"_CENSUS"} = \$Census;
        bless ($self, $class);
        ++ ${ $self->{"_CENSUS"} };
        return $self;
    }

    sub fullname {
        my $self = shift;
        return $self->{FULLNAME};
    }
```

Then to support old code, define Person::name() this way:

```
    sub name {
        my $self = shift;
        return $self->{FULLNAME}->nickname(@_)
          ||   $self->{FULLNAME}->christian(@_);
    }
```

Here's the Fullname class. We'll use the same technique of using a hash reference to hold data fields, and methods by the appropriate name to access them:

```
    package Fullname;
    use strict;

    sub new {
        my $class = shift;
        my $self  = {
            TITLE       => undef,
            CHRISTIAN   => undef,
            SURNAME     => undef,
            NICK        => undef,
        };
        bless ($self, $class);
        return $self;
    }

    sub christian {
        my $self = shift;
        if (@_) { $self->{CHRISTIAN} = shift }
        return $self->{CHRISTIAN};
    }

    sub surname {
        my $self = shift;
        if (@_) { $self->{SURNAME} = shift }
        return $self->{SURNAME};
    }

    sub nickname {
        my $self = shift;
        if (@_) { $self->{NICK} = shift }
        return $self->{NICK};
    }

    sub title {
        my $self = shift;
        if (@_) { $self->{TITLE} = shift }
        return $self->{TITLE};
    }

    sub as_string {
        my $self = shift;
        my $name = join(" ", @$self{'CHRISTIAN', 'SURNAME'});
        if ($self->{TITLE}) {
            $name = $self->{TITLE} . " " . $name;
        }
        return $name;
    }

    1;
```

Finally, here’s the test program:

```
    #!/usr/bin/perl -w
    use strict;
    use Person;
    sub END { show_census() }

    sub show_census ()  {
        printf "Current population: %d\n", Person->population;
    }

    Person->debug(1);
    show_census();

    my $him = Person->new();

    $him->fullname->christian("Thomas");
    $him->fullname->surname("Aquinas");
    $him->fullname->nickname("Tommy");
    $him->fullname->title("St");
    $him->age(1);

    printf "%s is really %s.\n", $him->name, $him->fullname->as_string;
    printf "%s's age: %d.\n", $him->name, $him->age;
    $him->happy_birthday;
    printf "%s's age: %d.\n", $him->name, $him->age;

    show_census();
```

9.5 Inheritance

Object-oriented programming systems all support some notion of inheritance. Inheritance means allowing one class to piggy-back on top of another one so you don't have to write the same code again and again. It's about software reuse, and therefore related to Laziness, the principal virtue of a programmer. (The import/export mechanisms in traditional modules are also a form of code reuse, but a simpler one than the true inheritance that you find in object modules.)

Sometimes the syntax of inheritance is built into the core of the language, and sometimes it's not. Perl has no special syntax for specifying the class (or classes) to inherit from. Instead, it's all strictly in the semantics. Each package can have a variable called @ISA, which governs (method) inheritance. If you try to call a method on an object or class, and that method is not found in that object's package, Perl then looks to @ISA for other packages to go looking through in search of the missing method.

Like the special per-package variables recognized by Exporter (such as @EXPORT, @EXPORT_OK, @EXPORT_FAIL, %EXPORT_TAGS, and $VERSION), the @ISA array *must* be a package-scoped global and not a file-scoped lexical created via my(). Most classes have just one item in their @ISA array. In this case, we have what's called "single inheritance", or SI for short.

Consider this class:

```
    package Employee;
    use Person;
    @ISA = ("Person");
    1;
```

Not a lot to it, eh? All it's doing so far is loading in another class and stating that this one will inherit methods from that other class if need be. We have given it none of its own methods. We rely upon an Employee to behave just like a Person.

Setting up an empty class like this is called the "empty subclass test"; that is, making a derived class that does nothing but inherit from a base class. If the original base class has been designed properly, then the new derived class can be used as a drop-in replacement for the old one. This means you should be able to write a program like this:

```
    use Employee;
    my $empl = Employee->new();
    $empl->name("Jason");
    $empl->age(23);
    printf "%s is age %d.\n", $empl->name, $empl->age;
```

By proper design, we mean always using the two-argument form of bless(), avoiding direct access of global data, and not exporting anything. If you look back at the Person::new() function we defined above, we were careful to do that. There's a bit of package data used in the constructor, but the reference to this is stored on the object itself and all other methods access package data via that reference, so we should be ok.

What do we mean by the Person::new() function – isn't that actually a method? Well, in principle, yes. A method is just a function that expects as its first argument a class name (package) or object (blessed reference). Person::new() is the function that both the `Person->new()` method and the `Employee->new()` method end up calling. Understand that while a method call looks a lot like a function call, they aren't really quite the same, and if you treat them as the same, you'll very soon be left with nothing but broken programs. First, the actual underlying calling conventions are different: method calls get an extra argument. Second, function calls don't do inheritance, but methods do.

```
        Method Call             Resulting Function Call
        -----------             ------------------------
        Person->new()           Person::new("Person")
        Employee->new()         Person::new("Employee")
```

So don't use function calls when you mean to call a method.

If an employee is just a Person, that's not all too very interesting. So let's add some other methods. We'll give our employee data fields to access their salary, their employee ID, and their start date.

If you're getting a little tired of creating all these nearly identical methods just to get at the object's data, do not despair. Later, we'll describe several different convenience mechanisms for shortening this up. Meanwhile, here's the straight-forward way:

```
    sub salary {
        my $self = shift;
        if (@_) { $self->{SALARY} = shift }
        return $self->{SALARY};
    }

    sub id_number {
        my $self = shift;
        if (@_) { $self->{ID} = shift }
        return $self->{ID};
    }

    sub start_date {
        my $self = shift;
        if (@_) { $self->{START_DATE} = shift }
        return $self->{START_DATE};
    }
```

9.5.1 Overridden Methods

What happens when both a derived class and its base class have the same method defined? Well, then you get the derived class's version of that method. For example, let's say that we want the peers() method called on an employee to act a bit differently. Instead of just returning the list of peer names, let's return slightly different strings. So doing this:

```
    $empl->peers("Peter", "Paul", "Mary");
    printf "His peers are: %s\n", join(", ", $empl->peers);
```

will produce:

```
    His peers are: PEON=PETER, PEON=PAUL, PEON=MARY
```

To do this, merely add this definition into the Employee.pm file:

```
    sub peers {
        my $self = shift;
        if (@_) { @{ $self->{PEERS} } = @_ }
        return map { "PEON=\U$_" } @{ $self->{PEERS} };
    }
```

There, we've just demonstrated the high-falutin' concept known in certain circles as *polymorphism*. We've taken on the form and behaviour of an existing object, and then we've altered it to suit our own purposes. This is a form of Laziness. (Getting polymorphed is also what happens when the wizard decides you'd look better as a frog.)

Every now and then you'll want to have a method call trigger both its derived class (also known as "subclass") version as well as its base class (also known as "superclass") version. In practice, constructors and destructors are likely to want to do this, and it probably also makes sense in the debug() method we showed previously.

To do this, add this to Employee.pm:

```
    use Carp;
    my $Debugging = 0;

    sub debug {
        my $self = shift;
        confess "usage: thing->debug(level)"    unless @_ == 1;
        my $level = shift;
        if (ref($self))  {
            $self->{"_DEBUG"} = $level;
        } else {
            $Debugging = $level;            # whole class
        }
        Person::debug($self, $Debugging);   # don't really do this
    }
```

As you see, we turn around and call the Person package's debug() function. But this is far too fragile for good design. What if Person doesn't have a debug() function, but is inheriting *its* debug() method from elsewhere? It would have been slightly better to say

```
    Person->debug($Debugging);
```

But even that's got too much hard-coded. It's somewhat better to say

```
    $self->Person::debug($Debugging);
```

Which is a funny way to say to start looking for a debug() method up in Person. This strategy is more often seen on overridden object methods than on overridden class methods.

There is still something a bit off here. We've hard-coded our superclass's name. This in particular is bad if you change which classes you inherit from, or add others. Fortunately, the pseudoclass SUPER comes to the rescue here.

```
    $self->SUPER::debug($Debugging);
```

This way it starts looking in my class's @ISA. This only makes sense from *within* a method call, though. Don't try to access anything in SUPER:: from anywhere else, because it doesn't exist outside an overridden method call. Note that `SUPER` refers to the superclass of the current package, *not* to the superclass of `$self`.

Things are getting a bit complicated here. Have we done anything we shouldn't? As before, one way to test whether we're designing a decent class is via the empty subclass test. Since we already have an Employee class that we're trying to check, we'd better get a new empty subclass that can derive from Employee. Here's one:

```
    package Boss;
    use Employee;        # :-)
    @ISA = qw(Employee);
```

And here's the test program:

```
    #!/usr/bin/perl -w
    use strict;
    use Boss;
    Boss->debug(1);

    my $boss = Boss->new();

    $boss->fullname->title("Don");
    $boss->fullname->surname("Pichon Alvarez");
    $boss->fullname->christian("Federico Jesus");
    $boss->fullname->nickname("Fred");

    $boss->age(47);
    $boss->peers("Frank", "Felipe", "Faust");

    printf "%s is age %d.\n", $boss->fullname->as_string, $boss->age;
    printf "His peers are: %s\n", join(", ", $boss->peers);
```

Running it, we see that we're still ok. If you'd like to dump out your object in a nice format, somewhat like the way the 'x' command works in the debugger, you could use the Data::Dumper module from CPAN this way:

```
    use Data::Dumper;
    print "Here's the boss:\n";
    print Dumper($boss);
```

Which shows us something like this:

```
    Here's the boss:
    $VAR1 = bless( {
         _CENSUS => \1,
         FULLNAME => bless( {
                              TITLE => 'Don',
                              SURNAME => 'Pichon Alvarez',
                              NICK => 'Fred',
                              CHRISTIAN => 'Federico Jesus'
                            }, 'Fullname' ),
         AGE => 47,
         PEERS => [
                    'Frank',
                    'Felipe',
                    'Faust'
                  ]
       }, 'Boss' );
```

Hm.... something's missing there. What about the salary, start date, and ID fields? Well, we never set them to anything, even undef, so they don't show up in the hash's keys. The Employee class has no new() method of its own, and the new() method in Person doesn't know about Employees. (Nor should it: proper OO design dictates that a subclass be allowed to know about its immediate superclass, but never vice-versa.) So let's fix up Employee::new() this way:

```
    sub new {
        my $class = shift;
        my $self  = $class->SUPER::new();
        $self->{SALARY}        = undef;
        $self->{ID}            = undef;
        $self->{START_DATE}    = undef;
        bless ($self, $class);          # reconsecrate
        return $self;
    }
```

Now if you dump out an Employee or Boss object, you'll find that new fields show up there now.

9.5.2 Multiple Inheritance

Ok, at the risk of confusing beginners and annoying OO gurus, it's time to confess that Perl's object system includes that controversial notion known as multiple inheritance, or MI for short. All this means is that rather than having just one parent class who in turn might itself have a parent class, etc., that you can directly inherit from two or more parents. It's true that some uses of MI can get you into trouble, although hopefully not quite so much trouble with Perl as with dubiously-OO languages like C++.

The way it works is actually pretty simple: just put more than one package name in your @ISA array. When it comes time for Perl to go finding methods for your object, it looks at each of these packages in order. Well, kinda. It's actually a fully recursive, depth-first order. Consider a bunch of @ISA arrays like this:

```
    @First::ISA    = qw( Alpha );
    @Second::ISA   = qw( Beta );
    @Third::ISA    = qw( First Second );
```

If you have an object of class Third:

```
    my $ob = Third->new();
    $ob->spin();
```

How do we find a spin() method (or a new() method for that matter)? Because the search is depth-first, classes will be looked up in the following order: Third, First, Alpha, Second, and Beta.

In practice, few class modules have been seen that actually make use of MI. One nearly always chooses simple containership of one class within another over MI. That's why our Person object *contained* a Fullname object. That doesn't mean it *was* one.

However, there is one particular area where MI in Perl is rampant: borrowing another class's class methods. This is rather common, especially with some bundled "objectless" classes, like Exporter, DynaLoader, AutoLoader, and SelfLoader. These classes do not provide constructors; they exist only so you may inherit their class methods. (It's not entirely clear why inheritance was done here rather than traditional module importation.)

For example, here is the POSIX module's @ISA:

```
    package POSIX;
    @ISA = qw(Exporter DynaLoader);
```

The POSIX module isn't really an object module, but then, neither are Exporter or DynaLoader. They're just lending their classes' behaviours to POSIX.

Why don't people use MI for object methods much? One reason is that it can have complicated side-effects. For one thing, your inheritance graph (no longer a tree) might converge back to the same base class. Although Perl guards against recursive inheritance, merely having parents who are related to each other via a common ancestor, incestuous though it sounds, is not forbidden. What if in our Third class shown above we wanted its new() method to also call both overridden constructors in its two parent classes? The SUPER notation would only find the first one. Also, what about if the Alpha and Beta classes both had a common ancestor, like Nought? If you kept climbing up the inheritance tree calling overridden methods, you'd end up calling Nought::new() twice, which might well be a bad idea.

9.5.3 UNIVERSAL: The Root of All Objects

Wouldn’t it be convenient if all objects were rooted at some ultimate base class? That way you could give every object common methods without having to go and add it to each and every @ISA. Well, it turns out that you can. You don’t see it, but Perl tacitly and irrevocably assumes that there’s an extra element at the end of @ISA: the class UNIVERSAL. In version 5.003, there were no predefined methods there, but you could put whatever you felt like into it.

However, as of version 5.004 (or some subversive releases, like 5.003_08), UNIVERSAL has some methods in it already. These are builtin to your Perl binary, so they don’t take any extra time to load. Predefined methods include isa(), can(), and VERSION(). isa() tells you whether an object or class "is" another one without having to traverse the hierarchy yourself:

```
$has_io = $fd->isa("IO::Handle");
$itza_handle = IO::Socket->isa("IO::Handle");
```

The can() method, called against that object or class, reports back whether its string argument is a callable method name in that class. In fact, it gives you back a function reference to that method:

```
$his_print_method = $obj->can('as_string');
```

Finally, the VERSION method checks whether the class (or the object’s class) has a package global called $VERSION that’s high enough, as in:

```
 Some_Module->VERSION(3.0);
 $his_vers = $ob->VERSION();
```

However, we don’t usually call VERSION ourselves. (Remember that an all uppercase function name is a Perl convention that indicates that the function will be automatically used by Perl in some way.) In this case, it happens when you say

```
 use Some_Module 3.0;
```

If you wanted to add version checking to your Person class explained above, just add this to Person.pm:

```
 our $VERSION = '1.1';
```

and then in Employee.pm you can say

```
 use Person 1.1;
```

And it would make sure that you have at least that version number or higher available. This is not the same as loading in that exact version number. No mechanism currently exists for concurrent installation of multiple versions of a module. Lamentably.

9.6 Alternate Object Representations

Nothing requires objects to be implemented as hash references. An object can be any sort of reference so long as its referent has been suitably blessed. That means scalar, array, and code references are also fair game.

A scalar would work if the object has only one datum to hold. An array would work for most cases, but makes inheritance a bit dodgy because you have to invent new indices for the derived classes.

9.6.1 Arrays as Objects

If the user of your class honors the contract and sticks to the advertised interface, then you can change its underlying interface if you feel like it. Here's another implementation that conforms to the same interface specification. This time we'll use an array reference instead of a hash reference to represent the object.

```
package Person;
use strict;

my($NAME, $AGE, $PEERS) = ( 0 .. 2 );

############################################
## the object constructor (array version) ##
############################################
sub new {
    my $self = [];
    $self->[$NAME]   = undef;  # this is unnecessary
    $self->[$AGE]    = undef;  # as is this
    $self->[$PEERS]  = [];     # but this isn't, really
    bless($self);
    return $self;
}

sub name {
    my $self = shift;
    if (@_) { $self->[$NAME] = shift }
    return $self->[$NAME];
}

sub age {
    my $self = shift;
    if (@_) { $self->[$AGE] = shift }
    return $self->[$AGE];
}

sub peers {
    my $self = shift;
    if (@_) { @{ $self->[$PEERS] } = @_ }
    return @{ $self->[$PEERS] };
}

1;  # so the require or use succeeds
```

You might guess that the array access would be a lot faster than the hash access, but they're actually comparable. The array is a *little* bit faster, but not more than ten or fifteen percent, even when you replace the variables above like $AGE with literal numbers, like 1. A bigger difference between the two approaches can be found in memory use. A hash representation takes up more memory than an array representation because you have to allocate memory for the keys as well as for the values. However, it really isn't that bad, especially since as of version 5.004, memory is only allocated once for a given hash key, no matter how many hashes have that key. It's expected that sometime in the future, even these differences will fade into obscurity as more efficient underlying representations are devised.

Still, the tiny edge in speed (and somewhat larger one in memory) is enough to make some programmers choose an array representation for simple classes. There's still a little problem with scalability, though, because later in life when you feel like creating subclasses, you'll find that hashes just work out better.

9.6.2 Closures as Objects

Using a code reference to represent an object offers some fascinating possibilities. We can create a new anonymous function (closure) who alone in all the world can see the object's data. This is because we put the data into an anonymous hash that's lexically visible only to the closure we create, bless, and return as the object. This object's methods turn around and call the closure as a regular subroutine call, passing it the field we want to affect. (Yes, the double-function call is slow, but if you wanted fast, you wouldn't be using objects at all, eh? :-)

Use would be similar to before:

```
use Person;
$him = Person->new();
$him->name("Jason");
$him->age(23);
$him->peers( [ "Norbert", "Rhys", "Phineas" ] );
printf "%s is %d years old.\n", $him->name, $him->age;
print "His peers are: ", join(", ", @{$him->peers}), "\n";
```

but the implementation would be radically, perhaps even sublimely different:

```
package Person;

sub new {
     my $class  = shift;
     my $self = {
        NAME  => undef,
        AGE   => undef,
        PEERS => [],
     };
     my $closure = sub {
        my $field = shift;
        if (@_) { $self->{$field} = shift }
        return    $self->{$field};
    };
    bless($closure, $class);
    return $closure;
}

sub name   { &{ $_[0] }("NAME",  @_[ 1 .. $#_ ] ) }
sub age    { &{ $_[0] }("AGE",   @_[ 1 .. $#_ ] ) }
sub peers  { &{ $_[0] }("PEERS", @_[ 1 .. $#_ ] ) }

1;
```

Because this object is hidden behind a code reference, it's probably a bit mysterious to those whose background is more firmly rooted in standard procedural or object-based programming languages than in functional programming languages whence closures derive. The object created and returned by the new() method is itself not a data reference as we've seen before. It's an anonymous code reference that has within it access to a specific version (lexical binding and instantiation) of the object's data, which are stored in the private variable $self. Although this is the same function each time, it contains a different version of $self.

When a method like `$him->name("Jason")` is called, its implicit zeroth argument is the invoking object–just as it is with all method calls. But in this case, it's our code reference (something like a function pointer in C++, but with deep binding of lexical variables). There's not a lot to be done with a code reference beyond calling it, so that's just what we do when we say `&{$_[0]}`. This is just a regular function call, not a method call. The initial argument is the string "NAME", and any remaining arguments are whatever had been passed to the method itself.

Once we're executing inside the closure that had been created in new(), the $self hash reference suddenly becomes visible. The closure grabs its first argument ("NAME" in this case because that's what the name() method passed it), and uses that string to subscript into the private hash hidden in its unique version of $self.

Nothing under the sun will allow anyone outside the executing method to be able to get at this hidden data. Well, nearly nothing. You *could* single step through the program using the debugger and find out the pieces while you're in the method, but everyone else is out of luck.

There, if that doesn't excite the Scheme folks, then I just don't know what will. Translation of this technique into C++, Java, or any other braindead-static language is left as a futile exercise for aficionados of those camps.

You could even add a bit of nosiness via the caller() function and make the closure refuse to operate unless called via its own package. This would no doubt satisfy certain fastidious concerns of programming police and related puritans.

If you were wondering when Hubris, the third principle virtue of a programmer, would come into play, here you have it. (More seriously, Hubris is just the pride in craftsmanship that comes from having written a sound bit of well-designed code.)

9.7 AUTOLOAD: Proxy Methods

Autoloading is a way to intercept calls to undefined methods. An autoload routine may choose to create a new function on the fly, either loaded from disk or perhaps just eval()ed right there. This define-on-the-fly strategy is why it's called autoloading.

But that's only one possible approach. Another one is to just have the autoloaded method itself directly provide the requested service. When used in this way, you may think of autoloaded methods as "proxy" methods.

When Perl tries to call an undefined function in a particular package and that function is not defined, it looks for a function in that same package called AUTOLOAD. If one exists, it's called with the same arguments as the original function would have had. The fully-qualified name of the function is stored in that package's global variable $AUTOLOAD. Once called, the function can do anything it would like, including defining a new function by the right name, and then doing a really fancy kind of `goto` right to it, erasing itself from the call stack.

What does this have to do with objects? After all, we keep talking about functions, not methods. Well, since a method is just a function with an extra argument and some fancier semantics about where it's found, we can use autoloading for methods, too. Perl doesn't start looking for an AUTOLOAD method until it has exhausted the recursive hunt up through @ISA, though. Some programmers have even been known to define a UNIVERSAL::AUTOLOAD method to trap unresolved method calls to any kind of object.

9.7.1 Autoloaded Data Methods

You probably began to get a little suspicious about the duplicated code way back earlier when we first showed you the Person class, and then later the Employee class. Each method used to access the hash fields looked virtually identical. This should have tickled that great programming virtue, Impatience, but for the time, we let Laziness win out, and so did nothing. Proxy methods can cure this.

Instead of writing a new function every time we want a new data field, we'll use the autoload mechanism to generate (actually, mimic) methods on the fly. To verify that we're accessing a valid member, we will check against an `_permitted` (pronounced "under-permitted") field, which is a reference to a file-scoped lexical (like a C file static) hash of permitted fields in this record called %fields. Why the underscore? For the same reason as the _CENSUS field we once used: as a marker that means "for internal use only".

Here's what the module initialization code and class constructor will look like when taking this approach:

```
package Person;
use Carp;
our $AUTOLOAD;  # it's a package global

my %fields = (
    name        => undef,
    age         => undef,
    peers       => undef,
);
```

```
    sub new {
        my $class = shift;
        my $self  = {
            _permitted => \%fields,
            %fields,
        };
        bless $self, $class;
        return $self;
    }
```

If we wanted our record to have default values, we could fill those in where current we have `undef` in the %fields hash.

Notice how we saved a reference to our class data on the object itself? Remember that it's important to access class data through the object itself instead of having any method reference %fields directly, or else you won't have a decent inheritance.

The real magic, though, is going to reside in our proxy method, which will handle all calls to undefined methods for objects of class Person (or subclasses of Person). It has to be called AUTOLOAD. Again, it's all caps because it's called for us implicitly by Perl itself, not by a user directly.

```
    sub AUTOLOAD {
        my $self = shift;
        my $type = ref($self)
                    or croak "$self is not an object";

        my $name = $AUTOLOAD;
        $name =~ s/.*://;   # strip fully-qualified portion

        unless (exists $self->{_permitted}->{$name} ) {
            croak "Can't access `$name' field in class $type";
        }

        if (@_) {
            return $self->{$name} = shift;
        } else {
            return $self->{$name};
        }
    }
```

Pretty nifty, eh? All we have to do to add new data fields is modify %fields. No new functions need be written.

I could have avoided the `_permitted` field entirely, but I wanted to demonstrate how to store a reference to class data on the object so you wouldn't have to access that class data directly from an object method.

9.7.2 Inherited Autoloaded Data Methods

But what about inheritance? Can we define our Employee class similarly? Yes, so long as we're careful enough.

Here's how to be careful:

```
    package Employee;
    use Person;
    use strict;
    our @ISA = qw(Person);

    my %fields = (
        id          => undef,
        salary      => undef,
    );
    sub new {
        my $class = shift;
        my $self  = $class->SUPER::new();
        my($element);
        foreach $element (keys %fields) {
            $self->{_permitted}->{$element} = $fields{$element};
        }
        @{$self}{keys %fields} = values %fields;
        return $self;
    }
```

Once we've done this, we don't even need to have an AUTOLOAD function in the Employee package, because we'll grab Person's version of that via inheritance, and it will all work out just fine.

9.8 Metaclassical Tools

Even though proxy methods can provide a more convenient approach to making more struct-like classes than tediously coding up data methods as functions, it still leaves a bit to be desired. For one thing, it means you have to handle bogus calls that you don't mean to trap via your proxy. It also means you have to be quite careful when dealing with inheritance, as detailed above.

Perl programmers have responded to this by creating several different class construction classes. These metaclasses are classes that create other classes. A couple worth looking at are Class::Struct and Alias. These and other related metaclasses can be found in the modules directory on CPAN.

9.8.1 Class::Struct

One of the older ones is Class::Struct. In fact, its syntax and interface were sketched out long before perl5 even solidified into a real thing. What it does is provide you a way to "declare" a class as having objects whose fields are of a specific type. The function that does this is called, not surprisingly enough, struct(). Because structures or records are not base types in Perl, each time you want to create a class to provide a record-like data object, you yourself have to define a new() method, plus separate data-access methods for each of that record's fields. You'll quickly become bored with this process. The Class::Struct::struct() function alleviates this tedium.

Here's a simple example of using it:

```
    use Class::Struct qw(struct);
    use Jobbie;  # user-defined; see below

    struct 'Fred' => {
        one        => '$',
        many       => '@',
        profession => 'Jobbie',  # does not call Jobbie->new()
    };

    $ob = Fred->new(profession => Jobbie->new());
    $ob->one("hmmmm");

    $ob->many(0, "here");
    $ob->many(1, "you");
    $ob->many(2, "go");
    print "Just set: ", $ob->many(2), "\n";

    $ob->profession->salary(10_000);
```

You can declare types in the struct to be basic Perl types, or user-defined types (classes). User types will be initialized by calling that class's new() method.

Take care that the `Jobbie` object is not created automatically by the `Fred` class's new() method, so you should specify a `Jobbie` object when you create an instance of `Fred`.

Here's a real-world example of using struct generation. Let's say you wanted to override Perl's idea of gethostbyname() and gethostbyaddr() so that they would return objects that acted like C structures. We don't care about high-falutin' OO gunk. All we want is for these objects to act like structs in the C sense.

```
use Socket;
use Net::hostent;
$h = gethostbyname("perl.com");  # object return
printf "perl.com's real name is %s, address %s\n",
    $h->name, inet_ntoa($h->addr);
```

Here's how to do this using the Class::Struct module. The crux is going to be this call:

```
struct 'Net::hostent' => [          # note bracket
    name       => '$',
    aliases    => '@',
    addrtype   => '$',
    'length'   => '$',
    addr_list  => '@',
 ];
```

Which creates object methods of those names and types. It even creates a new() method for us.

We could also have implemented our object this way:

```
struct 'Net::hostent' => {          # note brace
    name       => '$',
    aliases    => '@',
    addrtype   => '$',
    'length'   => '$',
    addr_list  => '@',
 };
```

and then Class::Struct would have used an anonymous hash as the object type, instead of an anonymous array. The array is faster and smaller, but the hash works out better if you eventually want to do inheritance. Since for this struct-like object we aren't planning on inheritance, this time we'll opt for better speed and size over better flexibility.

Here's the whole implementation:

```
package Net::hostent;
use strict;

BEGIN {
    use Exporter   ();
    our @EXPORT      = qw(gethostbyname gethostbyaddr gethost);
    our @EXPORT_OK   = qw(
                           $h_name         @h_aliases
                           $h_addrtype     $h_length
                           @h_addr_list    $h_addr
                       );
    our %EXPORT_TAGS = ( FIELDS => [ @EXPORT_OK, @EXPORT ] );
}
our @EXPORT_OK;
```

```
    # Class::Struct forbids use of @ISA
    sub import { goto &Exporter::import }

    use Class::Struct qw(struct);
    struct 'Net::hostent' => [
       name        => '$',
       aliases     => '@',
       addrtype    => '$',
       'length'    => '$',
       addr_list   => '@',
    ];

    sub addr { shift->addr_list->[0] }

    sub populate (@) {
        return unless @_;
        my $hob = new();  # Class::Struct made this!
        $h_name     =    $hob->[0]              = $_[0];
        @h_aliases  = @{ $hob->[1] } = split ' ', $_[1];
        $h_addrtype =    $hob->[2]              = $_[2];
        $h_length   =    $hob->[3]              = $_[3];
        $h_addr     =                             $_[4];
        @h_addr_list = @{ $hob->[4] } =         @_[ (4 .. $#_) ];
        return $hob;
    }

    sub gethostbyname ($)  { populate(CORE::gethostbyname(shift)) }

    sub gethostbyaddr ($;$) {
        my ($addr, $addrtype);
        $addr = shift;
        require Socket unless @_;
        $addrtype = @_ ? shift : Socket::AF_INET();
        populate(CORE::gethostbyaddr($addr, $addrtype))
    }

    sub gethost($) {
        if ($_[0] =~ /^\d+(?:\.\d+(?:\.\d+(?:\.\d+)?)?)?$/) {
           require Socket;
           &gethostbyaddr(Socket::inet_aton(shift));
        } else {
           &gethostbyname;
        }
    }

    1;
```

We've snuck in quite a fair bit of other concepts besides just dynamic class creation, like overriding core functions, import/export bits, function prototyping, short-cut function call via `&whatever`, and function replacement with `goto &whatever`. These all mostly make sense from the perspective of a traditional module, but as you can see, we can also use them in an object module.

You can look at other object-based, struct-like overrides of core functions in the 5.004 release of Perl in File::stat, Net::hostent, Net::netent, Net::protoent, Net::servent, Time::gmtime, Time::localtime, User::grent, and User::pwent. These modules have a final component that's all lowercase, by convention reserved for compiler pragmas, because they affect the compilation and change a builtin function. They also have the type names that a C programmer would most expect.

9.8.2 Data Members as Variables

If you're used to C++ objects, then you're accustomed to being able to get at an object's data members as simple variables from within a method. The Alias module provides for this, as well as a good bit more, such as the possibility of private methods that the object can call but folks outside the class cannot.

Here's an example of creating a Person using the Alias module. When you update these magical instance variables, you automatically update value fields in the hash. Convenient, eh?

```
package Person;

# this is the same as before...
sub new {
     my $class = shift;
     my $self = {
        NAME  => undef,
        AGE   => undef,
        PEERS => [],
    };
    bless($self, $class);
    return $self;
}

use Alias qw(attr);
our ($NAME, $AGE, $PEERS);

sub name {
    my $self = attr shift;
    if (@_) { $NAME = shift; }
    return    $NAME;
}

sub age {
    my $self = attr shift;
    if (@_) { $AGE = shift; }
    return    $AGE;
}

sub peers {
    my $self = attr shift;
    if (@_) { @PEERS = @_; }
    return    @PEERS;
}

sub exclaim {
    my $self = attr shift;
    return sprintf "Hi, I'm %s, age %d, working with %s",
        $NAME, $AGE, join(", ", @PEERS);
}

sub happy_birthday {
    my $self = attr shift;
    return ++$AGE;
}
```

The need for the `our` declaration is because what Alias does is play with package globals with the same name as the fields. To use globals while `use strict` is in effect, you have to predeclare them. These package variables are localized to the block enclosing the attr() call just as if you'd used a local() on them. However, that means that they're still considered global variables with temporary values, just as with any other local().

It would be nice to combine Alias with something like Class::Struct or Class::MethodMaker.

9.9 NOTES

9.9.1 Object Terminology

In the various OO literature, it seems that a lot of different words are used to describe only a few different concepts. If you're not already an object programmer, then you don't need to worry about all these fancy words. But if you are, then you might like to know how to get at the same concepts in Perl.

For example, it's common to call an object an *instance* of a class and to call those objects' methods *instance methods*. Data fields peculiar to each object are often called *instance data* or *object attributes*, and data fields common to all members of that class are *class data*, *class attributes*, or *static data members*.

Also, *base class*, *generic class*, and *superclass* all describe the same notion, whereas *derived class*, *specific class*, and *subclass* describe the other related one.

C++ programmers have *static methods* and *virtual methods*, but Perl only has *class methods* and *object methods*. Actually, Perl only has methods. Whether a method gets used as a class or object method is by usage only. You could accidentally call a class method (one expecting a string argument) on an object (one expecting a reference), or vice versa.

From the C++ perspective, all methods in Perl are virtual. This, by the way, is why they are never checked for function prototypes in the argument list as regular builtin and user-defined functions can be.

Because a class is itself something of an object, Perl's classes can be taken as describing both a "class as meta-object" (also called *object factory*) philosophy and the "class as type definition" (*declaring* behaviour, not *defining* mechanism) idea. C++ supports the latter notion, but not the former.

9.10 SEE ALSO

The following manpages will doubtless provide more background for this one: *perlmod*, *perlref*, *perlobj*, *perlbot*, *perltie*, and *overload*.

perlboot is a kinder, gentler introduction to object-oriented programming.

perltooc provides more detail on class data.

Some modules which might prove interesting are Class::Accessor, Class::Class, Class::Contract, Class::Data::Inheritable, Class::MethodMaker and Tie::SecureHash

Tom’s OO Tutorial for Class Data in Perl

10.1 DESCRIPTION

When designing an object class, you are sometimes faced with the situation of wanting common state shared by all objects of that class. Such *class attributes* act somewhat like global variables for the entire class, but unlike program-wide globals, class attributes have meaning only to the class itself.

Here are a few examples where class attributes might come in handy:

- to keep a count of the objects you’ve created, or how many are still extant.
- to extract the name or file descriptor for a logfile used by a debugging method.
- to access collective data, like the total amount of cash dispensed by all ATMs in a network in a given day.
- to access the last object created by a class, or the most accessed object, or to retrieve a list of all objects.

Unlike a true global, class attributes should not be accessed directly. Instead, their state should be inspected, and perhaps altered, only through the mediated access of *class methods*. These class attributes accessor methods are similar in spirit and function to accessors used to manipulate the state of instance attributes on an object. They provide a clear firewall between interface and implementation.

You should allow access to class attributes through either the class name or any object of that class. If we assume that $an_object is of type Some_Class, and the &Some_Class::population_count method accesses class attributes, then these two invocations should both be possible, and almost certainly equivalent.

```
    Some_Class->population_count()
    $an_object->population_count()
```

The question is, where do you store the state which that method accesses? Unlike more restrictive languages like C++, where these are called static data members, Perl provides no syntactic mechanism to declare class attributes, any more than it provides a syntactic mechanism to declare instance attributes. Perl provides the developer with a broad set of powerful but flexible features that can be uniquely crafted to the particular demands of the situation.

A class in Perl is typically implemented in a module. A module consists of two complementary feature sets: a package for interfacing with the outside world, and a lexical file scope for privacy. Either of these two mechanisms can be used to implement class attributes. That means you get to decide whether to put your class attributes in package variables or to put them in lexical variables.

And those aren’t the only decisions to make. If you choose to use package variables, you can make your class attribute accessor methods either ignorant of inheritance or sensitive to it. If you choose lexical variables, you can elect to permit access to them from anywhere in the entire file scope, or you can limit direct data access exclusively to the methods implementing those attributes.

10.2 Class Data in a Can

One of the easiest ways to solve a hard problem is to let someone else do it for you! In this case, Class::Data::Inheritable (available on a CPAN near you) offers a canned solution to the class data problem using closures. So before you wade into this document, consider having a look at that module.

10.3 Class Data as Package Variables

Because a class in Perl is really just a package, using package variables to hold class attributes is the most natural choice. This makes it simple for each class to have its own class attributes. Let's say you have a class called Some_Class that needs a couple of different attributes that you'd like to be global to the entire class. The simplest thing to do is to use package variables like $Some_Class::CData1 and $Some_Class::CData2 to hold these attributes. But we certainly don't want to encourage outsiders to touch those data directly, so we provide methods to mediate access.

In the accessor methods below, we'll for now just ignore the first argument–that part to the left of the arrow on method invocation, which is either a class name or an object reference.

```
    package Some_Class;
    sub CData1 {
        shift;  # XXX: ignore calling class/object
        $Some_Class::CData1 = shift if @_;
        return $Some_Class::CData1;
    }
    sub CData2 {
        shift;  # XXX: ignore calling class/object
        $Some_Class::CData2 = shift if @_;
        return $Some_Class::CData2;
    }
```

This technique is highly legible and should be completely straightforward to even the novice Perl programmer. By fully qualifying the package variables, they stand out clearly when reading the code. Unfortunately, if you misspell one of these, you've introduced an error that's hard to catch. It's also somewhat disconcerting to see the class name itself hard-coded in so many places.

Both these problems can be easily fixed. Just add the `use strict` pragma, then pre-declare your package variables. (The `our` operator will be new in 5.6, and will work for package globals just like `my` works for scoped lexicals.)

```
    package Some_Class;
    use strict;
    our($CData1, $CData2);      # our() is new to perl5.6
    sub CData1 {
        shift;  # XXX: ignore calling class/object
        $CData1 = shift if @_;
        return $CData1;
    }
    sub CData2 {
        shift;  # XXX: ignore calling class/object
        $CData2 = shift if @_;
        return $CData2;
    }
```

As with any other global variable, some programmers prefer to start their package variables with capital letters. This helps clarity somewhat, but by no longer fully qualifying the package variables, their significance can be lost when reading the code. You can fix this easily enough by choosing better names than were used here.

10.3.1 Putting All Your Eggs in One Basket

Just as the mindless enumeration of accessor methods for instance attributes grows tedious after the first few (see *perltoot*), so too does the repetition begin to grate when listing out accessor methods for class data. Repetition runs counter to the primary virtue of a programmer: Laziness, here manifesting as that innate urge every programmer feels to factor out duplicate code whenever possible.

Here's what to do. First, make just one hash to hold all class attributes.

```
    package Some_Class;
    use strict;
    our %ClassData = (          # our() is new to perl5.6
        CData1 => "",
        CData2 => "",
    );
```

Using closures (see *perlref*) and direct access to the package symbol table (see *perlmod*), now clone an accessor method for each key in the %ClassData hash. Each of these methods is used to fetch or store values to the specific, named class attribute.

```
    for my $datum (keys %ClassData) {
        no strict "refs";       # to register new methods in package
        *$datum = sub {
            shift;      # XXX: ignore calling class/object
            $ClassData{$datum} = shift if @_;
            return $ClassData{$datum};
        }
    }
```

It's true that you could work out a solution employing an &AUTOLOAD method, but this approach is unlikely to prove satisfactory. Your function would have to distinguish between class attributes and object attributes; it could interfere with inheritance; and it would have to careful about DESTROY. Such complexity is uncalled for in most cases, and certainly in this one.

You may wonder why we're rescinding strict refs for the loop. We're manipulating the package's symbol table to introduce new function names using symbolic references (indirect naming), which the strict pragma would otherwise forbid. Normally, symbolic references are a dodgy notion at best. This isn't just because they can be used accidentally when you aren't meaning to. It's also because for most uses to which beginning Perl programmers attempt to put symbolic references, we have much better approaches, like nested hashes or hashes of arrays. But there's nothing wrong with using symbolic references to manipulate something that is meaningful only from the perspective of the package symbol table, like method names or package variables. In other words, when you want to refer to the symbol table, use symbol references.

Clustering all the class attributes in one place has several advantages. They're easy to spot, initialize, and change. The aggregation also makes them convenient to access externally, such as from a debugger or a persistence package. The only possible problem is that we don't automatically know the name of each class's class object, should it have one. This issue is addressed below in §10.3.3.

10.3.2 Inheritance Concerns

Suppose you have an instance of a derived class, and you access class data using an inherited method call. Should that end up referring to the base class's attributes, or to those in the derived class? How would it work in the earlier examples? The derived class inherits all the base class's methods, including those that access class attributes. But what package are the class attributes stored in?

The answer is that, as written, class attributes are stored in the package into which those methods were compiled. When you invoke the &CData1 method on the name of the derived class or on one of that class's objects, the version shown above is still run, so you'll access $Some_Class::CData1–or in the method cloning version, `$Some_Class::ClassData{CData1}`.

Think of these class methods as executing in the context of their base class, not in that of their derived class. Sometimes this is exactly what you want. If Feline subclasses Carnivore, then the population of Carnivores in the world should go up when a new Feline is born. But what if you wanted to figure out how many Felines you have apart from Carnivores? The current approach doesn't support that.

You'll have to decide on a case-by-case basis whether it makes any sense for class attributes to be package-relative. If you want it to be so, then stop ignoring the first argument to the function. Either it will be a package name if the method was invoked directly on a class name, or else it will be an object reference if the method was invoked on an object reference. In the latter case, the ref() function provides the class of that object.

```
package Some_Class;
sub CData1 {
    my $obclass = shift;
    my $class   = ref($obclass) || $obclass;
    my $varname = $class . "::CData1";
    no strict "refs";       # to access package data symbolically
    $$varname = shift if @_;
    return $$varname;
}
```

And then do likewise for all other class attributes (such as CData2, etc.) that you wish to access as package variables in the invoking package instead of the compiling package as we had previously.

Once again we temporarily disable the strict references ban, because otherwise we couldn't use the fully-qualified symbolic name for the package global. This is perfectly reasonable: since all package variables by definition live in a package, there's nothing wrong with accessing them via that package's symbol table. That's what it's there for (well, somewhat).

What about just using a single hash for everything and then cloning methods? What would that look like? The only difference would be the closure used to produce new method entries for the class's symbol table.

```
no strict "refs";
*$datum = sub {
    my $obclass = shift;
    my $class   = ref($obclass) || $obclass;
    my $varname = $class . "::ClassData";
    $varname->{$datum} = shift if @_;
    return $varname->{$datum};
}
```

10.3.3 The Eponymous Meta-Object

It could be argued that the %ClassData hash in the previous example is neither the most imaginative nor the most intuitive of names. Is there something else that might make more sense, be more useful, or both?

As it happens, yes, there is. For the "class meta-object", we'll use a package variable of the same name as the package itself. Within the scope of a package Some_Class declaration, we'll use the eponymously named hash %Some_Class as that class's meta-object. (Using an eponymously named hash is somewhat reminiscent of classes that name their constructors eponymously in the Python or C++ fashion. That is, class Some_Class would use &Some_Class::Some_Class as a constructor, probably even exporting that name as well. The StrNum class in Recipe 13.14 in *The Perl Cookbook* does this, if you're looking for an example.)

This predictable approach has many benefits, including having a well-known identifier to aid in debugging, transparent persistence, or checkpointing. It's also the obvious name for monadic classes and translucent attributes, discussed later.

Here's an example of such a class. Notice how the name of the hash storing the meta-object is the same as the name of the package used to implement the class.

```
package Some_Class;
use strict;
```

```
    # create class meta-object using that most perfect of names
    our %Some_Class = (         # our() is new to perl5.6
        CData1 => "",
        CData2 => "",
    );

    # this accessor is calling-package-relative
    sub CData1 {
        my $obclass = shift;
        my $class   = ref($obclass) || $obclass;
        no strict "refs";       # to access eponymous meta-object
        $class->{CData1} = shift if @_;
        return $class->{CData1};
    }

    # but this accessor is not
    sub CData2 {
        shift;                  # XXX: ignore calling class/object
        no strict "refs";       # to access eponymous meta-object
        __PACKAGE__ -> {CData2} = shift if @_;
        return __PACKAGE__ -> {CData2};
    }
```

In the second accessor method, the __PACKAGE__ notation was used for two reasons. First, to avoid hardcoding the literal package name in the code in case we later want to change that name. Second, to clarify to the reader that what matters here is the package currently being compiled into, not the package of the invoking object or class. If the long sequence of non-alphabetic characters bothers you, you can always put the __PACKAGE__ in a variable first.

```
    sub CData2 {
        shift;                  # XXX: ignore calling class/object
        no strict "refs";       # to access eponymous meta-object
        my $class = __PACKAGE__;
        $class->{CData2} = shift if @_;
        return $class->{CData2};
    }
```

Even though we're using symbolic references for good not evil, some folks tend to become unnerved when they see so many places with strict ref checking disabled. Given a symbolic reference, you can always produce a real reference (the reverse is not true, though). So we'll create a subroutine that does this conversion for us. If invoked as a function of no arguments, it returns a reference to the compiling class's eponymous hash. Invoked as a class method, it returns a reference to the eponymous hash of its caller. And when invoked as an object method, this function returns a reference to the eponymous hash for whatever class the object belongs to.

```
    package Some_Class;
    use strict;

    our %Some_Class = (         # our() is new to perl5.6
        CData1 => "",
        CData2 => "",
    );

    # tri-natured: function, class method, or object method
    sub _classobj {
        my $obclass = shift || __PACKAGE__;
        my $class   = ref($obclass) || $obclass;
        no strict "refs";   # to convert sym ref to real one
        return \%$class;
    }
    for my $datum (keys %{ _classobj() } ) {
        # turn off strict refs so that we can
        # register a method in the symbol table
        no strict "refs";
        *$datum = sub {
            use strict "refs";
            my $self = shift->_classobj();
            $self->{$datum} = shift if @_;
            return $self->{$datum};
        }
    }
```

10.3.4 Indirect References to Class Data

A reasonably common strategy for handling class attributes is to store a reference to each package variable on the object itself. This is a strategy you've probably seen before, such as in *perltoot* and *perlbot*, but there may be variations in the example below that you haven't thought of before.

```
    package Some_Class;
    our($CData1, $CData2);              # our() is new to perl5.6

    sub new {
        my $obclass = shift;
        return bless my $self = {
            ObData1 => "",
            ObData2 => "",
            CData1  => \$CData1,
            CData2  => \$CData2,
        } => (ref $obclass || $obclass);
    }

    sub ObData1 {
        my $self = shift;
        $self->{ObData1} = shift if @_;
        return $self->{ObData1};
    }

    sub ObData2 {
        my $self = shift;
        $self->{ObData2} = shift if @_;
        return $self->{ObData2};
    }

    sub CData1 {
        my $self = shift;
        my $dataref = ref $self
                        ? $self->{CData1}
                        : \$CData1;
        $$dataref = shift if @_;
        return $$dataref;
    }

    sub CData2 {
        my $self = shift;
        my $dataref = ref $self
```

```
                        ? $self->{CData2}
                        : \$CData2;
        $$dataref = shift if @_;
        return $$dataref;
    }
```

As written above, a derived class will inherit these methods, which will consequently access package variables in the base class's package. This is not necessarily expected behavior in all circumstances. Here's an example that uses a variable meta-object, taking care to access the proper package's data.

```
        package Some_Class;
        use strict;

        our %Some_Class = (     # our() is new to perl5.6
            CData1 => "",
            CData2 => "",
        );

        sub _classobj {
            my $self  = shift;
            my $class = ref($self) || $self;
            no strict "refs";
            # get (hard) ref to eponymous meta-object
            return \%$class;
        }

        sub new {
            my $obclass  = shift;
            my $classobj = $obclass->_classobj();
            bless my $self = {
                ObData1 => "",
                ObData2 => "",
                CData1  => \$classobj->{CData1},
                CData2  => \$classobj->{CData2},
            } => (ref $obclass || $obclass);
            return $self;
        }

        sub ObData1 {
            my $self = shift;
            $self->{ObData1} = shift if @_;
            return $self->{ObData1};
        }

        sub ObData2 {
            my $self = shift;
            $self->{ObData2} = shift if @_;
            return $self->{ObData2};
        }

        sub CData1 {
            my $self = shift;
            $self = $self->_classobj() unless ref $self;
            my $dataref = $self->{CData1};
            $$dataref = shift if @_;
            return $$dataref;
        }
        sub CData2 {
            my $self = shift;
            $self = $self->_classobj() unless ref $self;
            my $dataref = $self->{CData2};
            $$dataref = shift if @_;
            return $$dataref;
        }
```

Not only are we now strict refs clean, using an eponymous meta-object seems to make the code cleaner. Unlike the previous version, this one does something interesting in the face of inheritance: it accesses the class meta-object in the invoking class instead of the one into which the method was initially compiled.

You can easily access data in the class meta-object, making it easy to dump the complete class state using an external mechanism such as when debugging or implementing a persistent class. This works because the class meta-object is a package variable, has a well-known name, and clusters all its data together. (Transparent persistence is not always feasible, but it's certainly an appealing idea.)

There's still no check that object accessor methods have not been invoked on a class name. If strict ref checking is enabled, you'd blow up. If not, then you get the eponymous meta-object. What you do with–or about–this is up to you. The next two sections demonstrate innovative uses for this powerful feature.

10.3.5 Monadic Classes

Some of the standard modules shipped with Perl provide class interfaces without any attribute methods whatsoever. The most commonly used module not numbered amongst the pragmata, the Exporter module, is a class with neither constructors nor attributes. Its job is simply to provide a standard interface for modules wishing to export part of their namespace into that of their caller. Modules use the Exporter's &import method by setting their inheritance list in their package's @ISA array to mention "Exporter". But class Exporter provides no constructor, so you can't have several instances of the class. In fact, you can't have any–it just doesn't make any sense. All you get is its methods. Its interface contains no statefulness, so state data is wholly superfluous.

Another sort of class that pops up from time to time is one that supports a unique instance. Such classes are called *monadic classes*, or less formally, *singletons* or *highlander classes*.

If a class is monadic, where do you store its state, that is, its attributes? How do you make sure that there's never more than one instance? While you could merely use a slew of package variables, it's a lot cleaner to use the eponymously named hash. Here's a complete example of a monadic class:

```
    package Cosmos;
    %Cosmos = ();

    # accessor method for "name" attribute
    sub name {
        my $self = shift;
        $self->{name} = shift if @_;
        return $self->{name};
    }

    # read-only accessor method for "birthday" attribute
    sub birthday {
        my $self = shift;
        die "can't reset birthday" if @_;  # XXX: croak() is better
        return $self->{birthday};
    }

    # accessor method for "stars" attribute
    sub stars {
        my $self = shift;
        $self->{stars} = shift if @_;
        return $self->{stars};
    }
    # oh my - one of our stars just went out!
    sub supernova {
        my $self = shift;
        my $count = $self->stars();
        $self->stars($count - 1) if $count > 0;
    }

    # constructor/initializer method - fix by reboot
    sub bigbang {
        my $self = shift;
        %$self = (
            name         => "the world according to tchrist",
            birthday     => time(),
            stars        => 0,
        );
        return $self;       # yes, it's probably a class.  SURPRISE!
    }

    # After the class is compiled, but before any use or require
    # returns, we start off the universe with a bang.
    __PACKAGE__ -> bigbang();
```

Hold on, that doesn't look like anything special. Those attribute accessors look no different than they would if this were a regular class instead of a monadic one. The crux of the matter is there's nothing that says that $self must hold a reference to a blessed object. It merely has to be something you can invoke methods on. Here the package name itself, Cosmos, works as an object. Look at the &supernova method. Is that a class method or an object method? The answer is that static analysis cannot reveal the answer. Perl doesn't care, and neither should you. In the three attribute methods, `%$self` is really accessing the %Cosmos package variable.

If like Stephen Hawking, you posit the existence of multiple, sequential, and unrelated universes, then you can invoke the &bigbang method yourself at any time to start everything all over again. You might think of &bigbang as more of an initializer than a constructor, since the function doesn't allocate new memory; it only initializes what's already there. But like any other constructor, it does return a scalar value to use for later method invocations.

Imagine that some day in the future, you decide that one universe just isn't enough. You could write a new class from scratch, but you already have an existing class that does what you want–except that it's monadic, and you want more than just one cosmos.

That's what code reuse via subclassing is all about. Look how short the new code is:

```
    package Multiverse;
    use Cosmos;
    @ISA = qw(Cosmos);

    sub new {
        my $protoverse = shift;
        my $class      = ref($protoverse) || $protoverse;
        my $self       = {};
        return bless($self, $class)->bigbang();
    }
    1;
```

Because we were careful to be good little creators when we designed our Cosmos class, we can now reuse it without touching a single line of code when it comes time to write our Multiverse class. The same code that worked when invoked as a class method continues to work perfectly well when invoked against separate instances of a derived class.

The astonishing thing about the Cosmos class above is that the value returned by the &bigbang "constructor" is not a reference to a blessed object at all. It's just the class's own name. A class name is, for virtually all intents and purposes, a perfectly acceptable object. It has state, behavior, and identity, the three crucial components of an object system. It even manifests inheritance, polymorphism, and encapsulation. And what more can you ask of an object?

To understand object orientation in Perl, it's important to recognize the unification of what other programming languages might think of as class methods and object methods into just plain methods. "Class methods" and "object methods" are distinct only in the compartmentalizing mind of the Perl programmer, not in the Perl language itself.

Along those same lines, a constructor is nothing special either, which is one reason why Perl has no pre-ordained name for them. "Constructor" is just an informal term loosely used to describe a method that returns a scalar value that you can make further method calls against. So long as it's either a class name or an object reference, that's good enough. It doesn't even have to be a reference to a brand new object.

You can have as many–or as few–constructors as you want, and you can name them whatever you care to. Blindly and obediently using new() for each and every constructor you ever write is to speak Perl with such a severe C++ accent that you do a disservice to both languages. There's no reason to insist that each class have but one constructor, or that a constructor be named new(), or that a constructor be used solely as a class method and not an object method.

The next section shows how useful it can be to further distance ourselves from any formal distinction between class method calls and object method calls, both in constructors and in accessor methods.

10.3.6 Translucent Attributes

A package's eponymous hash can be used for more than just containing per-class, global state data. It can also serve as a sort of template containing default settings for object attributes. These default settings can then be used in constructors for initialization of a particular object. The class's eponymous hash can also be used to implement *translucent attributes*. A translucent attribute is one that has a class-wide default. Each object can set its own value for the attribute, in which case `$object->attribute()` returns that value. But if no value has been set, then `$object->attribute()` returns the class-wide default.

We'll apply something of a copy-on-write approach to these translucent attributes. If you're just fetching values from them, you get translucency. But if you store a new value to them, that new value is set on the current object. On the other hand, if you use the class as an object and store the attribute value directly on the class, then the meta-object's value changes, and later fetch operations on objects with uninitialized values for those attributes will retrieve the meta-object's new values. Objects with their own initialized values, however, won't see any change.

Let's look at some concrete examples of using these properties before we show how to implement them. Suppose that a class named Some_Class had a translucent data attribute called "color". First you set the color in the meta-object, then you create three objects using a constructor that happens to be named &spawn.

```
    use Vermin;
    Vermin->color("vermilion");

    $ob1 = Vermin->spawn();     # so that's where Jedi come from
    $ob2 = Vermin->spawn();
    $ob3 = Vermin->spawn();

    print $obj3->color();       # prints "vermilion"
```

Each of these objects' colors is now "vermilion", because that's the meta-object's value for that attribute, and these objects do not have individual color values set.

Changing the attribute on one object has no effect on other objects previously created.

```
    $ob3->color("chartreuse");
    print $ob3->color();        # prints "chartreuse"
    print $ob1->color();        # prints "vermilion", translucently
```

If you now use $ob3 to spawn off another object, the new object will take the color its parent held, which now happens to be "chartreuse". That's because the constructor uses the invoking object as its template for initializing attributes. When that invoking object is the class name, the object used as a template is the eponymous meta-object. When the invoking object is a reference to an instantiated object, the &spawn constructor uses that existing object as a template.

```
    $ob4 = $ob3->spawn();       # $ob3 now template, not %Vermin
    print $ob4->color();        # prints "chartreuse"
```

Any actual values set on the template object will be copied to the new object. But attributes undefined in the template object, being translucent, will remain undefined and consequently translucent in the new one as well.

Now let's change the color attribute on the entire class:

```
    Vermin->color("azure");
    print $ob1->color();        # prints "azure"
    print $ob2->color();        # prints "azure"
    print $ob3->color();        # prints "chartreuse"
    print $ob4->color();        # prints "chartreuse"
```

That color change took effect only in the first pair of objects, which were still translucently accessing the meta-object's values. The second pair had per-object initialized colors, and so didn't change.

One important question remains. Changes to the meta-object are reflected in translucent attributes in the entire class, but what about changes to discrete objects? If you change the color of $ob3, does the value of $ob4 see that change? Or vice-versa. If you change the color of $ob4, does then the value of $ob3 shift?

```
    $ob3->color("amethyst");
    print $ob3->color();        # prints "amethyst"
    print $ob4->color();        # hmm: "chartreuse" or "amethyst"?
```

While one could argue that in certain rare cases it should, let's not do that. Good taste aside, we want the answer to the question posed in the comment above to be "chartreuse", not "amethyst". So we'll treat these attributes similar to the way process attributes like environment variables, user and group IDs, or the current working directory are treated across a fork(). You can change only yourself, but you will see those changes reflected in your unspawned children. Changes to one object will propagate neither up to the parent nor down to any existing child objects. Those objects made later, however, will see the changes.

If you have an object with an actual attribute value, and you want to make that object's attribute value translucent again, what do you do? Let's design the class so that when you invoke an accessor method with `undef` as its argument, that attribute returns to translucency.

```
    $ob4->color(undef);         # back to "azure"
```

Here's a complete implementation of Vermin as described above.

```
    package Vermin;

    # here's the class meta-object, eponymously named.
    # it holds all class attributes, and also all instance attributes
    # so the latter can be used for both initialization
    # and translucency.

    our %Vermin = (             # our() is new to perl5.6
        PopCount => 0,          # capital for class attributes
        color    => "beige",    # small for instance attributes
    );

    # constructor method
    # invoked as class method or object method
    sub spawn {
        my $obclass = shift;
        my $class   = ref($obclass) || $obclass;
        my $self = {};
        bless($self, $class);
        $class->{PopCount}++;
        # init fields from invoking object, or omit if
        # invoking object is the class to provide translucency
        %$self = %$obclass if ref $obclass;
        return $self;
    }

    # translucent accessor for "color" attribute
    # invoked as class method or object method
    sub color {
        my $self  = shift;
        my $class = ref($self) || $self;

        # handle class invocation
        unless (ref $self) {
            $class->{color} = shift if @_;
            return $class->{color}
        }

        # handle object invocation
        $self->{color} = shift if @_;
        if (defined $self->{color}) {  # not exists!
            return $self->{color};
        } else {
            return $class->{color};
        }
    }

    # accessor for "PopCount" class attribute
    # invoked as class method or object method
    # but uses object solely to locate meta-object
    sub population {
        my $obclass = shift;
        my $class   = ref($obclass) || $obclass;
        return $class->{PopCount};
    }

    # instance destructor
    # invoked only as object method
    sub DESTROY {
        my $self  = shift;
        my $class = ref $self;
        $class->{PopCount}--;
    }
```

Here are a couple of helper methods that might be convenient. They aren't accessor methods at all. They're used to detect accessibility of data attributes. The &is_translucent method determines whether a particular object attribute is coming from the meta-object. The &has_attribute method detects whether a class implements a particular property at all. It could also be used to distinguish undefined properties from non-existent ones.

```
    # detect whether an object attribute is translucent
    # (typically?) invoked only as object method
    sub is_translucent {
        my($self, $attr)  = @_;
        return !defined $self->{$attr};
    }
    # test for presence of attribute in class
    # invoked as class method or object method
    sub has_attribute {
        my($self, $attr)  = @_;
        my $class = ref($self) || $self;
        return exists $class->{$attr};
    }
```

If you prefer to install your accessors more generically, you can make use of the upper-case versus lower-case convention to register into the package appropriate methods cloned from generic closures.

```
    for my $datum (keys %{ +__PACKAGE__ }) {
        *$datum = ($datum =~ /^[A-Z]/)
            ? sub {  # install class accessor
                    my $obclass = shift;
                    my $class   = ref($obclass) || $obclass;
                    return $class->{$datum};
                  }
            : sub { # install translucent accessor
                    my $self  = shift;
                    my $class = ref($self) || $self;
                    unless (ref $self) {
                        $class->{$datum} = shift if @_;
                        return $class->{$datum}
                    }
                    $self->{$datum} = shift if @_;
                    return defined $self->{$datum}
                        ? $self  -> {$datum}
                        : $class -> {$datum}
                  }
    }
```

Translations of this closure-based approach into C++, Java, and Python have been left as exercises for the reader. Be sure to send us mail as soon as you're done.

10.4 Class Data as Lexical Variables

10.4.1 Privacy and Responsibility

Unlike conventions used by some Perl programmers, in the previous examples, we didn't prefix the package variables used for class attributes with an underscore, nor did we do so for the names of the hash keys used for instance attributes. You don't need little markers on data names to suggest nominal privacy on attribute variables or hash keys, because these are **already** notionally private! Outsiders have no business whatsoever playing with anything within a class save through the mediated access of its documented interface; in other words, through method invocations. And not even through just any method, either. Methods that begin with an underscore are traditionally considered off-limits outside the class. If outsiders skip the documented method interface to poke around the internals of your class and end up breaking something, that's not your fault–it's theirs.

Perl believes in individual responsibility rather than mandated control. Perl respects you enough to let you choose your own preferred level of pain, or of pleasure. Perl believes that you are creative, intelligent, and capable of making your own decisions–and fully expects you to take complete responsibility for your own actions. In a perfect world, these admonitions alone would suffice, and everyone would be intelligent, responsible, happy, and creative. And careful. One probably shouldn't forget careful, and that's a good bit harder to expect. Even Einstein would take wrong turns by accident and end up lost in the wrong part of town.

Some folks get the heebie-jeebies when they see package variables hanging out there for anyone to reach over and alter them. Some folks live in constant fear that someone somewhere might do something wicked. The solution to that problem is simply to fire the wicked, of course. But unfortunately, it's not as simple as all that. These cautious types are also afraid that they or others will do something not so much wicked as careless, whether by accident or out of desperation. If we fire everyone who ever gets careless, pretty soon there won't be anybody left to get any work done.

Whether it's needless paranoia or sensible caution, this uneasiness can be a problem for some people. We can take the edge off their discomfort by providing the option of storing class attributes as lexical variables instead of as package variables. The my() operator is the source of all privacy in Perl, and it is a powerful form of privacy indeed.

It is widely perceived, and indeed has often been written, that Perl provides no data hiding, that it affords the class designer no privacy nor isolation, merely a rag-tag assortment of weak and unenforcible social conventions instead. This perception is demonstrably false and easily disproven. In the next section, we show how to implement forms of privacy that are far stronger than those provided in nearly any other object-oriented language.

10.4.2 File-Scoped Lexicals

A lexical variable is visible only through the end of its static scope. That means that the only code able to access that variable is code residing textually below the my() operator through the end of its block if it has one, or through the end of the current file if it doesn't.

Starting again with our simplest example given at the start of this document, we replace our() variables with my() versions.

```
package Some_Class;
my($CData1, $CData2);   # file scope, not in any package
sub CData1 {
    shift;  # XXX: ignore calling class/object
    $CData1 = shift if @_;
    return $CData1;
}
sub CData2 {
    shift;  # XXX: ignore calling class/object
    $CData2 = shift if @_;
    return $CData2;
}
```

So much for that old $Some_Class::CData1 package variable and its brethren! Those are gone now, replaced with lexicals. No one outside the scope can reach in and alter the class state without resorting to the documented interface. Not even subclasses or superclasses of this one have unmediated access to $CData1. They have to invoke the &CData1 method against Some_Class or an instance thereof, just like anybody else.

To be scrupulously honest, that last statement assumes you haven't packed several classes together into the same file scope, nor strewn your class implementation across several different files. Accessibility of those variables is based uniquely on the static file scope. It has nothing to do with the package. That means that code in a different file but the same package (class) could not access those variables, yet code in the same file but a different package (class) could. There are sound reasons why we usually suggest a one-to-one mapping between files and packages and modules and classes. You don't have to stick to this suggestion if you really know what you're doing, but you're apt to confuse yourself otherwise, especially at first.

If you'd like to aggregate your class attributes into one lexically scoped, composite structure, you're perfectly free to do so.

```
package Some_Class;
my %ClassData = (
    CData1 => "",
    CData2 => "",
);
sub CData1 {
    shift;  # XXX: ignore calling class/object
    $ClassData{CData1} = shift if @_;
```

```
        return $ClassData{CData1};
    }
    sub CData2 {
        shift;  # XXX: ignore calling class/object
        $ClassData{CData2} = shift if @_;
        return $ClassData{CData2};
    }
```

To make this more scalable as other class attributes are added, we can again register closures into the package symbol table to create accessor methods for them.

```
    package Some_Class;
    my %ClassData = (
        CData1 => "",
        CData2 => "",
    );
    for my $datum (keys %ClassData) {
        no strict "refs";
        *$datum = sub {
            shift;      # XXX: ignore calling class/object
            $ClassData{$datum} = shift if @_;
            return $ClassData{$datum};
        };
    }
```

Requiring even your own class to use accessor methods like anybody else is probably a good thing. But demanding and expecting that everyone else, be they subclass or superclass, friend or foe, will all come to your object through mediation is more than just a good idea. It's absolutely critical to the model. Let there be in your mind no such thing as "public" data, nor even "protected" data, which is a seductive but ultimately destructive notion. Both will come back to bite at you. That's because as soon as you take that first step out of the solid position in which all state is considered completely private, save from the perspective of its own accessor methods, you have violated the envelope. And, having pierced that encapsulating envelope, you shall doubtless someday pay the price when future changes in the implementation break unrelated code. Considering that avoiding this infelicitous outcome was precisely why you consented to suffer the slings and arrows of obsequious abstraction by turning to object orientation in the first place, such breakage seems unfortunate in the extreme.

10.4.3 More Inheritance Concerns

Suppose that Some_Class were used as a base class from which to derive Another_Class. If you invoke a &CData method on the derived class or on an object of that class, what do you get? Would the derived class have its own state, or would it piggyback on its base class's versions of the class attributes?

The answer is that under the scheme outlined above, the derived class would **not** have its own state data. As before, whether you consider this a good thing or a bad one depends on the semantics of the classes involved.

The cleanest, sanest, simplest way to address per-class state in a lexical is for the derived class to override its base class's version of the method that accesses the class attributes. Since the actual method called is the one in the object's derived class if this exists, you automatically get per-class state this way. Any urge to provide an unadvertised method to sneak out a reference to the %ClassData hash should be strenuously resisted.

As with any other overridden method, the implementation in the derived class always has the option of invoking its base class's version of the method in addition to its own. Here's an example:

```
    package Another_Class;
    @ISA = qw(Some_Class);

    my %ClassData = (
        CData1 => "",
    );
```

```
sub CData1 {
    my($self, $newvalue) = @_;
    if (@_ > 1) {
        # set locally first
        $ClassData{CData1} = $newvalue;

        # then pass the buck up to the first
        # overridden version, if there is one
        if ($self->can("SUPER::CData1")) {
            $self->SUPER::CData1($newvalue);
        }
    }
    return $ClassData{CData1};
}
```

Those dabbling in multiple inheritance might be concerned about there being more than one override.

```
for my $parent (@ISA) {
    my $methname = $parent . "::CData1";
    if ($self->can($methname)) {
        $self->$methname($newvalue);
    }
}
```

Because the &UNIVERSAL::can method returns a reference to the function directly, you can use this directly for a significant performance improvement:

```
for my $parent (@ISA) {
    if (my $coderef = $self->can($parent . "::CData1")) {
        $self->$coderef($newvalue);
    }
}
```

10.4.4 Locking the Door and Throwing Away the Key

As currently implemented, any code within the same scope as the file-scoped lexical %ClassData can alter that hash directly. Is that ok? Is it acceptable or even desirable to allow other parts of the implementation of this class to access class attributes directly?

That depends on how careful you want to be. Think back to the Cosmos class. If the &supernova method had directly altered $Cosmos::Stars or `$Cosmos::Cosmos{stars}`, then we wouldn't have been able to reuse the class when it came to inventing a Multiverse. So letting even the class itself access its own class attributes without the mediating intervention of properly designed accessor methods is probably not a good idea after all.

Restricting access to class attributes from the class itself is usually not enforcible even in strongly object-oriented languages. But in Perl, you can.

Here's one way:

```
package Some_Class;

{  # scope for hiding $CData1
    my $CData1;
    sub CData1 {
        shift;      # XXX: unused
        $CData1 = shift if @_;
        return $CData1;
    }
}
```

```
{  # scope for hiding $CData2
    my $CData2;
    sub CData2 {
        shift;      # XXX: unused
        $CData2 = shift if @_;
        return $CData2;
    }
}
```

No one–absolutely no one–is allowed to read or write the class attributes without the mediation of the managing accessor method, since only that method has access to the lexical variable it's managing. This use of mediated access to class attributes is a form of privacy far stronger than most OO languages provide.

The repetition of code used to create per-datum accessor methods chafes at our Laziness, so we'll again use closures to create similar methods.

```
package Some_Class;

{  # scope for ultra-private meta-object for class attributes
    my %ClassData = (
        CData1 => "",
        CData2 => "",
    );

    for my $datum (keys %ClassData ) {
        no strict "refs";
        *$datum = sub {
            use strict "refs";
            my ($self, $newvalue) = @_;
            $ClassData{$datum} = $newvalue if @_ > 1;
            return $ClassData{$datum};
        }
    }

}
```

The closure above can be modified to take inheritance into account using the &UNIVERSAL::can method and SUPER as shown previously.

10.4.5 Translucency Revisited

The Vermin class demonstrates translucency using a package variable, eponymously named %Vermin, as its meta-object. If you prefer to use absolutely no package variables beyond those necessary to appease inheritance or possibly the Exporter, this strategy is closed to you. That's too bad, because translucent attributes are an appealing technique, so it would be valuable to devise an implementation using only lexicals.

There's a second reason why you might wish to avoid the eponymous package hash. If you use class names with double-colons in them, you would end up poking around somewhere you might not have meant to poke.

```
package Vermin;
$class = "Vermin";
$class->{PopCount}++;
# accesses $Vermin::Vermin{PopCount}

package Vermin::Noxious;
$class = "Vermin::Noxious";
$class->{PopCount}++;
# accesses $Vermin::Noxious{PopCount}
```

In the first case, because the class name had no double-colons, we got the hash in the current package. But in the second case, instead of getting some hash in the current package, we got the hash %Noxious in the Vermin package. (The noxious vermin just invaded another package and sprayed their data around it. :-) Perl doesn't support relative packages in its naming conventions, so any double-colons trigger a fully-qualified lookup instead of just looking in the current package.

In practice, it is unlikely that the Vermin class had an existing package variable named %Noxious that you just blew away. If you're still mistrustful, you could always stake out your own territory where you know the rules, such as using Eponymous::Vermin::Noxious or Hieronymus::Vermin::Boschious or Leave_Me_Alone::Vermin::Noxious as class names instead. Sure, it's in theory possible that someone else has a class named Eponymous::Vermin with its own %Noxious hash, but this kind of thing is always true. There's no arbiter of package names. It's always the case that globals like @Cwd::ISA would collide if more than one class uses the same Cwd package.

If this still leaves you with an uncomfortable twinge of paranoia, we have another solution for you. There's nothing that says that you have to have a package variable to hold a class meta-object, either for monadic classes or for translucent attributes. Just code up the methods so that they access a lexical instead.

Here's another implementation of the Vermin class with semantics identical to those given previously, but this time using no package variables.

```
    package Vermin;

    # Here's the class meta-object, eponymously named.
    # It holds all class data, and also all instance data
    # so the latter can be used for both initialization
    # and translucency.  it's a template.
    my %ClassData = (
        PopCount => 0,          # capital for class attributes
        color    => "beige",    # small for instance attributes
    );

    # constructor method
    # invoked as class method or object method
    sub spawn {
        my $obclass = shift;
        my $class   = ref($obclass) || $obclass;
        my $self = {};
        bless($self, $class);
        $ClassData{PopCount}++;
        # init fields from invoking object, or omit if
        # invoking object is the class to provide translucency
        %$self = %$obclass if ref $obclass;
        return $self;
    }

    # translucent accessor for "color" attribute
    # invoked as class method or object method
    sub color {
        my $self  = shift;

        # handle class invocation
        unless (ref $self) {
            $ClassData{color} = shift if @_;
            return $ClassData{color}
        }
        # handle object invocation
        $self->{color} = shift if @_;
        if (defined $self->{color}) {  # not exists!
            return $self->{color};
        } else {
            return $ClassData{color};
        }
    }

    # class attribute accessor for "PopCount" attribute
    # invoked as class method or object method
    sub population {
        return $ClassData{PopCount};
    }

    # instance destructor; invoked only as object method
    sub DESTROY {
        $ClassData{PopCount}--;
    }

    # detect whether an object attribute is translucent
    # (typically?) invoked only as object method
    sub is_translucent {
        my($self, $attr)  = @_;
        $self = \%ClassData if !ref $self;
        return !defined $self->{$attr};
    }

    # test for presence of attribute in class
    # invoked as class method or object method
    sub has_attribute {
        my($self, $attr)  = @_;
        return exists $ClassData{$attr};
    }
```

10.5 NOTES

Inheritance is a powerful but subtle device, best used only after careful forethought and design. Aggregation instead of inheritance is often a better approach.

You can't use file-scoped lexicals in conjunction with the SelfLoader or the AutoLoader, because they alter the lexical scope in which the module's methods wind up getting compiled.

The usual mealy-mouthed package-mungeing doubtless applies to setting up names of object attributes. For example, `$self->{ObData1}` should probably be `$self->{ __PACKAGE__ .  "_ObData1" }`, but that would just confuse the examples.

Bag'o Object Tricks (the BOT)

11.1 DESCRIPTION

The following collection of tricks and hints is intended to whet curious appetites about such things as the use of instance variables and the mechanics of object and class relationships. The reader is encouraged to consult relevant textbooks for discussion of Object Oriented definitions and methodology. This is not intended as a tutorial for object-oriented programming or as a comprehensive guide to Perl's object oriented features, nor should it be construed as a style guide. If you're looking for tutorials, be sure to read *perlboot*, *perltoot*, and *perltooc*.

The Perl motto still holds: There's more than one way to do it.

11.2 OO SCALING TIPS

1. Do not attempt to verify the type of $self. That'll break if the class is inherited, when the type of $self is valid but its package isn't what you expect. See rule 5.

2. If an object-oriented (OO) or indirect-object (IO) syntax was used, then the object is probably the correct type and there's no need to become paranoid about it. Perl isn't a paranoid language anyway. If people subvert the OO or IO syntax then they probably know what they're doing and you should let them do it. See rule 1.

3. Use the two-argument form of bless(). Let a subclass use your constructor. See INHERITING A CONSTRUCTOR.

4. The subclass is allowed to know things about its immediate superclass, the superclass is allowed to know nothing about a subclass.

5. Don't be trigger happy with inheritance. A "using", "containing", or "delegation" relationship (some sort of aggregation, at least) is often more appropriate. See OBJECT RELATIONSHIPS, USING RELATIONSHIP WITH SDBM, and §11.12.

6. The object is the namespace. Make package globals accessible via the object. This will remove the guess work about the symbol's home package. See CLASS CONTEXT AND THE OBJECT.

7. IO syntax is certainly less noisy, but it is also prone to ambiguities that can cause difficult-to-find bugs. Allow people to use the sure-thing OO syntax, even if you don't like it.

8. Do not use function-call syntax on a method. You're going to be bitten someday. Someone might move that method into a superclass and your code will be broken. On top of that you're feeding the paranoia in rule 2.

9. Don't assume you know the home package of a method. You're making it difficult for someone to override that method. See THINKING OF CODE REUSE.

11.3 INSTANCE VARIABLES

An anonymous array or anonymous hash can be used to hold instance variables. Named parameters are also demonstrated.

```
        package Foo;

        sub new {
                my $type = shift;
                my %params = @_;
                my $self = {};
                $self->{'High'} = $params{'High'};
                $self->{'Low'}  = $params{'Low'};
                bless $self, $type;
        }

        package Bar;

        sub new {
                my $type = shift;
                my %params = @_;
                my $self = [];
                $self->[0] = $params{'Left'};
                $self->[1] = $params{'Right'};
                bless $self, $type;
        }

        package main;

        $a = Foo->new( 'High' => 42, 'Low' => 11 );
        print "High=$a->{'High'}\n";
        print "Low=$a->{'Low'}\n";

        $b = Bar->new( 'Left' => 78, 'Right' => 40 );
        print "Left=$b->[0]\n";
        print "Right=$b->[1]\n";
```

11.4 SCALAR INSTANCE VARIABLES

An anonymous scalar can be used when only one instance variable is needed.

```
        package Foo;

        sub new {
                my $type = shift;
                my $self;
                $self = shift;
                bless \$self, $type;
        }

        package main;

        $a = Foo->new( 42 );
        print "a=$$a\n";
```

11.5 INSTANCE VARIABLE INHERITANCE

This example demonstrates how one might inherit instance variables from a superclass for inclusion in the new class. This requires calling the superclass's constructor and adding one's own instance variables to the new object.

```
package Bar;

sub new {
        my $type = shift;
        my $self = {};
        $self->{'buz'} = 42;
        bless $self, $type;
}

package Foo;
@ISA = qw( Bar );

sub new {
        my $type = shift;
        my $self = Bar->new;
        $self->{'biz'} = 11;
        bless $self, $type;
}

package main;

$a = Foo->new;
print "buz = ", $a->{'buz'}, "\n";
print "biz = ", $a->{'biz'}, "\n";
```

11.6 OBJECT RELATIONSHIPS

The following demonstrates how one might implement "containing" and "using" relationships between objects.

```
package Bar;

sub new {
        my $type = shift;
        my $self = {};
        $self->{'buz'} = 42;
        bless $self, $type;
}

package Foo;

sub new {
        my $type = shift;
        my $self = {};
        $self->{'Bar'} = Bar->new;
        $self->{'biz'} = 11;
        bless $self, $type;
}

package main;

$a = Foo->new;
print "buz = ", $a->{'Bar'}->{'buz'}, "\n";
print "biz = ", $a->{'biz'}, "\n";
```

11.7 OVERRIDING SUPERCLASS METHODS

The following example demonstrates how to override a superclass method and then call the overridden method. The **SUPER** pseudo-class allows the programmer to call an overridden superclass method without actually knowing where that method is defined.

```
package Buz;
sub goo { print "here’s the goo\n" }

package Bar; @ISA = qw( Buz );
sub google { print "google here\n" }

package Baz;
sub mumble { print "mumbling\n" }

package Foo;
@ISA = qw( Bar Baz );

sub new {
        my $type = shift;
        bless [], $type;
}
sub grr { print "grumble\n" }
sub goo {
        my $self = shift;
        $self->SUPER::goo();
}
sub mumble {
        my $self = shift;
        $self->SUPER::mumble();
}
sub google {
        my $self = shift;
        $self->SUPER::google();
}

package main;

$foo = Foo->new;
$foo->mumble;
$foo->grr;
$foo->goo;
$foo->google;
```

Note that `SUPER` refers to the superclasses of the current package (`Foo`), not to the superclasses of `$self`.

11.8 USING RELATIONSHIP WITH SDBM

This example demonstrates an interface for the SDBM class. This creates a "using" relationship between the SDBM class and the new class Mydbm.

```
package Mydbm;
```

```
        require SDBM_File;
        require Tie::Hash;
        @ISA = qw( Tie::Hash );

        sub TIEHASH {
            my $type = shift;
            my $ref  = SDBM_File->new(@_);
            bless {'dbm' => $ref}, $type;
        }
        sub FETCH {
            my $self = shift;
            my $ref  = $self->{'dbm'};
            $ref->FETCH(@_);
        }
        sub STORE {
            my $self = shift;
            if (defined $_[0]){
                my $ref = $self->{'dbm'};
                $ref->STORE(@_);
            } else {
                die "Cannot STORE an undefined key in Mydbm\n";
            }
        }

        package main;
        use Fcntl qw( O_RDWR O_CREAT );

        tie %foo, "Mydbm", "Sdbm", O_RDWR|O_CREAT, 0640;
        $foo{'bar'} = 123;
        print "foo-bar = $foo{'bar'}\n";

        tie %bar, "Mydbm", "Sdbm2", O_RDWR|O_CREAT, 0640;
        $bar{'Cathy'} = 456;
        print "bar-Cathy = $bar{'Cathy'}\n";
```

11.9 THINKING OF CODE REUSE

One strength of Object-Oriented languages is the ease with which old code can use new code. The following examples will demonstrate first how one can hinder code reuse and then how one can promote code reuse.

This first example illustrates a class which uses a fully-qualified method call to access the "private" method BAZ(). The second example will show that it is impossible to override the BAZ() method.

```
        package FOO;

        sub new {
                my $type = shift;
                bless {}, $type;
        }
        sub bar {
                my $self = shift;
                $self->FOO::private::BAZ;
        }

        package FOO::private;
```

```
    sub BAZ {
            print "in BAZ\n";
    }

    package main;

    $a = FOO->new;
    $a->bar;
```

Now we try to override the BAZ() method. We would like FOO::bar() to call GOOP::BAZ(), but this cannot happen because FOO::bar() explicitly calls FOO::private::BAZ().

```
    package FOO;

    sub new {
            my $type = shift;
            bless {}, $type;
    }
    sub bar {
            my $self = shift;
            $self->FOO::private::BAZ;
    }

    package FOO::private;

    sub BAZ {
            print "in BAZ\n";
    }

    package GOOP;
    @ISA = qw( FOO );
    sub new {
            my $type = shift;
            bless {}, $type;
    }

    sub BAZ {
            print "in GOOP::BAZ\n";
    }

    package main;

    $a = GOOP->new;
    $a->bar;
```

To create reusable code we must modify class FOO, flattening class FOO::private. The next example shows a reusable class FOO which allows the method GOOP::BAZ() to be used in place of FOO::BAZ().

```
    package FOO;

    sub new {
            my $type = shift;
            bless {}, $type;
    }
    sub bar {
            my $self = shift;
            $self->BAZ;
    }
```

```
        sub BAZ {
                print "in BAZ\n";
        }

        package GOOP;
        @ISA = qw( FOO );

        sub new {
                my $type = shift;
                bless {}, $type;
        }
        sub BAZ {
                print "in GOOP::BAZ\n";
        }

        package main;

        $a = GOOP->new;
        $a->bar;
```

11.10 CLASS CONTEXT AND THE OBJECT

Use the object to solve package and class context problems. Everything a method needs should be available via the object or should be passed as a parameter to the method.

A class will sometimes have static or global data to be used by the methods. A subclass may want to override that data and replace it with new data. When this happens the superclass may not know how to find the new copy of the data.

This problem can be solved by using the object to define the context of the method. Let the method look in the object for a reference to the data. The alternative is to force the method to go hunting for the data ("Is it in my class, or in a subclass? Which subclass?"), and this can be inconvenient and will lead to hackery. It is better just to let the object tell the method where that data is located.

```
        package Bar;

        %fizzle = ( 'Password' => 'XYZZY' );

        sub new {
                my $type = shift;
                my $self = {};
                $self->{'fizzle'} = \%fizzle;
                bless $self, $type;
        }

        sub enter {
                my $self = shift;

                # Don't try to guess if we should use %Bar::fizzle
                # or %Foo::fizzle.  The object already knows which
                # we should use, so just ask it.
                #
                my $fizzle = $self->{'fizzle'};

                print "The word is ", $fizzle->{'Password'}, "\n";
        }
        package Foo;
        @ISA = qw( Bar );

        %fizzle = ( 'Password' => 'Rumple' );

        sub new {
                my $type = shift;
                my $self = Bar->new;
                $self->{'fizzle'} = \%fizzle;
                bless $self, $type;
        }

        package main;

        $a = Bar->new;
        $b = Foo->new;
        $a->enter;
        $b->enter;
```

11.11 INHERITING A CONSTRUCTOR

An inheritable constructor should use the second form of bless() which allows blessing directly into a specified class. Notice in this example that the object will be a BAR not a FOO, even though the constructor is in class FOO.

```
        package FOO;

        sub new {
                my $type = shift;
                my $self = {};
                bless $self, $type;
        }

        sub baz {
                print "in FOO::baz()\n";
        }

        package BAR;
        @ISA = qw(FOO);

        sub baz {
                print "in BAR::baz()\n";
        }

        package main;

        $a = BAR->new;
        $a->baz;
```

11.12 DELEGATION

Some classes, such as SDBM_File, cannot be effectively subclassed because they create foreign objects. Such a class can be extended with some sort of aggregation technique such as the "using" relationship mentioned earlier or by delegation.

The following example demonstrates delegation using an AUTOLOAD() function to perform message-forwarding. This will allow the Mydbm object to behave exactly like an SDBM_File object. The Mydbm class could now extend the behavior by adding custom FETCH() and STORE() methods, if this is desired.

```
        package Mydbm;

        require SDBM_File;
        require Tie::Hash;
        @ISA = qw(Tie::Hash);

        sub TIEHASH {
                my $type = shift;
                my $ref = SDBM_File->new(@_);
                bless {'delegate' => $ref};
        }

        sub AUTOLOAD {
                my $self = shift;

                # The Perl interpreter places the name of the
                # message in a variable called $AUTOLOAD.

                # DESTROY messages should never be propagated.
                return if $AUTOLOAD =~ /::DESTROY$/;

                # Remove the package name.
                $AUTOLOAD =~ s/^Mydbm:://;

                # Pass the message to the delegate.
                $self->{'delegate'}->$AUTOLOAD(@_);
        }

        package main;
        use Fcntl qw( O_RDWR O_CREAT );

        tie %foo, "Mydbm", "adbm", O_RDWR|O_CREAT, 0640;
        $foo{'bar'} = 123;
        print "foo-bar = $foo{'bar'}\n";
```

perlstyle

Perl style guide

12.1 DESCRIPTION

Each programmer will, of course, have his or her own preferences in regards to formatting, but there are some general guidelines that will make your programs easier to read, understand, and maintain.

The most important thing is to run your programs under the `-w` flag at all times. You may turn it off explicitly for particular portions of code via the `no warnings` pragma or the `$^W` variable if you must. You should also always run under `use strict` or know the reason why not. The `use sigtrap` and even `use diagnostics` pragmas may also prove useful.

Regarding aesthetics of code lay out, about the only thing Larry cares strongly about is that the closing curly bracket of a multi-line BLOCK should line up with the keyword that started the construct. Beyond that, he has other preferences that aren't so strong:

- 4-column indent.
- Opening curly on same line as keyword, if possible, otherwise line up.
- Space before the opening curly of a multi-line BLOCK.
- One-line BLOCK may be put on one line, including curlies.
- No space before the semicolon.
- Semicolon omitted in "short" one-line BLOCK.
- Space around most operators.
- Space around a "complex" subscript (inside brackets).
- Blank lines between chunks that do different things.
- Uncuddled elses.
- No space between function name and its opening parenthesis.
- Space after each comma.
- Long lines broken after an operator (except "and" and "or").
- Space after last parenthesis matching on current line.
- Line up corresponding items vertically.

- Omit redundant punctuation as long as clarity doesn't suffer.

Larry has his reasons for each of these things, but he doesn't claim that everyone else's mind works the same as his does. Here are some other more substantive style issues to think about:

- Just because you *CAN* do something a particular way doesn't mean that you *SHOULD* do it that way. Perl is designed to give you several ways to do anything, so consider picking the most readable one. For instance

  ```
  open(FOO,$foo) || die "Can't open $foo: $!";
  ```

  is better than

  ```
  die "Can't open $foo: $!" unless open(FOO,$foo);
  ```

  because the second way hides the main point of the statement in a modifier. On the other hand

  ```
  print "Starting analysis\n" if $verbose;
  ```

  is better than

  ```
  $verbose && print "Starting analysis\n";
  ```

  because the main point isn't whether the user typed **-v** or not.

  Similarly, just because an operator lets you assume default arguments doesn't mean that you have to make use of the defaults. The defaults are there for lazy systems programmers writing one-shot programs. If you want your program to be readable, consider supplying the argument.

  Along the same lines, just because you *CAN* omit parentheses in many places doesn't mean that you ought to:

  ```
  return print reverse sort num values %array;
  return print(reverse(sort num (values(%array))));
  ```

  When in doubt, parenthesize. At the very least it will let some poor schmuck bounce on the % key in **vi**.

  Even if you aren't in doubt, consider the mental welfare of the person who has to maintain the code after you, and who will probably put parentheses in the wrong place.

- Don't go through silly contortions to exit a loop at the top or the bottom, when Perl provides the `last` operator so you can exit in the middle. Just "outdent" it a little to make it more visible:

  ```
  LINE:
      for (;;) {
          statements;
        last LINE if $foo;
          next LINE if /^#/;
          statements;
      }
  ```

- Don't be afraid to use loop labels–they're there to enhance readability as well as to allow multilevel loop breaks. See the previous example.

- Avoid using grep() (or map()) or ‘backticks‘ in a void context, that is, when you just throw away their return values. Those functions all have return values, so use them. Otherwise use a foreach() loop or the system() function instead.

- For portability, when using features that may not be implemented on every machine, test the construct in an eval to see if it fails. If you know what version or patchlevel a particular feature was implemented, you can test `$]` (`$PERL_VERSION` in `English`) to see if it will be there. The `Config` module will also let you interrogate values determined by the **Configure** program when Perl was installed.
- Choose mnemonic identifiers. If you can't remember what mnemonic means, you've got a problem.
- While short identifiers like $gotit are probably ok, use underscores to separate words. It is generally easier to read $var_names_like_this than $VarNamesLikeThis, especially for non-native speakers of English. It's also a simple rule that works consistently with VAR_NAMES_LIKE_THIS.

  Package names are sometimes an exception to this rule. Perl informally reserves lowercase module names for "pragma" modules like `integer` and `strict`. Other modules should begin with a capital letter and use mixed case, but probably without underscores due to limitations in primitive file systems' representations of module names as files that must fit into a few sparse bytes.
- You may find it helpful to use letter case to indicate the scope or nature of a variable. For example:

```
    $ALL_CAPS_HERE   constants only (beware clashes with perl vars!)
    $Some_Caps_Here  package-wide global/static
    $no_caps_here    function scope my() or local() variables
```

  Function and method names seem to work best as all lowercase. E.g., $obj->as_string().

  You can use a leading underscore to indicate that a variable or function should not be used outside the package that defined it.
- If you have a really hairy regular expression, use the `/x` modifier and put in some whitespace to make it look a little less like line noise. Don't use slash as a delimiter when your regexp has slashes or backslashes.
- Use the new "and" and "or" operators to avoid having to parenthesize list operators so much, and to reduce the incidence of punctuation operators like && and ||. Call your subroutines as if they were functions or list operators to avoid excessive ampersands and parentheses.
- Use here documents instead of repeated print() statements.
- Line up corresponding things vertically, especially if it'd be too long to fit on one line anyway.

```
    $IDX = $ST_MTIME;
    $IDX = $ST_ATIME       if $opt_u;
    $IDX = $ST_CTIME       if $opt_c;
    $IDX = $ST_SIZE        if $opt_s;

    mkdir $tmpdir, 0700 or die "can't mkdir $tmpdir: $!";
    chdir($tmpdir)      or die "can't chdir $tmpdir: $!";
    mkdir 'tmp',   0777 or die "can't mkdir $tmpdir/tmp: $!";
```

- Always check the return codes of system calls. Good error messages should go to STDERR, include which program caused the problem, what the failed system call and arguments were, and (VERY IMPORTANT) should contain the standard system error message for what went wrong. Here's a simple but sufficient example:

```
    opendir(D, $dir)     or die "can't opendir $dir: $!";
```

- Line up your transliterations when it makes sense:

```
    tr [abc]
       [xyz];
```

- Think about reusability. Why waste brainpower on a one-shot when you might want to do something like it again? Consider generalizing your code. Consider writing a module or object class. Consider making your code run cleanly with `use strict` and `use warnings` (or **-w**) in effect. Consider giving away your code. Consider changing your whole world view. Consider... oh, never mind.
- Be consistent.
- Be nice.

Chapter 13

perlcheat

Perl 5 Cheat Sheet

13.1 DESCRIPTION

This 'cheat sheet' is a handy reference, meant for beginning Perl programmers. Not everything is mentioned, but 194 features may already be overwhelming.

13.1.1 The sheet

```
  CONTEXTS  SIGILS             ARRAYS        HASHES
  void      $scalar   whole:   @array        %hash
  scalar    @array    slice:   @array[0, 2]  @hash{'a', 'b'}
  list      %hash     element: $array[0]     $hash{'a'}
            &sub
            *glob    SCALAR VALUES
                     number, string, reference, glob, undef
  REFERENCES
  \     references      $$foo[1]       aka $foo->[1]

13.2 ACKNOWLEDGEMENTS

The first version of this document appeared on Perl Monks, where several people had useful suggestions. Thank you, Perl Monks.

A special thanks to Damian Conway, who didn't only suggest important changes, but also took the time to count the number of listed features and make a Perl 6 version to show that Perl will stay Perl.

13.3 AUTHOR

Juerd Waalboer <juerd@cpan.org>, with the help of many Perl Monks.

Chapter 14

perltrap

Perl traps for the unwary

14.1 DESCRIPTION

The biggest trap of all is forgetting to `use warnings` or use the **-w** switch; see *perllexwarn* and *perlrun*. The second biggest trap is not making your entire program runnable under `use strict`. The third biggest trap is not reading the list of changes in this version of Perl; see *perldelta*.

14.1.1 Awk Traps

Accustomed **awk** users should take special note of the following:

- A Perl program executes only once, not once for each input line. You can do an implicit loop with `-n` or `-p`.
- The English module, loaded via

  ```
      use English;
  ```

  allows you to refer to special variables (like `$/`) with names (like $RS), as though they were in **awk**; see *perlvar* for details.
- Semicolons are required after all simple statements in Perl (except at the end of a block). Newline is not a statement delimiter.
- Curly brackets are required on `if`s and `while`s.
- Variables begin with "$", "@" or "%" in Perl.
- Arrays index from 0. Likewise string positions in substr() and index().
- You have to decide whether your array has numeric or string indices.
- Hash values do not spring into existence upon mere reference.
- You have to decide whether you want to use string or numeric comparisons.
- Reading an input line does not split it for you. You get to split it to an array yourself. And the split() operator has different arguments than **awk**'s.
- The current input line is normally in $_, not $0. It generally does not have the newline stripped. ($0 is the name of the program executed.) See *perlvar*.

- $<*digit*> does not refer to fields–it refers to substrings matched by the last match pattern.
- The print() statement does not add field and record separators unless you set `$,` and `$\`. You can set $OFS and $ORS if you're using the English module.
- You must open your files before you print to them.
- The range operator is "..", not comma. The comma operator works as in C.
- The match operator is "=~", not "~". ("~" is the one's complement operator, as in C.)
- The exponentiation operator is "**", not "^". "^" is the XOR operator, as in C. (You know, one could get the feeling that **awk** is basically incompatible with C.)
- The concatenation operator is ".", not the null string. (Using the null string would render `/pat/ /pat/` unparsable, because the third slash would be interpreted as a division operator–the tokenizer is in fact slightly context sensitive for operators like "/", "?", and ">". And in fact, "." itself can be the beginning of a number.)
- The `next`, `exit`, and `continue` keywords work differently.
- The following variables work differently:

```
Awk       Perl
ARGC      scalar @ARGV (compare with $#ARGV)
ARGV[0]   $0
FILENAME  $ARGV
FNR       $. - something
FS        (whatever you like)
NF        $#Fld, or some such
NR        $.
OFMT      $#
OFS       $,
ORS       $\
RLENGTH   length($&)
RS        $/
RSTART    length($`)
SUBSEP    $;
```

- You cannot set $RS to a pattern, only a string.
- When in doubt, run the **awk** construct through **a2p** and see what it gives you.

14.1.2 C/C++ Traps

Cerebral C and C++ programmers should take note of the following:

- Curly brackets are required on `if`'s and `while`'s.
- You must use `elsif` rather than `else if`.
- The `break` and `continue` keywords from C become in Perl `last` and `next`, respectively. Unlike in C, these do *not* work within a `do { } while` construct. See Loop Control in *perlsyn*.
- There's no switch statement. (But it's easy to build one on the fly, see Basic BLOCKs and Switch Statements in *perlsyn*)
- Variables begin with "$", "@" or "%" in Perl.
- Comments begin with "#", not "/*" or "//". Perl may interpret C/C++ comments as division operators, unterminated regular expressions or the defined-or operator.

- You can't take the address of anything, although a similar operator in Perl is the backslash, which creates a reference.
- `ARGV` must be capitalized. `$ARGV[0]` is C's `argv[1]`, and `argv[0]` ends up in `$0`.
- System calls such as link(), unlink(), rename(), etc. return nonzero for success, not 0. (system(), however, returns zero for success.)
- Signal handlers deal with signal names, not numbers. Use `kill -l` to find their names on your system.

14.1.3 Sed Traps

Seasoned **sed** programmers should take note of the following:

- A Perl program executes only once, not once for each input line. You can do an implicit loop with `-n` or `-p`.
- Backreferences in substitutions use "$" rather than "\".
- The pattern matching metacharacters "(", ")", and "|" do not have backslashes in front.
- The range operator is `...`, rather than comma.

14.1.4 Shell Traps

Sharp shell programmers should take note of the following:

- The backtick operator does variable interpolation without regard to the presence of single quotes in the command.
- The backtick operator does no translation of the return value, unlike **csh**.
- Shells (especially **csh**) do several levels of substitution on each command line. Perl does substitution in only certain constructs such as double quotes, backticks, angle brackets, and search patterns.
- Shells interpret scripts a little bit at a time. Perl compiles the entire program before executing it (except for `BEGIN` blocks, which execute at compile time).
- The arguments are available via @ARGV, not $1, $2, etc.
- The environment is not automatically made available as separate scalar variables.

14.1.5 Perl Traps

Practicing Perl Programmers should take note of the following:

- Remember that many operations behave differently in a list context than they do in a scalar one. See *perldata* for details.
- Avoid barewords if you can, especially all lowercase ones. You can't tell by just looking at it whether a bareword is a function or a string. By using quotes on strings and parentheses on function calls, you won't ever get them confused.
- You cannot discern from mere inspection which builtins are unary operators (like chop() and chdir()) and which are list operators (like print() and unlink()). (Unless prototyped, user-defined subroutines can **only** be list operators, never unary ones.) See *perlop* and *perlsub*.
- People have a hard time remembering that some functions default to $_, or @ARGV, or whatever, but that others which you might expect to do not.
- The <FH> construct is not the name of the filehandle, it is a readline operation on that handle. The data read is assigned to $_ only if the file read is the sole condition in a while loop:

```
while (<FH>)      { }
while (defined($_ = <FH>)) { }..
<FH>;  # data discarded!
```

- Remember not to use = when you need =˜; these two constructs are quite different:

```
$x =  /foo/;
$x =~ /foo/;
```

- The `do {}` construct isn't a real loop that you can use loop control on.
- Use `my()` for local variables whenever you can get away with it (but see *perlform* for where you can't). Using `local()` actually gives a local value to a global variable, which leaves you open to unforeseen side-effects of dynamic scoping.
- If you localize an exported variable in a module, its exported value will not change. The local name becomes an alias to a new value but the external name is still an alias for the original.

14.1.6 Perl4 to Perl5 Traps

Practicing Perl4 Programmers should take note of the following Perl4-to-Perl5 specific traps.
They're crudely ordered according to the following list:

Discontinuance, Deprecation, and BugFix traps

Anything that's been fixed as a perl4 bug, removed as a perl4 feature or deprecated as a perl4 feature with the intent to encourage usage of some other perl5 feature.

Parsing Traps

Traps that appear to stem from the new parser.

Numerical Traps

Traps having to do with numerical or mathematical operators.

General data type traps

Traps involving perl standard data types.

Context Traps - scalar, list contexts

Traps related to context within lists, scalar statements/declarations.

Precedence Traps

Traps related to the precedence of parsing, evaluation, and execution of code.

General Regular Expression Traps using s///, etc.

Traps related to the use of pattern matching.

Subroutine, Signal, Sorting Traps

Traps related to the use of signals and signal handlers, general subroutines, and sorting, along with sorting subroutines.

OS Traps

OS-specific traps.

DBM Traps

Traps specific to the use of `dbmopen()`, and specific dbm implementations.

Unclassified Traps

Everything else.

If you find an example of a conversion trap that is not listed here, please submit it to <*perlbug@perl.org*> for inclusion. Also note that at least some of these can be caught with the `use warnings` pragma or the **-w** switch.

14.1.7 Discontinuance, Deprecation, and BugFix traps

Anything that has been discontinued, deprecated, or fixed as a bug from perl4.

- Discontinuance

  Symbols starting with "_" are no longer forced into package main, except for `$_` itself (and `@_`, etc.).

  ```
  package test;
  $_legacy = 1;

  package main;
  print "\$_legacy is ",$_legacy,"\n";

  # perl4 prints: $_legacy is 1
  # perl5 prints: $_legacy is
  ```

- Deprecation

  Double-colon is now a valid package separator in a variable name. Thus these behave differently in perl4 vs. perl5, because the packages don't exist.

  ```
  $a=1;$b=2;$c=3;$var=4;
  print "$a::$b::$c ";
  print "$var::abc::xyz\n";

  # perl4 prints: 1::2::3 4::abc::xyz
  # perl5 prints: 3
  ```

  Given that `::` is now the preferred package delimiter, it is debatable whether this should be classed as a bug or not. (The older package delimiter, ' ,is used here)

  ```
  $x = 10 ;
  print "x=${'x}\n" ;

  # perl4 prints: x=10
  # perl5 prints: Can't find string terminator "'" anywhere before EOF
  ```

  You can avoid this problem, and remain compatible with perl4, if you always explicitly include the package name:

  ```
  $x = 10 ;
  print "x=${main'x}\n" ;
  ```

  Also see precedence traps, for parsing `$:`.

- BugFix

  The second and third arguments of `splice()` are now evaluated in scalar context (as the Camel says) rather than list context.

  ```
  sub sub1{return(0,2) }          # return a 2-element list
  sub sub2{ return(1,2,3)}        # return a 3-element list
  @a1 = ("a","b","c","d","e");
  @a2 = splice(@a1,&sub1,&sub2);
  print join(' ',@a2),"\n";

  # perl4 prints: a b
  # perl5 prints: c d e
  ```

- Discontinuance

  You can't do a `goto` into a block that is optimized away. Darn.

  ```
  goto marker1;

  for(1){
  marker1:
      print "Here I is!\n";
  }

  # perl4 prints: Here I is!
  # perl5 errors: Can't "goto" into the middle of a foreach loop
  ```

- Discontinuance

  It is no longer syntactically legal to use whitespace as the name of a variable, or as a delimiter for any kind of quote construct. Double darn.

  ```
  $a = ("foo bar");
  $b = q baz ;
  print "a is $a, b is $b\n";

  # perl4 prints: a is foo bar, b is baz
  # perl5 errors: Bareword found where operator expected
  ```

- Discontinuance

  The archaic while/if BLOCK BLOCK syntax is no longer supported.

  ```
  if { 1 } {
      print "True!";
  }
  else {
      print "False!";
  }

  # perl4 prints: True!
  # perl5 errors: syntax error at test.pl line 1, near "if {"
  ```

- BugFix

  The ** operator now binds more tightly than unary minus. It was documented to work this way before, but didn't.

  ```
  print -4**2,"\n";

  # perl4 prints: 16
  # perl5 prints: -16
  ```

- Discontinuance

  The meaning of `foreach{}` has changed slightly when it is iterating over a list which is not an array. This used to assign the list to a temporary array, but no longer does so (for efficiency). This means that you'll now be iterating over the actual values, not over copies of the values. Modifications to the loop variable can change the original values.

```
@list = ('ab','abc','bcd','def');
foreach $var (grep(/ab/,@list)){
    $var = 1;
}
print (join(':',@list));

# perl4 prints: ab:abc:bcd:def
# perl5 prints: 1:1:bcd:def
```

To retain Perl4 semantics you need to assign your list explicitly to a temporary array and then iterate over that. For example, you might need to change

```
foreach $var (grep(/ab/,@list)){
```

to

```
foreach $var (@tmp = grep(/ab/,@list)){
```

Otherwise changing $var will clobber the values of @list. (This most often happens when you use `$_` for the loop variable, and call subroutines in the loop that don't properly localize `$_`.)

- Discontinuance

  `split` with no arguments now behaves like `split ' '` (which doesn't return an initial null field if $_ starts with whitespace), it used to behave like `split /\s+/` (which does).

  ```
  $_ = ' hi mom';
  print join(':', split);

  # perl4 prints: :hi:mom
  # perl5 prints: hi:mom
  ```

- BugFix

  Perl 4 would ignore any text which was attached to an **-e** switch, always taking the code snippet from the following arg. Additionally, it would silently accept an **-e** switch without a following arg. Both of these behaviors have been fixed.

  ```
  perl -e'print "attached to -e"' 'print "separate arg"'

  # perl4 prints: separate arg
  # perl5 prints: attached to -e

  perl -e

  # perl4 prints:
  # perl5 dies: No code specified for -e.
  ```

- Discontinuance

  In Perl 4 the return value of `push` was undocumented, but it was actually the last value being pushed onto the target list. In Perl 5 the return value of `push` is documented, but has changed, it is the number of elements in the resulting list.

  ```
  @x = ('existing');
  print push(@x, 'first new', 'second new');
  ```

```
    # perl4 prints: second new
    # perl5 prints: 3
```

- Deprecation

  Some error messages will be different.

- Discontinuance

  In Perl 4, if in list context the delimiters to the first argument of `split()` were `??`, the result would be placed in `@_` as well as being returned. Perl 5 has more respect for your subroutine arguments.

- Discontinuance

  Some bugs may have been inadvertently removed. :-)

14.1.8 Parsing Traps

Perl4-to-Perl5 traps from having to do with parsing.

- Parsing

  Note the space between . and =

  ```
      $string . = "more string";
      print $string;

      # perl4 prints: more string
      # perl5 prints: syntax error at - line 1, near ". ="
  ```

- Parsing

  Better parsing in perl 5

  ```
      sub foo {}
      &foo
      print("hello, world\n");

      # perl4 prints: hello, world
      # perl5 prints: syntax error
  ```

- Parsing

  "if it looks like a function, it is a function" rule.

  ```
    print
      ($foo == 1) ? "is one\n" : "is zero\n";

      # perl4 prints: is zero
      # perl5 warns: "Useless use of a constant in void context" if using -w
  ```

- Parsing

  String interpolation of the `$#array` construct differs when braces are to used around the name.

  ```
      @a = (1..3);
      print "${#a}";

      # perl4 prints: 2
      # perl5 fails with syntax error
  ```

```
@ = (1..3);
print "$#{a}";

# perl4 prints: {a}
# perl5 prints: 2
```

- Parsing

  When perl sees `map {` (or `grep {`), it has to guess whether the `{` starts a BLOCK or a hash reference. If it guesses wrong, it will report a syntax error near the `}` and the missing (or unexpected) comma.

  Use unary + before `{` on a hash reference, and unary + applied to the first thing in a BLOCK (after `{`), for perl to guess right all the time. (See map in *perlfunc*.)

14.1.9 Numerical Traps

Perl4-to-Perl5 traps having to do with numerical operators, operands, or output from same.

- Numerical

  Formatted output and significant digits. In general, Perl 5 tries to be more precise. For example, on a Solaris Sparc:

  ```
  print 7.373504 - 0, "\n";
  printf "%20.18f\n", 7.373504 - 0;

  # Perl4 prints:
  7.3750399999999996141
  7.375039999999999614

  # Perl5 prints:
  7.373504
  7.375039999999999614
  ```

  Notice how the first result looks better in Perl 5.

  Your results may vary, since your floating point formatting routines and even floating point format may be slightly different.

- Numerical

  This specific item has been deleted. It demonstrated how the auto-increment operator would not catch when a number went over the signed int limit. Fixed in version 5.003_04. But always be wary when using large integers. If in doubt:

  ```
  use Math::BigInt;
  ```

- Numerical

  Assignment of return values from numeric equality tests does not work in perl5 when the test evaluates to false (0). Logical tests now return a null, instead of 0

  ```
  $p = ($test == 1);
  print $p,"\n";

  # perl4 prints: 0
  # perl5 prints:
  ```

  Also see §14.1.13 for another example of this new feature...

- Bitwise string ops

  When bitwise operators which can operate upon either numbers or strings (`& | ^ ~`) are given only strings as arguments, perl4 would treat the operands as bitstrings so long as the program contained a call to the `vec()` function. perl5 treats the string operands as bitstrings. (See Bitwise String Operators in *perlop* for more details.)

  ```
  $fred = "10";
  $barney = "12";
  $betty = $fred & $barney;
  print "$betty\n";
  # Uncomment the next line to change perl4's behavior
  # ($dummy) = vec("dummy", 0, 0);

  # Perl4 prints:
  8

  # Perl5 prints:
  10

  # If vec() is used anywhere in the program, both print:
  10
  ```

14.1.10 General data type traps

Perl4-to-Perl5 traps involving most data-types, and their usage within certain expressions and/or context.

- (Arrays)

  Negative array subscripts now count from the end of the array.

  ```
  @a = (1, 2, 3, 4, 5);
  print "The third element of the array is $a[3] also expressed as $a[-2] \n";

  # perl4 prints: The third element of the array is 4 also expressed as
  # perl5 prints: The third element of the array is 4 also expressed as 4
  ```

- (Arrays)

  Setting `$#array` lower now discards array elements, and makes them impossible to recover.

  ```
  @a = (a,b,c,d,e);
  print "Before: ",join('',@a);
  $#a =1;
  print ", After: ",join('',@a);
  $#a =3;
  print ", Recovered: ",join('',@a),"\n";

  # perl4 prints: Before: abcde, After: ab, Recovered: abcd
  # perl5 prints: Before: abcde, After: ab, Recovered: ab
  ```

- (Hashes)

  Hashes get defined before use

  ```
  local($s,@a,%h);
  die "scalar \$s defined" if defined($s);
  die "array \@a defined" if defined(@a);
  die "hash \%h defined" if defined(%h);
  ```

```
    # perl4 prints:
    # perl5 dies: hash %h defined
```

Perl will now generate a warning when it sees defined(@a) and defined(%h).

- (Globs)

  glob assignment from variable to variable will fail if the assigned variable is localized subsequent to the assignment

  ```
  @a = ("This is Perl 4");
  *b = *a;
  local(@a);
  print @b,"\n";

  # perl4 prints: This is Perl 4
  # perl5 prints:
  ```

- (Globs)

  Assigning `undef` to a glob has no effect in Perl 5. In Perl 4 it undefines the associated scalar (but may have other side effects including SEGVs). Perl 5 will also warn if `undef` is assigned to a typeglob. (Note that assigning `undef` to a typeglob is different than calling the `undef` function on a typeglob (`undef *foo`), which has quite a few effects.

  ```
  $foo = "bar";
  *foo = undef;
  print $foo;

  # perl4 prints:
  # perl4 warns: "Use of uninitialized variable" if using -w
  # perl5 prints: bar
  # perl5 warns: "Undefined value assigned to typeglob" if using -w
  ```

- (Scalar String)

  Changes in unary negation (of strings) This change effects both the return value and what it does to auto(magic)increment.

  ```
  $x = "aaa";
  print ++$x," : ";
  print -$x," : ";
  print ++$x,"\n";

  # perl4 prints: aab : -0 : 1
  # perl5 prints: aab : -aab : aac
  ```

- (Constants)

  perl 4 lets you modify constants:

  ```
  $foo = "x";
  &mod($foo);
  for ($x = 0; $x < 3; $x++) {
      &mod("a");
  }
  sub mod {
      print "before: $_[0]";
      $_[0] = "m";
      print "  after: $_[0]\n";
  }
  ```

```
# perl4:
# before: x  after: m
# before: a  after: m
# before: m  after: m
# before: m  after: m

# Perl5:
# before: x  after: m
# Modification of a read-only value attempted at foo.pl line 12.
# before: a
```

- (Scalars)

  The behavior is slightly different for:

```
print "$x", defined $x

# perl 4: 1
# perl 5: <no output, $x is not called into existence>
```

- (Variable Suicide)

  Variable suicide behavior is more consistent under Perl 5. Perl5 exhibits the same behavior for hashes and scalars, that perl4 exhibits for only scalars.

```
$aGlobal{ "aKey" } = "global value";
print "MAIN:", $aGlobal{"aKey"}, "\n";
$GlobalLevel = 0;
&test( *aGlobal );

sub test {
    local( *theArgument ) = @_;
    local( %aNewLocal ); # perl 4 != 5.001l,m
    $aNewLocal{"aKey"} = "this should never appear";
    print "SUB: ", $theArgument{"aKey"}, "\n";
    $aNewLocal{"aKey"} = "level $GlobalLevel";   # what should print
    $GlobalLevel++;
    if( $GlobalLevel<4 ) {
        &test( *aNewLocal );
    }
}

# Perl4:
# MAIN:global value
# SUB: global value
# SUB: level 0
# SUB: level 1
# SUB: level 2

# Perl5:
# MAIN:global value
# SUB: global value
# SUB: this should never appear
# SUB: this should never appear
# SUB: this should never appear
```

14.1.11 Context Traps - scalar, list contexts

- (list context)

  The elements of argument lists for formats are now evaluated in list context. This means you can interpolate list values now.

  ```
  @fmt = ("foo","bar","baz");
  format STDOUT=
  @<<<<< @||||| @>>>>>
  @fmt;
  .
  write;

  # perl4 errors:  Please use commas to separate fields in file
  # perl5 prints: foo     bar      baz
  ```

- (scalar context)

  The `caller()` function now returns a false value in a scalar context if there is no caller. This lets library files determine if they're being required.

  ```
  caller() ? (print "You rang?\n") : (print "Got a 0\n");

  # perl4 errors: There is no caller
  # perl5 prints: Got a 0
  ```

- (scalar context)

  The comma operator in a scalar context is now guaranteed to give a scalar context to its arguments.

  ```
  @y= ('a','b','c');
  $x = (1, 2, @y);
  print "x = $x\n";

  # Perl4 prints:  x = c   # Thinks list context interpolates list
  # Perl5 prints:  x = 3   # Knows scalar uses length of list
  ```

- (list, builtin)

  `sprintf()` is prototyped as ($;@), so its first argument is given scalar context. Thus, if passed an array, it will probably not do what you want, unlike Perl 4:

  ```
  @z = ('%s%s', 'foo', 'bar');
  $x = sprintf(@z);
  print $x;

  # perl4 prints: foobar
  # perl5 prints: 3
  ```

  `printf()` works the same as it did in Perl 4, though:

  ```
  @z = ('%s%s', 'foo', 'bar');
  printf STDOUT (@z);

  # perl4 prints: foobar
  # perl5 prints: foobar
  ```

14.1.12 Precedence Traps

Perl4-to-Perl5 traps involving precedence order.

Perl 4 has almost the same precedence rules as Perl 5 for the operators that they both have. Perl 4 however, seems to have had some inconsistencies that made the behavior differ from what was documented.

- Precedence

  LHS vs. RHS of any assignment operator. LHS is evaluated first in perl4, second in perl5; this can affect the relationship between side-effects in sub-expressions.

  ```
  @arr = ( 'left', 'right' );
  $a{shift @arr} = shift @arr;
  print join( ' ', keys %a );

  # perl4 prints: left
  # perl5 prints: right
  ```

- Precedence

  These are now semantic errors because of precedence:

  ```
  @list = (1,2,3,4,5);
  %map = ("a",1,"b",2,"c",3,"d",4);
  $n = shift @list + 2;   # first item in list plus 2
  print "n is $n, ";
  $m = keys %map + 2;     # number of items in hash plus 2
  print "m is $m\n";

  # perl4 prints: n is 3, m is 6
  # perl5 errors and fails to compile
  ```

- Precedence

  The precedence of assignment operators is now the same as the precedence of assignment. Perl 4 mistakenly gave them the precedence of the associated operator. So you now must parenthesize them in expressions like

  ```
  /foo/ ? ($a += 2) : ($a -= 2);
  ```

  Otherwise

  ```
  /foo/ ? $a += 2 : $a -= 2
  ```

  would be erroneously parsed as

  ```
  (/foo/ ? $a += 2 : $a) -= 2;
  ```

  On the other hand,

  ```
  $a += /foo/ ? 1 : 2;
  ```

  now works as a C programmer would expect.

- Precedence

  ```
  open FOO || die;
  ```

is now incorrect. You need parentheses around the filehandle. Otherwise, perl5 leaves the statement as its default precedence:

```
open(FOO || die);

# perl4 opens or dies
# perl5 opens FOO, dying only if 'FOO' is false, i.e. never
```

- Precedence

  perl4 gives the special variable, `$:` precedence, where perl5 treats `$::` as main `package`

```
$a = "x"; print "$::a";

# perl 4 prints: -:a
# perl 5 prints: x
```

- Precedence

  perl4 had buggy precedence for the file test operators vis-a-vis the assignment operators. Thus, although the precedence table for perl4 leads one to believe `-e $foo .= "q"` should parse as `((-e $foo) .= "q")`, it actually parses as `(-e ($foo .= "q"))`. In perl5, the precedence is as documented.

```
-e $foo .= "q"

# perl4 prints: no output
# perl5 prints: Can't modify -e in concatenation
```

- Precedence

  In perl4, keys(), each() and values() were special high-precedence operators that operated on a single hash, but in perl5, they are regular named unary operators. As documented, named unary operators have lower precedence than the arithmetic and concatenation operators `+ - .`, but the perl4 variants of these operators actually bind tighter than `+ - .`. Thus, for:

```
%foo = 1..10;
print keys %foo - 1

# perl4 prints: 4
# perl5 prints: Type of arg 1 to keys must be hash (not subtraction)
```

  The perl4 behavior was probably more useful, if less consistent.

14.1.13 General Regular Expression Traps using s///, etc.

All types of RE traps.

- Regular Expression

  `s'$lhs'$rhs'` now does no interpolation on either side. It used to interpolate $lhs but not $rhs. (And still does not match a literal '$' in string)

```
$a=1;$b=2;
$string = '1 2 $a $b';
$string =~ s'$a'$b';
print $string,"\n";
```

```
    # perl4 prints: $b 2 $a $b
    # perl5 prints: 1 2 $a $b
```

- Regular Expression

  m//g now attaches its state to the searched string rather than the regular expression. (Once the scope of a block is left for the sub, the state of the searched string is lost)

```
    $_ = "ababab";
    while(m/ab/g){
        &doit("blah");
    }
    sub doit{local($_) = shift; print "Got $_ "}

    # perl4 prints: Got blah Got blah Got blah Got blah
    # perl5 prints: infinite loop blah...
```

- Regular Expression

  Currently, if you use the m//o qualifier on a regular expression within an anonymous sub, *all* closures generated from that anonymous sub will use the regular expression as it was compiled when it was used the very first time in any such closure. For instance, if you say

```
    sub build_match {
        my($left,$right) = @_;
        return sub { $_[0] =~ /$left stuff $right/o; };
    }
    $good = build_match('foo','bar');
    $bad = build_match('baz','blarch');
    print $good->('foo stuff bar') ? "ok\n" : "not ok\n";
    print $bad->('baz stuff blarch') ? "ok\n" : "not ok\n";
    print $bad->('foo stuff bar') ? "not ok\n" : "ok\n";
```

  For most builds of Perl5, this will print: ok not ok not ok

  build_match() will always return a sub which matches the contents of $left and $right as they were the *first* time that build_match() was called, not as they are in the current call.

- Regular Expression

  If no parentheses are used in a match, Perl4 sets $+ to the whole match, just like $&. Perl5 does not.

```
    "abcdef" =~ /b.*e/;
    print "\$+ = $+\n";

    # perl4 prints: bcde
    # perl5 prints:
```

- Regular Expression

  substitution now returns the null string if it fails

```
    $string = "test";
    $value = ($string =~ s/foo//);
    print $value, "\n";

    # perl4 prints: 0
    # perl5 prints:
```

Also see Numerical Traps for another example of this new feature.

- Regular Expression

  `s‘lhs‘rhs‘` (using backticks) is now a normal substitution, with no backtick expansion

```
$string = "";
$string =~ s‘^‘hostname‘;
print $string, "\n";

# perl4 prints: <the local hostname>
# perl5 prints: hostname
```

- Regular Expression

  Stricter parsing of variables used in regular expressions

```
s/^([^$grpc]*$grpc[$opt$plus$rep]?)//o;

# perl4: compiles w/o error
# perl5: with Scalar found where operator expected ..., near "$opt$plus"
```

  an added component of this example, apparently from the same script, is the actual value of the s’d string after the substitution. `[$opt]` is a character class in perl4 and an array subscript in perl5

```
$grpc = ’a’;
$opt  = ’r’;
$_ = ’bar’;
s/^([^$grpc]*$grpc[$opt]?)/foo/;
print ;

# perl4 prints: foo
# perl5 prints: foobar
```

- Regular Expression

  Under perl5, `m?x?` matches only once, like `?x?`. Under perl4, it matched repeatedly, like `/x/` or `m!x!`.

```
$test = "once";
sub match { $test =~ m?once?; }
&match();
if( &match() ) {
    # m?x? matches more then once
    print "perl4\n";
} else {
    # m?x? matches only once
    print "perl5\n";
}

# perl4 prints: perl4
# perl5 prints: perl5
```

- Regular Expression

  Unlike in Ruby, failed matches in Perl do not reset the match variables ($1, $2, ..., `$‘`, ...).

14.1.14 Subroutine, Signal, Sorting Traps

The general group of Perl4-to-Perl5 traps having to do with Signals, Sorting, and their related subroutines, as well as general subroutine traps. Includes some OS-Specific traps.

- (Signals)

  Barewords that used to look like strings to Perl will now look like subroutine calls if a subroutine by that name is defined before the compiler sees them.

```
sub SeeYa { warn"Hasta la vista, baby!" }
$SIG{'TERM'} = SeeYa;
print "SIGTERM is now $SIG{'TERM'}\n";

# perl4 prints: SIGTERM is now main'SeeYa
# perl5 prints: SIGTERM is now main::1 (and warns "Hasta la vista, baby!")
```

  Use **-w** to catch this one

- (Sort Subroutine)

  reverse is no longer allowed as the name of a sort subroutine.

```
sub reverse{ print "yup "; $a <=> $b }
print sort reverse (2,1,3);

# perl4 prints: yup yup 123
# perl5 prints: 123
# perl5 warns (if using -w): Ambiguous call resolved as CORE::reverse()
```

- warn() won't let you specify a filehandle.

  Although it _always_ printed to STDERR, warn() would let you specify a filehandle in perl4. With perl5 it does not.

```
warn STDERR "Foo!";

# perl4 prints: Foo!
# perl5 prints: String found where operator expected
```

14.1.15 OS Traps

- (SysV)

  Under HPUX, and some other SysV OSes, one had to reset any signal handler, within the signal handler function, each time a signal was handled with perl4. With perl5, the reset is now done correctly. Any code relying on the handler _not_ being reset will have to be reworked.

  Since version 5.002, Perl uses sigaction() under SysV.

```
sub gotit {
    print "Got @_... ";
}
$SIG{'INT'} = 'gotit';
```

```
$| = 1;
$pid = fork;
if ($pid) {
    kill('INT', $pid);
    sleep(1);
    kill('INT', $pid);
} else {
    while (1) {sleep(10);}
}

# perl4 (HPUX) prints: Got INT...
# perl5 (HPUX) prints: Got INT... Got INT...
```

- (SysV)

  Under SysV OSes, `seek()` on a file opened to append >> now does the right thing w.r.t. the fopen() manpage. e.g., - When a file is opened for append, it is impossible to overwrite information already in the file.

```
open(TEST,">>seek.test");
$start = tell TEST ;
foreach(1 .. 9){
    print TEST "$_ ";
}
$end = tell TEST ;
seek(TEST,$start,0);
print TEST "18 characters here";

# perl4 (solaris) seek.test has: 18 characters here
# perl5 (solaris) seek.test has: 1 2 3 4 5 6 7 8 9 18 characters here
```

14.1.16 Interpolation Traps

Perl4-to-Perl5 traps having to do with how things get interpolated within certain expressions, statements, contexts, or whatever.

- Interpolation

  @ now always interpolates an array in double-quotish strings.

```
print "To: someone@somewhere.com\n";

# perl4 prints: To:someone@somewhere.com
# perl < 5.6.1, error : In string, @somewhere now must be written as \@somewhere
# perl >= 5.6.1, warning : Possible unintended interpolation of @somewhere in string
```

- Interpolation

  Double-quoted strings may no longer end with an unescaped $.

```
$foo = "foo$";
print "foo is $foo\n";

# perl4 prints: foo is foo$
# perl5 errors: Final $ should be \$ or $name
```

Note: perl5 DOES NOT error on the terminating @ in $bar

- Interpolation

  Perl now sometimes evaluates arbitrary expressions inside braces that occur within double quotes (usually when the opening brace is preceded by `$` or `@`).

```
@www = "buz";
$foo = "foo";
$bar = "bar";
sub foo { return "bar" };
print "|@{w.w.w}|${main'foo}|";

# perl4 prints: |@{w.w.w}|foo|
# perl5 prints: |buz|bar|
```

  Note that you can `use strict;` to ward off such trappiness under perl5.

- Interpolation

  The construct "this is $$x" used to interpolate the pid at that point, but now tries to dereference $x. `$$` by itself still works fine, however.

```
$s = "a reference";
$x = *s;
print "this is $$x\n";

# perl4 prints: this is XXXx   (XXX is the current pid)
# perl5 prints: this is a reference
```

- Interpolation

  Creation of hashes on the fly with `eval "EXPR"` now requires either both `$`'s to be protected in the specification of the hash name, or both curlies to be protected. If both curlies are protected, the result will be compatible with perl4 and perl5. This is a very common practice, and should be changed to use the block form of `eval{}` if possible.

```
$hashname = "foobar";
$key = "baz";
$value = 1234;
eval "\$$hashname{'$key'} = q|$value|";
(defined($foobar{'baz'})) ?  (print "Yup") : (print "Nope");

# perl4 prints: Yup
# perl5 prints: Nope
```

  Changing

```
eval "\$$hashname{'$key'} = q|$value|";
```

  to

```
eval "\$\$hashname{'$key'} = q|$value|";
```

  causes the following result:

```
# perl4 prints: Nope
# perl5 prints: Yup
```

  or, changing to

```
    eval "\$$hashname\{'$key'\} = q|$value|";
```

causes the following result:

```
    # perl4 prints: Yup
    # perl5 prints: Yup
    # and is compatible for both versions
```

- Interpolation

  perl4 programs which unconsciously rely on the bugs in earlier perl versions.

```
    perl -e '$bar=q/not/; print "This is $foo{$bar} perl5"'

    # perl4 prints: This is not perl5
    # perl5 prints: This is perl5
```

- Interpolation

  You also have to be careful about array and hash brackets during interpolation.

```
    print "$foo["

    perl 4 prints: [
    perl 5 prints: syntax error

    print "$foo{"

    perl 4 prints: {
    perl 5 prints: syntax error
```

  Perl 5 is expecting to find an index or key name following the respective brackets, as well as an ending bracket of the appropriate type. In order to mimic the behavior of Perl 4, you must escape the bracket like so.

```
    print "$foo\[";
    print "$foo\{";
```

- Interpolation

  Similarly, watch out for:

```
    $foo = "baz";
    print "\$$foo{bar}\n";

    # perl4 prints: $baz{bar}
    # perl5 prints: $
```

  Perl 5 is looking for `$foo{bar}` which doesn't exist, but perl 4 is happy just to expand $foo to "baz" by itself. Watch out for this especially in `eval`'s.

- Interpolation

  `qq()` string passed to `eval`

```
    eval qq(
        foreach \$y (keys %\$x\) {
            \$count++;
        }
    );

    # perl4 runs this ok
    # perl5 prints: Can't find string terminator ")"
```

14.1.17 DBM Traps

General DBM traps.

- DBM

  Existing dbm databases created under perl4 (or any other dbm/ndbm tool) may cause the same script, run under perl5, to fail. The build of perl5 must have been linked with the same dbm/ndbm as the default for `dbmopen()` to function properly without `tie`'ing to an extension dbm implementation.

  ```
  dbmopen (%dbm, "file", undef);
  print "ok\n";

  # perl4 prints: ok
  # perl5 prints: ok (IFF linked with -ldbm or -lndbm)
  ```

- DBM

  Existing dbm databases created under perl4 (or any other dbm/ndbm tool) may cause the same script, run under perl5, to fail. The error generated when exceeding the limit on the key/value size will cause perl5 to exit immediately.

  ```
  dbmopen(DB, "testdb",0600) || die "couldn't open db! $!";
  $DB{'trap'} = "x" x 1024;  # value too large for most dbm/ndbm
  print "YUP\n";

  # perl4 prints:
  dbm store returned -1, errno 28, key "trap" at - line 3.
  YUP

  # perl5 prints:
  dbm store returned -1, errno 28, key "trap" at - line 3.
  ```

14.1.18 Unclassified Traps

Everything else.

- `require`/`do` trap using returned value

  If the file doit.pl has:

  ```
  sub foo {
      $rc = do "./do.pl";
      return 8;
  }
  print &foo, "\n";
  ```

  And the do.pl file has the following single line:

  ```
  return 3;
  ```

  Running doit.pl gives the following:

  ```
  # perl 4 prints: 3 (aborts the subroutine early)
  # perl 5 prints: 8
  ```

  Same behavior if you replace `do` with `require`.

- `split` on empty string with LIMIT specified

  ```
  $string = '';
  @list = split(/foo/, $string, 2)
  ```

  Perl4 returns a one element list containing the empty string but Perl5 returns an empty list.

As always, if any of these are ever officially declared as bugs, they'll be fixed and removed.

Chapter 15

perldebtut

Perl debugging tutorial

15.1 DESCRIPTION

A (very) lightweight introduction in the use of the perl debugger, and a pointer to existing, deeper sources of information on the subject of debugging perl programs.

There’s an extraordinary number of people out there who don’t appear to know anything about using the perl debugger, though they use the language every day. This is for them.

15.2 use strict

First of all, there’s a few things you can do to make your life a lot more straightforward when it comes to debugging perl programs, without using the debugger at all. To demonstrate, here’s a simple script, named "hello", with a problem:

```
#!/usr/bin/perl

$var1 = ’Hello World’; # always wanted to do that :-)
$var2 = "$varl\n";

print $var2;
exit;
```

While this compiles and runs happily, it probably won’t do what’s expected, namely it doesn’t print "Hello World\n" at all; It will on the other hand do exactly what it was told to do, computers being a bit that way inclined. That is, it will print out a newline character, and you’ll get what looks like a blank line. It looks like there’s 2 variables when (because of the typo) there’s really 3:

```
$var1 = ’Hello World’;
$varl = undef;
$var2 = "\n";
```

To catch this kind of problem, we can force each variable to be declared before use by pulling in the strict module, by putting ’use strict;’ after the first line of the script.

Now when you run it, perl complains about the 3 undeclared variables and we get four error messages because one variable is referenced twice:

```
 Global symbol "$var1" requires explicit package name at ./t1 line 4.
 Global symbol "$var2" requires explicit package name at ./t1 line 5.
 Global symbol "$varl" requires explicit package name at ./t1 line 5.
 Global symbol "$var2" requires explicit package name at ./t1 line 7.
 Execution of ./hello aborted due to compilation errors.
```

Luvverly! and to fix this we declare all variables explicitly and now our script looks like this:

```
        #!/usr/bin/perl
        use strict;

        my $var1 = 'Hello World';
        my $varl = undef;
        my $var2 = "$varl\n";

        print $var2;
        exit;
```

We then do (always a good idea) a syntax check before we try to run it again:

```
        > perl -c hello
        hello syntax OK
```

And now when we run it, we get "\n" still, but at least we know why. Just getting this script to compile has exposed the '$varl' (with the letter 'l') variable, and simply changing $varl to $var1 solves the problem.

15.3 Looking at data and -w and v

Ok, but how about when you want to really see your data, what's in that dynamic variable, just before using it?

```
        #!/usr/bin/perl
        use strict;

        my $key = 'welcome';
        my %data = (
                'this' => qw(that),
                'tom' => qw(and jerry),
                'welcome' => q(Hello World),
                'zip' => q(welcome),
        );
        my @data = keys %data;

        print "$data{$key}\n";
        exit;
```

Looks OK, after it's been through the syntax check (perl -c scriptname), we run it and all we get is a blank line again! Hmmmm.

One common debugging approach here, would be to liberally sprinkle a few print statements, to add a check just before we print out our data, and another just after:

```
        print "All OK\n" if grep($key, keys %data);
        print "$data{$key}\n";
        print "done: '$data{$key}'\n";
```

And try again:

```
> perl data
All OK

done: ''
```

After much staring at the same piece of code and not seeing the wood for the trees for some time, we get a cup of coffee and try another approach. That is, we bring in the cavalry by giving perl the '**-d**' switch on the command line:

```
> perl -d data
Default die handler restored.

Loading DB routines from perl5db.pl version 1.07
Editor support available.

Enter h or ‘h h’ for help, or ‘man perldebug’ for more help.

main::(./data:4):     my $key = 'welcome';
```

Now, what we've done here is to launch the built-in perl debugger on our script. It's stopped at the first line of executable code and is waiting for input.

Before we go any further, you'll want to know how to quit the debugger: use just the letter '**q**', not the words 'quit' or 'exit':

```
DB<1> q
>
```

That's it, you're back on home turf again.

15.4 help

Fire the debugger up again on your script and we'll look at the help menu. There's a couple of ways of calling help: a simple '**h**' will get the summary help list, '**|h**' (pipe-h) will pipe the help through your pager (which is (probably 'more' or 'less'), and finally, '**h h**' (h-space-h) will give you the entire help screen. Here is the summary page:

D**1**h

```
 List/search source lines:               Control script execution:
  l [ln|sub]  List source code            T           Stack trace
  - or .      List previous/current line  s [expr]    Single step [in expr]
  v [line]    View around line            n [expr]    Next, steps over subs
  f filename  View source in file         <CR/Enter>  Repeat last n or s
  /pattern/ ?patt?   Search forw/backw    r           Return from subroutine
  M           Show module versions        c [ln|sub]  Continue until position
 Debugger controls:                       L           List break/watch/actions
  o [...]     Set debugger options        t [expr]    Toggle trace [trace expr]

  |[|]db_cmd  Send output to pager        ![!] syscmd Run cmd in a subprocess
  q or ^D     Quit                        R           Attempt a restart
 Data Examination:     expr     Execute perl code, also see: s,n,t expr
  x|m expr       Evals expr in list context, dumps the result or lists methods.
  p expr         Print expression (uses script's current package).
  S [[!]pat]     List subroutine names [not] matching pattern
  V [Pk [Vars]]  List Variables in Package.  Vars can be ~pattern or !pattern.
  X [Vars]       Same as "V current_package [Vars]".
  y [n [Vars]]   List lexicals in higher scope <n>.  Vars same as V.
 For more help, type h cmd_letter, or run man perldebug for all docs.
```

More confusing options than you can shake a big stick at! It's not as bad as it looks and it's very useful to know more about all of it, and fun too!

There's a couple of useful ones to know about straight away. You wouldn't think we're using any libraries at all at the moment, but '**M**' will show which modules are currently loaded, and their version number, while '**m**' will show the methods, and '**S**' shows all subroutines (by pattern) as shown below. '**V**' and '**X**' show variables in the program by package scope and can be constrained by pattern.

```
        DB<2>S str
        dumpvar::stringify
        strict::bits
        strict::import
        strict::unimport
```

Using 'X' and cousins requires you not to use the type identifiers ($@%), just the 'name':

```
        DM<3>X ~err
        FileHandle(stderr) => fileno(2)
```

Remember we're in our tiny program with a problem, we should have a look at where we are, and what our data looks like. First of all let's view some code at our present position (the first line of code in this case), via '**v**':

```
        DB<4> v
        1       #!/usr/bin/perl
        2:      use strict;
        3
        4==>    my $key = 'welcome';
        5:      my %data = (
        6               'this' => qw(that),
        7               'tom' => qw(and jerry),
        8               'welcome' => q(Hello World),
        9               'zip' => q(welcome),
        10      );
```

At line number 4 is a helpful pointer, that tells you where you are now. To see more code, type 'v' again:

```
        DB<4> v
        8               'welcome' => q(Hello World),
        9               'zip' => q(welcome),
        10      );
        11:     my @data = keys %data;
        12:     print "All OK\n" if grep($key, keys %data);
        13:     print "$data{$key}\n";
        14:     print "done: '$data{$key}'\n";
        15:     exit;
```

And if you wanted to list line 5 again, type 'l 5', (note the space):

```
        DB<4> l 5
        5:      my %data = (
```

In this case, there's not much to see, but of course normally there's pages of stuff to wade through, and 'l' can be very useful. To reset your view to the line we're about to execute, type a lone period '.':

```
        DB<5> .
        main::(./data_a:4):     my $key = 'welcome';
```

The line shown is the one that is about to be executed **next**, it hasn't happened yet. So while we can print a variable with the letter '**p**', at this point all we'd get is an empty (undefined) value back. What we need to do is to step through the next executable statement with an '**s**':

```
        DB<6> s
        main::(./data_a:5):     my %data = (
        main::(./data_a:6):             'this' => qw(that),
        main::(./data_a:7):             'tom' => qw(and jerry),
        main::(./data_a:8):             'welcome' => q(Hello World),
        main::(./data_a:9):             'zip' => q(welcome),
        main::(./data_a:10):    );
```

Now we can have a look at that first ($key) variable:

```
        DB<7> p $key
        welcome
```

line 13 is where the action is, so let's continue down to there via the letter '**c**', which by the way, inserts a 'one-time-only' breakpoint at the given line or sub routine:

```
        DB<8> c 13
        All OK
        main::(./data_a:13):    print "$data{$key}\n";
```

We've gone past our check (where 'All OK' was printed) and have stopped just before the meat of our task. We could try to print out a couple of variables to see what is happening:

```
        DB<9> p $data{$key}
```

Not much in there, lets have a look at our hash:

```
        DB<10> p %data
        Hello Worldziptomandwelcomejerrywelcomethisthat

        DB<11> p keys %data
        Hello Worldtomwelcomejerrythis
```

Well, this isn't very easy to read, and using the helpful manual (**h h**), the '**x**' command looks promising:

```
        DB<12> x %data
        0  'Hello World'
        1  'zip'
        2  'tom'
        3  'and'
        4  'welcome'
        5  undef
        6  'jerry'
        7  'welcome'
        8  'this'
        9  'that'
```

That’s not much help, a couple of welcomes in there, but no indication of which are keys, and which are values, it’s just a listed array dump and, in this case, not particularly helpful. The trick here, is to use a **reference** to the data structure:

```
DB<13> x \%data
0  HASH(0x8194bc4)
   'Hello World' => 'zip'
   'jerry' => 'welcome'
   'this' => 'that'
   'tom' => 'and'
   'welcome' => undef
```

The reference is truly dumped and we can finally see what we’re dealing with. Our quoting was perfectly valid but wrong for our purposes, with ’and jerry’ being treated as 2 separate words rather than a phrase, thus throwing the evenly paired hash structure out of alignment.

The ’**-w**’ switch would have told us about this, had we used it at the start, and saved us a lot of trouble:

```
> perl -w data
Odd number of elements in hash assignment at ./data line 5.
```

We fix our quoting: ’tom’ => q(and jerry), and run it again, this time we get our expected output:

```
> perl -w data
Hello World
```

While we’re here, take a closer look at the ’**x**’ command, it’s really useful and will merrily dump out nested references, complete objects, partial objects - just about whatever you throw at it:

Let’s make a quick object and x-plode it, first we’ll start the debugger: it wants some form of input from STDIN, so we give it something non-commital, a zero:

```
> perl -de 0
Default die handler restored.

Loading DB routines from perl5db.pl version 1.07
Editor support available.

Enter h or ‘h h’ for help, or ‘man perldebug’ for more help.

main::(-e:1):   0
```

Now build an on-the-fly object over a couple of lines (note the backslash):

```
DB<1> $obj = bless({'unique_id'=>'123', 'attr'=> \
cont:   {'col' => 'black', 'things' => [qw(this that etc)]}}, 'MY_class')
```

And let’s have a look at it:

```
DB<2> x $obj
0  MY_class=HASH(0x828ad98)
        'attr' => HASH(0x828ad68)
'col' => 'black'
'things' => ARRAY(0x828abb8)
        0  'this'
        1  'that'
        2  'etc'
        'unique_id' => 123
DB<3>
```

Useful, huh? You can eval nearly anything in there, and experiment with bits of code or regexes until the cows come home:

```
DB<3> @data = qw(this that the other atheism leather theory scythe)

DB<4> p 'saw -> '.($cnt += map { print "\t:\t$_\n" } grep(/the/, sort @data))
atheism
leather
other
scythe
the
theory
saw -> 6
```

If you want to see the command History, type an '**H**':

```
DB<5> H
4: p 'saw -> '.($cnt += map { print "\t:\t$_\n" } grep(/the/, sort @data))
3: @data = qw(this that the other atheism leather theory scythe)
2: x $obj
1: $obj = bless({'unique_id'=>'123', 'attr'=>
{'col' => 'black', 'things' => [qw(this that etc)]}}, 'MY_class')
DB<5>
```

And if you want to repeat any previous command, use the exclamation: '**!**':

```
DB<5> !4
p 'saw -> '.($cnt += map { print "$_\n" } grep(/the/, sort @data))
atheism
leather
other
scythe
the
theory
saw -> 12
```

For more on references see *perlref* and *perlreftut*

15.5 Stepping through code

Here's a simple program which converts between Celsius and Fahrenheit, it too has a problem:

```
#!/usr/bin/perl -w
use strict;

my $arg = $ARGV[0] || '-c20';

if ($arg =~ /^\-(c|f)((\-|\+)*\d+(\.\d+)*)$/) {
        my ($deg, $num) = ($1, $2);
        my ($in, $out) = ($num, $num);
        if ($deg eq 'c') {
                $deg = 'f';
                $out = &c2f($num);
        } else {
                $deg = 'c';
                $out = &f2c($num);
        }
        $out = sprintf('%0.2f', $out);
        $out =~ s/^((\-|\+)*\d+)\.0+$/$1/;
        print "$out $deg\n";
} else {
        print "Usage: $0 -[c|f] num\n";
}
exit;

sub f2c {
        my $f = shift;
        my $c = 5 * $f - 32 / 9;
        return $c;
}

sub c2f {
        my $c = shift;
        my $f = 9 * $c / 5 + 32;
        return $f;
}
```

For some reason, the Fahrenheit to Celsius conversion fails to return the expected output. This is what it does:

```
> temp -c0.72
33.30 f

> temp -f33.3
162.94 c
```

Not very consistent! We'll set a breakpoint in the code manually and run it under the debugger to see what's going on. A breakpoint is a flag, to which the debugger will run without interruption, when it reaches the breakpoint, it will stop execution and offer a prompt for further interaction. In normal use, these debugger commands are completely ignored, and they are safe - if a little messy, to leave in production code.

```
my ($in, $out) = ($num, $num);
$DB::single=2; # insert at line 9!
if ($deg eq 'c')
        ...

> perl -d temp -f33.3
Default die handler restored.

Loading DB routines from perl5db.pl version 1.07
Editor support available.

Enter h or `h h' for help, or `man perldebug' for more help.

main::(temp:4): my $arg = $ARGV[0] || '-c100';
```

We'll simply continue down to our pre-set breakpoint with a '**c**':

```
DB<1> c
main::(temp:10):                if ($deg eq 'c') {
```

Followed by a view command to see where we are:

```
DB<1> v
7:              my ($deg, $num) = ($1, $2);
8:              my ($in, $out) = ($num, $num);
9:              $DB::single=2;
10==>           if ($deg eq 'c') {
11:                     $deg = 'f';
12:                     $out = &c2f($num);
13              } else {
14:                     $deg = 'c';
15:                     $out = &f2c($num);
16              }
```

And a print to show what values we're currently using:

```
DB<1> p $deg, $num
f33.3
```

We can put another break point on any line beginning with a colon, we'll use line 17 as that's just as we come out of the subroutine, and we'd like to pause there later on:

```
DB<2> b 17
```

There's no feedback from this, but you can see what breakpoints are set by using the list 'L' command:

```
DB<3> L
temp:
        17:            print "$out $deg\n";
        break if (1)
```

Note that to delete a breakpoint you use 'd' or 'D'.

Now we'll continue down into our subroutine, this time rather than by line number, we'll use the subroutine name, followed by the now familiar 'v':

```
DB<3> c f2c
main::f2c(temp:30):             my $f = shift;

DB<4> v
24:     exit;
25
26      sub f2c {
27==>           my $f = shift;
28:             my $c = 5 * $f - 32 / 9;
29:             return $c;
30      }
31
32      sub c2f {
33:             my $c = shift;
```

Note that if there was a subroutine call between us and line 29, and we wanted to **single-step** through it, we could use the '**s**' command, and to step over it we would use '**n**' which would execute the sub, but not descend into it for inspection. In this case though, we simply continue down to line 29:

```
DB<4> c 29
main::f2c(temp:29):             return $c;
```

And have a look at the return value:

```
DB<5> p $c
162.944444444444
```

This is not the right answer at all, but the sum looks correct. I wonder if it's anything to do with operator precedence? We'll try a couple of other possibilities with our sum:

```
DB<6> p (5 * $f - 32 / 9)
162.944444444444

DB<7> p 5 * $f - (32 / 9)
162.944444444444

DB<8> p (5 * $f) - 32 / 9
162.944444444444

DB<9> p 5 * ($f - 32) / 9
0.722222222222221
```

:-) that's more like it! Ok, now we can set our return variable and we'll return out of the sub with an 'r':

```
DB<10> $c = 5 * ($f - 32) / 9

DB<11> r
scalar context return from main::f2c: 0.722222222222221
```

Looks good, let's just continue off the end of the script:

```
DB<12> c
0.72 c
Debugged program terminated.  Use q to quit or R to restart,
use O inhibit_exit to avoid stopping after program termination,
h q, h R or h O to get additional info.
```

A quick fix to the offending line (insert the missing parentheses) in the actual program and we're finished.

15.6 Placeholder for a, w, t, T

Actions, watch variables, stack traces etc.: on the TODO list.

```
a

w

t

T
```

15.7 REGULAR EXPRESSIONS

Ever wanted to know what a regex looked like? You'll need perl compiled with the DEBUGGING flag for this one:

```
        > perl -Dr -e '/^pe(a)*rl$/i'
        Compiling REx `^pe(a)*rl$'
        size 17 first at 2
        rarest char
         at 0
           1: BOL(2)
           2: EXACTF <pe>(4)
           4: CURLYN[1] {0,32767}(14)
           6:   NOTHING(8)
           8:   EXACTF <a>(0)
          12:   WHILEM(0)
          13: NOTHING(14)
          14: EXACTF <rl>(16)
          16: EOL(17)
          17: END(0)
        floating `'$ at 4..2147483647 (checking floating) stclass `EXACTF <pe>'
anchored(BOL) minlen 4
        Omitting $` $& $' support.

        EXECUTING...

        Freeing REx: `^pe(a)*rl$'
```

Did you really want to know? :-) For more gory details on getting regular expressions to work, have a look at *perlre*, *perlretut*, and to decode the mysterious labels (BOL and CURLYN, etc. above), see *perldebguts*.

15.8 OUTPUT TIPS

To get all the output from your error log, and not miss any messages via helpful operating system buffering, insert a line like this, at the start of your script:

```
        $|=1;
```

To watch the tail of a dynamically growing logfile, (from the command line):

```
        tail -f $error_log
```

Wrapping all die calls in a handler routine can be useful to see how, and from where, they're being called, *perlvar* has more information:

```
        BEGIN { $SIG{__DIE__} = sub { require Carp; Carp::confess(@_) } }
```

Various useful techniques for the redirection of STDOUT and STDERR filehandles are explained in *perlopentut* and *perlfaq8*.

15.9 CGI

Just a quick hint here for all those CGI programmers who can't figure out how on earth to get past that 'waiting for input' prompt, when running their CGI script from the command-line, try something like this:

```
        > perl -d my_cgi.pl -nodebug
```

Of course *CGI* and *perlfaq9* will tell you more.

15.10 GUIs

The command line interface is tightly integrated with an **emacs** extension and there's a **vi** interface too.

You don't have to do this all on the command line, though, there are a few GUI options out there. The nice thing about these is you can wave a mouse over a variable and a dump of its data will appear in an appropriate window, or in a popup balloon, no more tiresome typing of 'x $varname' :-)

In particular have a hunt around for the following:

ptkdb perlTK based wrapper for the built-in debugger

ddd data display debugger

PerlDevKit and **PerlBuilder** are NT specific

NB. (more info on these and others would be appreciated).

15.11 SUMMARY

We've seen how to encourage good coding practices with **use strict** and **-w**. We can run the perl debugger **perl -d scriptname** to inspect your data from within the perl debugger with the **p** and **x** commands. You can walk through your code, set breakpoints with **b** and step through that code with **s** or **n**, continue with **c** and return from a sub with **r**. Fairly intuitive stuff when you get down to it.

There is of course lots more to find out about, this has just scratched the surface. The best way to learn more is to use perldoc to find out more about the language, to read the on-line help (*perldebug* is probably the next place to go), and of course, experiment.

Chapter 16

perlfaq

Frequently asked questions about Perl ($Date: 2003/01/31 17:37:17 $)

16.1 DESCRIPTION

The perlfaq is divided into several documents based on topics. A table of contents is at the end of this document.

16.1.1 Where to get the perlfaq

Extracts of the perlfaq are posted regularly to comp.lang.perl.misc. It is available on many web sites: http://www.perldoc.com/ and http://faq.perl.org/

16.1.2 How to contribute to the perlfaq

You may mail corrections, additions, and suggestions to perlfaq-workers@perl.org . This alias should not be used to *ask* FAQs. It's for fixing the current FAQ. Send questions to the comp.lang.perl.misc newsgroup. You can view the source tree at http://cvs.perl.org/cvsweb/perlfaq/ (which is outside of the main Perl source tree). The CVS repository notes all changes to the FAQ.

16.1.3 What will happen if you mail your Perl programming problems to the authors

Your questions will probably go unread, unless they're suggestions of new questions to add to the FAQ, in which case they should have gone to the perlfaq-workers@perl.org instead.

You should have read section 2 of this faq. There you would have learned that comp.lang.perl.misc is the appropriate place to go for free advice. If your question is really important and you require a prompt and correct answer, you should hire a consultant.

16.2 Credits

The original perlfaq was written by Tom Christiansen, then expanded by collaboration between Tom and Nathan Torkington. The current document is maintained by the perlfaq-workers (perlfaq-workers@perl.org). Several people have contributed answers, corrections, and comments.

16.3 Author and Copyright Information

Copyright (c) 1997-2003 Tom Christiansen, Nathan Torkington, and other contributors noted in the answers.

All rights reserved.

16.3.1 Bundled Distributions

This documentation is free; you can redistribute it and/or modify it under the same terms as Perl itself.

Irrespective of its distribution, all code examples in these files are hereby placed into the public domain. You are permitted and encouraged to use this code in your own programs for fun or for profit as you see fit. A simple comment in the code giving credit would be courteous but is not required.

16.3.2 Disclaimer

This information is offered in good faith and in the hope that it may be of use, but is not guaranteed to be correct, up to date, or suitable for any particular purpose whatsoever. The authors accept no liability in respect of this information or its use.

16.4 Table of Contents

16.5 The Questions

16.5.1 *perlfaq1*: General Questions About Perl

Very general, high-level questions about Perl.

- What is Perl?
- Who supports Perl? Who develops it? Why is it free?
- Which version of Perl should I use?
- What are perl4 and perl5?
- What is perl6?
- How stable is Perl?
- Is Perl difficult to learn?
- How does Perl compare with other languages like Java, Python, REXX, Scheme, or Tcl?
- Can I do [task] in Perl?

- When shouldn't I program in Perl?
- What's the difference between "perl" and "Perl"?
- Is it a Perl program or a Perl script?
- What is a JAPH?
- Where can I get a list of Larry Wall witticisms?
- How can I convince my sysadmin/supervisor/employees to use version 5/5.6.1/Perl instead of some other language?

16.5.2 *perlfaq2*: Obtaining and Learning about Perl

Where to find source and documentation for Perl, support, and related matters.

- What machines support Perl? Where do I get it?
- How can I get a binary version of Perl?
- I don't have a C compiler on my system. How can I compile perl?
- I copied the Perl binary from one machine to another, but scripts don't work.
- I grabbed the sources and tried to compile but gdbm/dynamic loading/malloc/linking/... failed. How do I make it work?
- What modules and extensions are available for Perl? What is CPAN? What does CPAN/src/... mean?
- Is there an ISO or ANSI certified version of Perl?
- Where can I get information on Perl?
- What are the Perl newsgroups on Usenet? Where do I post questions?
- Where should I post source code?
- Perl Books
- Perl in Magazines
- Perl on the Net: FTP and WWW Access
- What mailing lists are there for Perl?
- Archives of comp.lang.perl.misc
- Where can I buy a commercial version of Perl?
- Where do I send bug reports?
- What is perl.com? Perl Mongers? pm.org? perl.org? cpan.org?

16.5.3 *perlfaq3*: Programming Tools

Programmer tools and programming support.

- How do I do (anything)?
- How can I use Perl interactively?
- Is there a Perl shell?
- How do I find which modules are installed on my system?
- How do I debug my Perl programs?
- How do I profile my Perl programs?
- How do I cross-reference my Perl programs?
- Is there a pretty-printer (formatter) for Perl?
- Is there a ctags for Perl?
- Is there an IDE or Windows Perl Editor?
- Where can I get Perl macros for vi?
- Where can I get perl-mode for emacs?
- How can I use curses with Perl?
- How can I use X or Tk with Perl?
- How can I generate simple menus without using CGI or Tk?
- How can I make my Perl program run faster?
- How can I make my Perl program take less memory?
- Is it safe to return a reference to local or lexical data?
- How can I free an array or hash so my program shrinks?
- How can I make my CGI script more efficient?
- How can I hide the source for my Perl program?
- How can I compile my Perl program into byte code or C?
- How can I compile Perl into Java?
- How can I get `#!perl` to work on [MS-DOS,NT,...]?
- Can I write useful Perl programs on the command line?
- Why don’t Perl one-liners work on my DOS/Mac/VMS system?
- Where can I learn about CGI or Web programming in Perl?
- Where can I learn about object-oriented Perl programming?
- Where can I learn about linking C with Perl? [h2xs, xsubpp]
- I’ve read perlembed, perlguts, etc., but I can’t embed perl in my C program; what am I doing wrong?
- When I tried to run my script, I got this message. What does it mean?
- What’s MakeMaker?

16.5.4 *perlfaq4*: Data Manipulation

Manipulating numbers, dates, strings, arrays, hashes, and miscellaneous data issues.

- Why am I getting long decimals (eg, 19.9499999999999) instead of the numbers I should be getting (eg, 19.95)?
- Why isn't my octal data interpreted correctly?
- Does Perl have a round() function? What about ceil() and floor()? Trig functions?
- How do I convert between numeric representations?
- Why doesn't & work the way I want it to?
- How do I multiply matrices?
- How do I perform an operation on a series of integers?
- How can I output Roman numerals?
- Why aren't my random numbers random?
- How do I get a random number between X and Y?
- How do I find the day or week of the year?
- How do I find the current century or millennium?
- How can I compare two dates and find the difference?
- How can I take a string and turn it into epoch seconds?
- How can I find the Julian Day?
- How do I find yesterday's date?
- Does Perl have a Year 2000 problem? Is Perl Y2K compliant?
- How do I validate input?
- How do I unescape a string?
- How do I remove consecutive pairs of characters?
- How do I expand function calls in a string?
- How do I find matching/nesting anything?
- How do I reverse a string?
- How do I expand tabs in a string?
- How do I reformat a paragraph?
- How can I access or change N characters of a string?
- How do I change the Nth occurrence of something?
- How can I count the number of occurrences of a substring within a string?
- How do I capitalize all the words on one line?
- How can I split a [character] delimited string except when inside [character]?
- How do I strip blank space from the beginning/end of a string?
- How do I pad a string with blanks or pad a number with zeroes?

- How do I extract selected columns from a string?
- How do I find the soundex value of a string?
- How can I expand variables in text strings?
- What's wrong with always quoting "$vars"?
- Why don't my <<HERE documents work?
- What is the difference between a list and an array?
- What is the difference between $array[1] and @array[1]?
- How can I remove duplicate elements from a list or array?
- How can I tell whether a certain element is contained in a list or array?
- How do I compute the difference of two arrays? How do I compute the intersection of two arrays?
- How do I test whether two arrays or hashes are equal?
- How do I find the first array element for which a condition is true?
- How do I handle linked lists?
- How do I handle circular lists?
- How do I shuffle an array randomly?
- How do I process/modify each element of an array?
- How do I select a random element from an array?
- How do I permute N elements of a list?
- How do I sort an array by (anything)?
- How do I manipulate arrays of bits?
- Why does defined() return true on empty arrays and hashes?
- How do I process an entire hash?
- What happens if I add or remove keys from a hash while iterating over it?
- How do I look up a hash element by value?
- How can I know how many entries are in a hash?
- How do I sort a hash (optionally by value instead of key)?
- How can I always keep my hash sorted?
- What's the difference between "delete" and "undef" with hashes?
- Why don't my tied hashes make the defined/exists distinction?
- How do I reset an each() operation part-way through?
- How can I get the unique keys from two hashes?
- How can I store a multidimensional array in a DBM file?
- How can I make my hash remember the order I put elements into it?
- Why does passing a subroutine an undefined element in a hash create it?

- How can I make the Perl equivalent of a C structure/C++ class/hash or array of hashes or arrays?
- How can I use a reference as a hash key?
- How do I handle binary data correctly?
- How do I determine whether a scalar is a number/whole/integer/float?
- How do I keep persistent data across program calls?
- How do I print out or copy a recursive data structure?
- How do I define methods for every class/object?
- How do I verify a credit card checksum?
- How do I pack arrays of doubles or floats for XS code?

16.5.5 *perlfaq5*: Files and Formats

I/O and the "f" issues: filehandles, flushing, formats, and footers.

- How do I flush/unbuffer an output filehandle? Why must I do this?
- How do I change one line in a file/delete a line in a file/insert a line in the middle of a file/append to the beginning of a file?
- How do I count the number of lines in a file?
- How can I use Perl's `-i` option from within a program?
- How do I make a temporary file name?
- How can I manipulate fixed-record-length files?
- How can I make a filehandle local to a subroutine? How do I pass filehandles between subroutines? How do I make an array of filehandles?
- How can I use a filehandle indirectly?
- How can I set up a footer format to be used with write()?
- How can I write() into a string?
- How can I output my numbers with commas added?
- How can I translate tildes (˜) in a filename?
- How come when I open a file read-write it wipes it out?
- Why do I sometimes get an "Argument list too long" when I use <*>?
- Is there a leak/bug in glob()?
- How can I open a file with a leading ">" or trailing blanks?
- How can I reliably rename a file?
- How can I lock a file?
- Why can't I just open(FH, ">file.lock")?
- I still don't get locking. I just want to increment the number in the file. How can I do this?
- All I want to do is append a small amount of text to the end of a file. Do I still have to use locking?

- How do I randomly update a binary file?
- How do I get a file's timestamp in perl?
- How do I set a file's timestamp in perl?
- How do I print to more than one file at once?
- How can I read in an entire file all at once?
- How can I read in a file by paragraphs?
- How can I read a single character from a file? From the keyboard?
- How can I tell whether there's a character waiting on a filehandle?
- How do I do a `tail -f` in perl?
- How do I dup() a filehandle in Perl?
- How do I close a file descriptor by number?
- Why can't I use "C:\temp\foo" in DOS paths? What doesn't ‘C:\temp\foo.exe‘ work?
- Why doesn't glob("*.*") get all the files?
- Why does Perl let me delete read-only files? Why does `-i` clobber protected files? Isn't this a bug in Perl?
- How do I select a random line from a file?
- Why do I get weird spaces when I print an array of lines?

16.5.6 *perlfaq6*: Regular Expressions

Pattern matching and regular expressions.

- How can I hope to use regular expressions without creating illegible and unmaintainable code?
- I'm having trouble matching over more than one line. What's wrong?
- How can I pull out lines between two patterns that are themselves on different lines?
- I put a regular expression into $/ but it didn't work. What's wrong?
- How do I substitute case insensitively on the LHS while preserving case on the RHS?
- How can I make `\w` match national character sets?
- How can I match a locale-smart version of `/[a-zA-Z]/`?
- How can I quote a variable to use in a regex?
- What is `/o` really for?
- How do I use a regular expression to strip C style comments from a file?
- Can I use Perl regular expressions to match balanced text?
- What does it mean that regexes are greedy? How can I get around it?
- How do I process each word on each line?
- How can I print out a word-frequency or line-frequency summary?
- How can I do approximate matching?

- How do I efficiently match many regular expressions at once?
- Why don't word-boundary searches with `\b` work for me?
- Why does using $&, $‘, or $’ slow my program down?
- What good is `\G` in a regular expression?
- Are Perl regexes DFAs or NFAs? Are they POSIX compliant?
- What's wrong with using grep or map in a void context?
- How can I match strings with multibyte characters?
- How do I match a pattern that is supplied by the user?

16.5.7 *perlfaq7*: General Perl Language Issues

General Perl language issues that don't clearly fit into any of the other sections.

- Can I get a BNF/yacc/RE for the Perl language?
- What are all these $@%&* punctuation signs, and how do I know when to use them?
- Do I always/never have to quote my strings or use semicolons and commas?
- How do I skip some return values?
- How do I temporarily block warnings?
- What's an extension?
- Why do Perl operators have different precedence than C operators?
- How do I declare/create a structure?
- How do I create a module?
- How do I create a class?
- How can I tell if a variable is tainted?
- What's a closure?
- What is variable suicide and how can I prevent it?
- How can I pass/return a {Function, FileHandle, Array, Hash, Method, Regex}?
- How do I create a static variable?
- What's the difference between dynamic and lexical (static) scoping? Between local() and my()?
- How can I access a dynamic variable while a similarly named lexical is in scope?
- What's the difference between deep and shallow binding?
- Why doesn't "my($foo) = <FILE>;" work right?
- How do I redefine a builtin function, operator, or method?
- What's the difference between calling a function as &foo and foo()?
- How do I create a switch or case statement?
- How can I catch accesses to undefined variables, functions, or methods?

- Why can't a method included in this same file be found?
- How can I find out my current package?
- How can I comment out a large block of perl code?
- How do I clear a package?
- How can I use a variable as a variable name?
- What does "bad interpreter" mean?

16.5.8 *perlfaq8*: System Interaction

Interprocess communication (IPC), control over the user-interface (keyboard, screen and pointing devices).

- How do I find out which operating system I'm running under?
- How come exec() doesn't return?
- How do I do fancy stuff with the keyboard/screen/mouse?
- How do I print something out in color?
- How do I read just one key without waiting for a return key?
- How do I check whether input is ready on the keyboard?
- How do I clear the screen?
- How do I get the screen size?
- How do I ask the user for a password?
- How do I read and write the serial port?
- How do I decode encrypted password files?
- How do I start a process in the background?
- How do I trap control characters/signals?
- How do I modify the shadow password file on a Unix system?
- How do I set the time and date?
- How can I sleep() or alarm() for under a second?
- How can I measure time under a second?
- How can I do an atexit() or setjmp()/longjmp()? (Exception handling)
- Why doesn't my sockets program work under System V (Solaris)? What does the error message "Protocol not supported" mean?
- How can I call my system's unique C functions from Perl?
- Where do I get the include files to do ioctl() or syscall()?
- Why do setuid perl scripts complain about kernel problems?
- How can I open a pipe both to and from a command?
- Why can't I get the output of a command with system()?
- How can I capture STDERR from an external command?

- Why doesn't open() return an error when a pipe open fails?
- What's wrong with using backticks in a void context?
- How can I call backticks without shell processing?
- Why can't my script read from STDIN after I gave it EOF (ˆD on Unix, ˆZ on MS-DOS)?
- How can I convert my shell script to perl?
- Can I use perl to run a telnet or ftp session?
- How can I write expect in Perl?
- Is there a way to hide perl's command line from programs such as "ps"?
- I {changed directory, modified my environment} in a perl script. How come the change disappeared when I exited the script? How do I get my changes to be visible?
- How do I close a process's filehandle without waiting for it to complete?
- How do I fork a daemon process?
- How do I find out if I'm running interactively or not?
- How do I timeout a slow event?
- How do I set CPU limits?
- How do I avoid zombies on a Unix system?
- How do I use an SQL database?
- How do I make a system() exit on control-C?
- How do I open a file without blocking?
- How do I install a module from CPAN?
- What's the difference between require and use?
- How do I keep my own module/library directory?
- How do I add the directory my program lives in to the module/library search path?
- How do I add a directory to my include path at runtime?
- What is socket.ph and where do I get it?

16.5.9 *perlfaq9*: Networking

Networking, the internet, and a few on the web.

- What is the correct form of response from a CGI script?
- My CGI script runs from the command line but not the browser. (500 Server Error)
- How can I get better error messages from a CGI program?
- How do I remove HTML from a string?
- How do I extract URLs?
- How do I download a file from the user's machine? How do I open a file on another machine?
- How do I make a pop-up menu in HTML?

- How do I fetch an HTML file?
- How do I automate an HTML form submission?
- How do I decode or create those %-encodings on the web?
- How do I redirect to another page?
- How do I put a password on my web pages?
- How do I edit my .htpasswd and .htgroup files with Perl?
- How do I make sure users can’t enter values into a form that cause my CGI script to do bad things?
- How do I parse a mail header?
- How do I decode a CGI form?
- How do I check a valid mail address?
- How do I decode a MIME/BASE64 string?
- How do I return the user’s mail address?
- How do I send mail?
- How do I use MIME to make an attachment to a mail message?
- How do I read mail?
- How do I find out my hostname/domainname/IP address?
- How do I fetch a news article or the active newsgroups?
- How do I fetch/put an FTP file?
- How can I do RPC in Perl?

Chapter 17

perlfaq1

General Questions About Perl ($Revision: 1.14 $, $Date: 2003/11/23 08:02:29 $)

17.1 DESCRIPTION

This section of the FAQ answers very general, high-level questions about Perl.

17.1.1 What is Perl?

Perl is a high-level programming language with an eclectic heritage written by Larry Wall and a cast of thousands. It derives from the ubiquitous C programming language and to a lesser extent from sed, awk, the Unix shell, and at least a dozen other tools and languages. Perl's process, file, and text manipulation facilities make it particularly well-suited for tasks involving quick prototyping, system utilities, software tools, system management tasks, database access, graphical programming, networking, and world wide web programming. These strengths make it especially popular with system administrators and CGI script authors, but mathematicians, geneticists, journalists, and even managers also use Perl. Maybe you should, too.

17.1.2 Who supports Perl? Who develops it? Why is it free?

The original culture of the pre-populist Internet and the deeply-held beliefs of Perl's author, Larry Wall, gave rise to the free and open distribution policy of perl. Perl is supported by its users. The core, the standard Perl library, the optional modules, and the documentation you're reading now were all written by volunteers. See the personal note at the end of the README file in the perl source distribution for more details. See *perlhist* (new as of 5.005) for Perl's milestone releases.

In particular, the core development team (known as the Perl Porters) are a rag-tag band of highly altruistic individuals committed to producing better software for free than you could hope to purchase for money. You may snoop on pending developments via the archives at http://www.xray.mpe.mpg.de/mailing-lists/perl5-porters/ and http://archive.develooper.com/perl5-porters@perl.org/ or the news gateway nntp://nntp.perl.org/perl.perl5.porters or its web interface at http://nntp.perl.org/group/perl.perl5.porters , or read the faq at http://simon-cozens.org/writings/p5p-faq , or you can subscribe to the mailing list by sending perl5-porters-request@perl.org a subscription request (an empty message with no subject is fine).

While the GNU project includes Perl in its distributions, there's no such thing as "GNU Perl". Perl is not produced nor maintained by the Free Software Foundation. Perl's licensing terms are also more open than GNU software's tend to be.

You can get commercial support of Perl if you wish, although for most users the informal support will more than suffice. See the answer to "Where can I buy a commercial version of perl?" for more information.

17.1.3 Which version of Perl should I use?

You should definitely use version 5. Version 4 is old, limited, and no longer maintained; its last patch (4.036) was in 1992, long ago and far away. Sure, it's stable, but so is anything that's dead; in fact, perl4 had been called a dead, flea-bitten camel carcass. The most recent production release is 5.8.2 (although 5.005_03 and 5.6.2 are still supported). The most cutting-edge development release is 5.9. Further references to the Perl language in this document refer to the production release unless otherwise specified. There may be one or more official bug fixes by the time you read this, and also perhaps some experimental versions on the way to the next release. All releases prior to 5.004 were subject to buffer overruns, a grave security issue.

17.1.4 What are perl4 and perl5?

Perl4 and perl5 are informal names for different versions of the Perl programming language. It's easier to say "perl5" than it is to say "the 5(.004) release of Perl", but some people have interpreted this to mean there's a language called "perl5", which isn't the case. Perl5 is merely the popular name for the fifth major release (October 1994), while perl4 was the fourth major release (March 1991). There was also a perl1 (in January 1988), a perl2 (June 1988), and a perl3 (October 1989).

The 5.0 release is, essentially, a ground-up rewrite of the original perl source code from releases 1 through 4. It has been modularized, object-oriented, tweaked, trimmed, and optimized until it almost doesn't look like the old code. However, the interface is mostly the same, and compatibility with previous releases is very high. See Perl4 to Perl5 Traps in *perltrap*.

To avoid the "what language is perl5?" confusion, some people prefer to simply use "perl" to refer to the latest version of perl and avoid using "perl5" altogether. It's not really that big a deal, though.

See *perlhist* for a history of Perl revisions.

17.1.5 What is Ponie?

At The O'Reilly Open Source Software Convention in 2003, Artur Bergman, Fotango, and The Perl Foundation announced a project to run perl5 on the Parrot virtual machine named Ponie. Ponie stands for Perl On New Internal Engine. The Perl 5.10 language implementation will be used for Ponie, and there will be no language level differences between perl5 and ponie. Ponie is not a complete rewrite of perl5.

For more details, see http://www.poniecode.org/

17.1.6 What is perl6?

At The Second O'Reilly Open Source Software Convention, Larry Wall announced Perl6 development would begin in earnest. Perl6 was an oft used term for Chip Salzenberg's project to rewrite Perl in C++ named Topaz. However, Topaz provided valuable insights to the next version of Perl and its implementation, but was ultimately abandoned.

If you want to learn more about Perl6, or have a desire to help in the crusade to make Perl a better place then peruse the Perl6 developers page at http://dev.perl.org/perl6/ and get involved.

Perl6 is not scheduled for release yet, and Perl5 will still be supported for quite awhile after its release. Do not wait for Perl6 to do whatever you need to do.

"We're really serious about reinventing everything that needs reinventing." –Larry Wall

17.1.7 How stable is Perl?

Production releases, which incorporate bug fixes and new functionality, are widely tested before release. Since the 5.000 release, we have averaged only about one production release per year.

Larry and the Perl development team occasionally make changes to the internal core of the language, but all possible efforts are made toward backward compatibility. While not quite all perl4 scripts run flawlessly under perl5, an update to perl should nearly never invalidate a program written for an earlier version of perl (barring accidental bug fixes and the rare new keyword).

17.1.8 Is Perl difficult to learn?

No, Perl is easy to start learning–and easy to keep learning. It looks like most programming languages you're likely to have experience with, so if you've ever written a C program, an awk script, a shell script, or even a BASIC program, you're already partway there.

Most tasks only require a small subset of the Perl language. One of the guiding mottos for Perl development is "there's more than one way to do it" (TMTOWTDI, sometimes pronounced "tim toady"). Perl's learning curve is therefore shallow (easy to learn) and long (there's a whole lot you can do if you really want).

Finally, because Perl is frequently (but not always, and certainly not by definition) an interpreted language, you can write your programs and test them without an intermediate compilation step, allowing you to experiment and test/debug quickly and easily. This ease of experimentation flattens the learning curve even more.

Things that make Perl easier to learn: Unix experience, almost any kind of programming experience, an understanding of regular expressions, and the ability to understand other people's code. If there's something you need to do, then it's probably already been done, and a working example is usually available for free. Don't forget the new perl modules, either. They're discussed in Part 3 of this FAQ, along with CPAN, which is discussed in Part 2.

17.1.9 How does Perl compare with other languages like Java, Python, REXX, Scheme, or Tcl?

Favorably in some areas, unfavorably in others. Precisely which areas are good and bad is often a personal choice, so asking this question on Usenet runs a strong risk of starting an unproductive Holy War.

Probably the best thing to do is try to write equivalent code to do a set of tasks. These languages have their own newsgroups in which you can learn about (but hopefully not argue about) them.

Some comparison documents can be found at http://language.perl.com/versus/ if you really can't stop yourself.

17.1.10 Can I do [task] in Perl?

Perl is flexible and extensible enough for you to use on virtually any task, from one-line file-processing tasks to large, elaborate systems. For many people, Perl serves as a great replacement for shell scripting. For others, it serves as a convenient, high-level replacement for most of what they'd program in low-level languages like C or C++. It's ultimately up to you (and possibly your management) which tasks you'll use Perl for and which you won't.

If you have a library that provides an API, you can make any component of it available as just another Perl function or variable using a Perl extension written in C or C++ and dynamically linked into your main perl interpreter. You can also go the other direction, and write your main program in C or C++, and then link in some Perl code on the fly, to create a powerful application. See *perlembed*.

That said, there will always be small, focused, special-purpose languages dedicated to a specific problem domain that are simply more convenient for certain kinds of problems. Perl tries to be all things to all people, but nothing special to anyone. Examples of specialized languages that come to mind include prolog and matlab.

17.1.11 When shouldn't I program in Perl?

When your manager forbids it–but do consider replacing them :-).

Actually, one good reason is when you already have an existing application written in another language that's all done (and done well), or you have an application language specifically designed for a certain task (e.g. prolog, make).

For various reasons, Perl is probably not well-suited for real-time embedded systems, low-level operating systems development work like device drivers or context-switching code, complex multi-threaded shared-memory applications, or extremely large applications. You'll notice that perl is not itself written in Perl.

The new, native-code compiler for Perl may eventually reduce the limitations given in the previous statement to some degree, but understand that Perl remains fundamentally a dynamically typed language, not a statically typed one. You certainly won't be chastised if you don't trust nuclear-plant or brain-surgery monitoring code to it. And Larry will sleep easier, too–Wall Street programs not withstanding. :-)

17.1.12 What's the difference between "perl" and "Perl"?

One bit. Oh, you weren't talking ASCII? :-) Larry now uses "Perl" to signify the language proper and "perl" the implementation of it, i.e. the current interpreter. Hence Tom's quip that "Nothing but perl can parse Perl." You may or may not choose to follow this usage. For example, parallelism means "awk and perl" and "Python and Perl" look OK, while "awk and Perl" and "Python and perl" do not. But never write "PERL", because perl is not an acronym, apocryphal folklore and post-facto expansions notwithstanding.

17.1.13 Is it a Perl program or a Perl script?

Larry doesn't really care. He says (half in jest) that "a script is what you give the actors. A program is what you give the audience."

Originally, a script was a canned sequence of normally interactive commands–that is, a chat script. Something like a UUCP or PPP chat script or an expect script fits the bill nicely, as do configuration scripts run by a program at its start up, such *.cshrc* or *.ircrc*, for example. Chat scripts were just drivers for existing programs, not stand-alone programs in their own right.

A computer scientist will correctly explain that all programs are interpreted and that the only question is at what level. But if you ask this question of someone who isn't a computer scientist, they might tell you that a *program* has been compiled to physical machine code once and can then be run multiple times, whereas a *script* must be translated by a program each time it's used.

Perl programs are (usually) neither strictly compiled nor strictly interpreted. They can be compiled to a byte-code form (something of a Perl virtual machine) or to completely different languages, like C or assembly language. You can't tell just by looking at it whether the source is destined for a pure interpreter, a parse-tree interpreter, a byte-code interpreter, or a native-code compiler, so it's hard to give a definitive answer here.

Now that "script" and "scripting" are terms that have been seized by unscrupulous or unknowing marketeers for their own nefarious purposes, they have begun to take on strange and often pejorative meanings, like "non serious" or "not real programming". Consequently, some Perl programmers prefer to avoid them altogether.

17.1.14 What is a JAPH?

These are the "just another perl hacker" signatures that some people sign their postings with. Randal Schwartz made these famous. About 100 of the earlier ones are available from http://www.cpan.org/misc/japh .

17.1.15 Where can I get a list of Larry Wall witticisms?

Over a hundred quips by Larry, from postings of his or source code, can be found at http://www.cpan.org/misc/lwall-quotes.txt.gz .

17.1.16 How can I convince my sysadmin/supervisor/employees to use version 5/5.6.1/Perl instead of some other language?

If your manager or employees are wary of unsupported software, or software which doesn't officially ship with your operating system, you might try to appeal to their self-interest. If programmers can be more productive using and utilizing Perl constructs, functionality, simplicity, and power, then the typical manager/supervisor/employee may be persuaded. Regarding using Perl in general, it's also sometimes helpful to point out that delivery times may be reduced using Perl compared to other languages.

If you have a project which has a bottleneck, especially in terms of translation or testing, Perl almost certainly will provide a viable, quick solution. In conjunction with any persuasion effort, you should not fail to point out that Perl is used, quite extensively, and with extremely reliable and valuable results, at many large computer software and hardware companies throughout the world. In fact, many Unix vendors now ship Perl by default. Support is usually just a news-posting away, if you can't find the answer in the *comprehensive* documentation, including this FAQ.

See http://www.perl.org/advocacy/ for more information.

If you face reluctance to upgrading from an older version of perl, then point out that version 4 is utterly unmaintained and unsupported by the Perl Development Team. Another big sell for Perl5 is the large number of modules and extensions which greatly reduce development time for any given task. Also mention that the difference between version 4 and version 5 of Perl is like the difference between awk and C++. (Well, OK, maybe it's not quite that distinct, but you get the idea.) If you want support and a reasonable guarantee that what you're developing will continue to work in the future, then you have to run the supported version. As of December 2003 that means running either 5.8.2 (released in November 2003), or one of the older releases like 5.6.2 (also released in November 2003; a maintenance release to let perl 5.6 compile on newer systems as 5.6.1 was released in April 2001) or 5.005_03 (released in March 1999), although 5.004_05 isn't that bad if you **absolutely** need such an old version (released in April 1999) for stability reasons. Anything older than 5.004_05 shouldn't be used.

Of particular note is the massive bug hunt for buffer overflow problems that went into the 5.004 release. All releases prior to that, including perl4, are considered insecure and should be upgraded as soon as possible.

In August 2000 in all Linux distributions a new security problem was found in the optional 'suidperl' (not built or installed by default) in all the Perl branches 5.6, 5.005, and 5.004, see http://www.cpan.org/src/5.0/sperl-2000-08-05/ Perl maintenance releases 5.6.1 and 5.8.0 have this security hole closed. Most, if not all, Linux distribution have patches for this vulnerability available, see http://www.linuxsecurity.com/advisories/ , but the most recommendable way is to upgrade to at least Perl 5.6.1.

perlfaq2

Obtaining and Learning about Perl ($Revision: 1.25 $, $Date: 2003/10/16 04:57:38 $)

18.1 DESCRIPTION

This section of the FAQ answers questions about where to find source and documentation for Perl, support, and related matters.

18.1.1 What machines support Perl? Where do I get it?

The standard release of Perl (the one maintained by the perl development team) is distributed only in source code form. You can find this at http://www.cpan.org/src/latest.tar.gz , which is in a standard Internet format (a gzipped archive in POSIX tar format).

Perl builds and runs on a bewildering number of platforms. Virtually all known and current Unix derivatives are supported (Perl's native platform), as are other systems like VMS, DOS, OS/2, Windows, QNX, BeOS, OS X, MPE/iX and the Amiga.

Binary distributions for some proprietary platforms, including Apple systems, can be found http://www.cpan.org/ports/ directory. Because these are not part of the standard distribution, they may and in fact do differ from the base Perl port in a variety of ways. You'll have to check their respective release notes to see just what the differences are. These differences can be either positive (e.g. extensions for the features of the particular platform that are not supported in the source release of perl) or negative (e.g. might be based upon a less current source release of perl).

18.1.2 How can I get a binary version of Perl?

If you don't have a C compiler because your vendor for whatever reasons did not include one with your system, the best thing to do is grab a binary version of gcc from the net and use that to compile perl with. CPAN only has binaries for systems that are terribly hard to get free compilers for, not for Unix systems.

Some URLs that might help you are:

```
http://www.cpan.org/ports/
http://www.perl.com/pub/language/info/software.html
```

Someone looking for a Perl for Win16 might look to Laszlo Molnar's djgpp port in http://www.cpan.org/ports/#msdos , which comes with clear installation instructions. A simple installation guide for MS-DOS using Ilya Zakharevich's OS/2 port is available at http://www.cs.ruu.nl/%7Epiet/perl5dos.html and similarly for Windows 3.1 at http://www.cs.ruu.nl/%7Epiet/perlwin3.html .

18.1.3 I don't have a C compiler on my system. How can I compile perl?

Since you don't have a C compiler, you're doomed and your vendor should be sacrificed to the Sun gods. But that doesn't help you.

What you need to do is get a binary version of gcc for your system first. Consult the Usenet FAQs for your operating system for information on where to get such a binary version.

18.1.4 I copied the Perl binary from one machine to another, but scripts don't work.

That's probably because you forgot libraries, or library paths differ. You really should build the whole distribution on the machine it will eventually live on, and then type `make install`. Most other approaches are doomed to failure.

One simple way to check that things are in the right place is to print out the hard-coded @INC that perl looks through for libraries:

```
    % perl -le 'print for @INC'
```

If this command lists any paths that don't exist on your system, then you may need to move the appropriate libraries to these locations, or create symbolic links, aliases, or shortcuts appropriately. @INC is also printed as part of the output of

```
    % perl -V
```

You might also want to check out How do I keep my own module/library directory? in *perlfaq8*.

18.1.5 I grabbed the sources and tried to compile but gdbm/dynamic loading/malloc/linking/... failed. How do I make it work?

Read the *INSTALL* file, which is part of the source distribution. It describes in detail how to cope with most idiosyncrasies that the Configure script can't work around for any given system or architecture.

18.1.6 What modules and extensions are available for Perl? What is CPAN? What does CPAN/src/... mean?

CPAN stands for Comprehensive Perl Archive Network, a ˜1.2Gb archive replicated on nearly 200 machines all over the world. CPAN contains source code, non-native ports, documentation, scripts, and many third-party modules and extensions, designed for everything from commercial database interfaces to keyboard/screen control to web walking and CGI scripts. The master web site for CPAN is http://www.cpan.org/ and there is the CPAN Multiplexer at http://www.cpan.org/CPAN.html which will choose a mirror near you via DNS. See http://www.perl.com/CPAN (without a slash at the end) for how this process works. Also, http://mirror.cpan.org/ has a nice interface to the http://www.cpan.org/MIRRORED.BY mirror directory.

See the CPAN FAQ at http://www.cpan.org/misc/cpan-faq.html for answers to the most frequently asked questions about CPAN including how to become a mirror.

CPAN/path/... is a naming convention for files available on CPAN sites. CPAN indicates the base directory of a CPAN mirror, and the rest of the path is the path from that directory to the file. For instance, if you're using ftp://ftp.funet.fi/pub/languages/perl/CPAN as your CPAN site, the file CPAN/misc/japh is downloadable as ftp://ftp.funet.fi/pub/languages/perl/CPAN/misc/japh .

Considering that there are close to two thousand existing modules in the archive, one probably exists to do nearly anything you can think of. Current categories under CPAN/modules/by-category/ include Perl core modules; development support; operating system interfaces; networking, devices, and interprocess communication; data type utilities; database interfaces; user interfaces; interfaces to other languages; filenames, file systems, and file locking; internationalization and locale; world wide web support; server and daemon utilities; archiving and compression; image manipulation; mail and news; control flow utilities; filehandle and I/O; Microsoft Windows modules; and miscellaneous modules.

See http://www.cpan.org/modules/00modlist.long.html or http://search.cpan.org/ for a more complete list of modules by category.

CPAN is not affiliated with O'Reilly and Associates.

18.1.7 Is there an ISO or ANSI certified version of Perl?

Certainly not. Larry expects that he'll be certified before Perl is.

18.1.8 Where can I get information on Perl?

The complete Perl documentation is available with the Perl distribution. If you have Perl installed locally, you probably have the documentation installed as well: type `man perl` if you're on a system resembling Unix. This will lead you to other important man pages, including how to set your $MANPATH. If you're not on a Unix system, access to the documentation will be different; for example, documentation might only be in HTML format. All proper Perl installations have fully-accessible documentation.

You might also try `perldoc perl` in case your system doesn't have a proper man command, or it's been misinstalled. If that doesn't work, try looking in /usr/local/lib/perl5/pod for documentation.

If all else fails, consult http://perldoc.cpan.org/ or http://www.perldoc.com/ both offer the complete documentation in html format.

Many good books have been written about Perl–see the section below for more details.

Tutorial documents are included in current or upcoming Perl releases include *perltoot* for objects or *perlboot* for a beginner's approach to objects, *perlopentut* for file opening semantics, *perlreftut* for managing references, *perlretut* for regular expressions, *perlthrtut* for threads, *perldebtut* for debugging, and *perlxstut* for linking C and Perl together. There may be more by the time you read this. The following URLs might also be of assistance:

```
    http://perldoc.cpan.org/
    http://www.perldoc.com/
    http://bookmarks.cpan.org/search.cgi?cat=Training%2FTutorials
```

18.1.9 What are the Perl newsgroups on Usenet? Where do I post questions?

Several groups devoted to the Perl language are on Usenet:

```
    comp.lang.perl.announce             Moderated announcement group
    comp.lang.perl.misc                 High traffic general Perl discussion
    comp.lang.perl.moderated        Moderated discussion group
    comp.lang.perl.modules              Use and development of Perl modules
    comp.lang.perl.tk                   Using Tk (and X) from Perl

    comp.infosystems.www.authoring.cgi  Writing CGI scripts for the Web.
```

Some years ago, comp.lang.perl was divided into those groups, and comp.lang.perl itself officially removed. While that group may still be found on some news servers, it is unwise to use it, because postings there will not appear on news servers which honour the official list of group names. Use comp.lang.perl.misc for topics which do not have a more-appropriate specific group.

There is also a Usenet gateway to Perl mailing lists sponsored by perl.org at nntp://nntp.perl.org , a web interface to the same lists at http://nntp.perl.org/group/ and these lists are also available under the `perl.*` hierarchy at http://groups.google.com . Other groups are listed at http://lists.perl.org/ (also known as http://lists.cpan.org/).

A nice place to ask questions is the PerlMonks site, http://www.perlmonks.org/ , or the Perl Beginners mailing list http://lists.perl.org/showlist.cgi?name=beginners .

Note that none of the above are supposed to write your code for you: asking questions about particular problems or general advice is fine, but asking someone to write your code for free is not very cool.

18.1.10 Where should I post source code?

You should post source code to whichever group is most appropriate, but feel free to cross-post to comp.lang.perl.misc. If you want to cross-post to alt.sources, please make sure it follows their posting standards, including setting the Followup-To header line to NOT include alt.sources; see their FAQ (http://www.faqs.org/faqs/alt-sources-intro/) for details.

If you're just looking for software, first use Google (http://www.google.com), Google's usenet search interface (http://groups.google.com), and CPAN Search (http://search.cpan.org). This is faster and more productive than just posting a request.

18.1.11 Perl Books

A number of books on Perl and/or CGI programming are available. A few of these are good, some are OK, but many aren't worth your money. Tom Christiansen maintains a list of these books, some with extensive reviews, at http://www.perl.com/perl/critiques/index.html .

The incontestably definitive reference book on Perl, written by the creator of Perl, is now (July 2000) in its third edition:

```
Programming Perl (the "Camel Book"):
    by Larry Wall, Tom Christiansen, and Jon Orwant
    0-596-00027-8  [3rd edition July 2000]
    http://www.oreilly.com/catalog/pperl3/
(English, translations to several languages are also available)
```

The companion volume to the Camel containing thousands of real-world examples, mini-tutorials, and complete programs is:

```
The Perl Cookbook (the "Ram Book"):
    by Tom Christiansen and Nathan Torkington,
        with Foreword by Larry Wall
    ISBN 1-56592-243-3 [1st Edition August 1998]
    http://perl.oreilly.com/catalog/cookbook/
```

If you're already a seasoned programmer, then the Camel Book might suffice for you to learn Perl from. If you're not, check out the Llama book:

```
Learning Perl (the "Llama Book")
    by Randal L. Schwartz and Tom Phoenix
    ISBN 0-596-00132-0 [3rd edition July 2001]
    http://www.oreilly.com/catalog/lperl3/
```

And for more advanced information on writing larger programs, presented in the same style as the Llama book, continue your education with the Alpaca book:

```
Learning Perl Objects, References, and Modules (the "Alpaca Book")
   by Randal L. Schwartz, with Tom Phoenix (foreword by Damian Conway)
   ISBN 0-596-00478-8 [1st edition June 2003]
   http://www.oreilly.com/catalog/lrnperlorm/
```

If you're not an accidental programmer, but a more serious and possibly even degreed computer scientist who doesn't need as much hand-holding as we try to provide in the Llama, please check out the delightful book

```
Perl: The Programmer's Companion
    by Nigel Chapman
    ISBN 0-471-97563-X [1997, 3rd printing Spring 1998]
    http://www.wiley.com/compbooks/catalog/97563-X.htm
    http://www.wiley.com/compbooks/chapman/perl/perltpc.html (errata etc)
```

If you are more at home in Windows the following is available (though unfortunately rather dated).

```
    Learning Perl on Win32 Systems (the "Gecko Book")
        by Randal L. Schwartz, Erik Olson, and Tom Christiansen,
            with foreword by Larry Wall
        ISBN 1-56592-324-3 [1st edition August 1997]
        http://www.oreilly.com/catalog/lperlwin/
```

Addison-Wesley (http://www.awlonline.com/) and Manning (http://www.manning.com/) are also publishers of some fine Perl books such as *Object Oriented Programming with Perl* by Damian Conway and *Network Programming with Perl* by Lincoln Stein.

An excellent technical book discounter is Bookpool at http://www.bookpool.com/ where a 30% discount or more is not unusual.

What follows is a list of the books that the FAQ authors found personally useful. Your mileage may (but, we hope, probably won't) vary.

Recommended books on (or mostly on) Perl follow.

           http://www.manning.com/jenness
```

18.1.12 Perl in Magazines

The first (and for a long time, only) periodical devoted to All Things Perl, *The Perl Journal* contains tutorials, demonstrations, case studies, announcements, contests, and much more. *TPJ* has columns on web development, databases, Win32 Perl, graphical programming, regular expressions, and networking, and sponsors the Obfuscated Perl Contest and the Perl Poetry Contests. Beginning in November 2002, TPJ moved to a reader-supported monthly e-zine format in which subscribers can download issues as PDF documents. For more details on TPJ, see http://www.tpj.com/

Beyond this, magazines that frequently carry quality articles on Perl are *The Perl Review* (http://www.theperlreview.com), *Unix Review* (http://www.unixreview.com/), *Linux Magazine* (http://www.linuxmagazine.com/), and Usenix's newsletter/magazine to its members, *login:* (http://www.usenix.org/)

The Perl columns of Randal L. Schwartz are available on the web at http://www.stonehenge.com/merlyn/WebTechniques/ , http://www.stonehenge.com/merlyn/UnixReview/ , and http://www.stonehenge.com/merlyn/LinuxMag/ .

18.1.13 Perl on the Net: FTP and WWW Access

To get the best performance, pick a site from the list at http://www.cpan.org/SITES.html . From there you can find the quickest site for you.

You may also use xx.cpan.org where "xx" is the 2-letter country code for your domain; e.g. Australia would use au.cpan.org. [Note: This only applies to countries that host at least one mirror.]

18.1.14 What mailing lists are there for Perl?

Most of the major modules (Tk, CGI, libwww-perl) have their own mailing lists. Consult the documentation that came with the module for subscription information.

A comprehensive list of Perl related mailing lists can be found at:

```
        http://lists.perl.org/
```

18.1.15 Archives of comp.lang.perl.misc

The Google search engine now carries archived and searchable newsgroup content.

http://groups.google.com/groups?group=comp.lang.perl.misc

If you have a question, you can be sure someone has already asked the same question at some point on c.l.p.m. It requires some time and patience to sift through all the content but often you will find the answer you seek.

18.1.16 Where can I buy a commercial version of Perl?

In a real sense, Perl already *is* commercial software: it has a license that you can grab and carefully read to your manager. It is distributed in releases and comes in well-defined packages. There is a very large user community and an extensive literature. The comp.lang.perl.* newsgroups and several of the mailing lists provide free answers to your questions in near real-time. Perl has traditionally been supported by Larry, scores of software designers and developers, and myriad programmers, all working for free to create a useful thing to make life better for everyone.

However, these answers may not suffice for managers who require a purchase order from a company whom they can sue should anything go awry. Or maybe they need very serious hand-holding and contractual obligations. Shrink-wrapped CDs with Perl on them are available from several sources if that will help. For example, many Perl books include a distribution of Perl, as do the O'Reilly Perl Resource Kits (in both the Unix flavor and in the proprietary Microsoft flavor); the free Unix distributions also all come with Perl.

Alternatively, you can purchase commercial incidence based support through the Perl Clinic. The following is a commercial from them:

"The Perl Clinic is a commercial Perl support service operated by ActiveState Tool Corp. and The Ingram Group. The operators have many years of in-depth experience with Perl applications and Perl internals on a wide range of platforms.

"Through our group of highly experienced and well-trained support engineers, we will put our best effort into understanding your problem, providing an explanation of the situation, and a recommendation on how to proceed."

Contact The Perl Clinic at

```
    www.PerlClinic.com

    North America Pacific Standard Time (GMT-8)
    Tel:    1 604 606-4611 hours 8am-6pm
    Fax:    1 604 606-4640

    Europe (GMT)
    Tel:    00 44 1483 862814
    Fax:    00 44 1483 862801
```

See also www.perl.com for updates on tutorials, training, and support.

18.1.17 Where do I send bug reports?

If you are reporting a bug in the perl interpreter or the modules shipped with Perl, use the *perlbug* program in the Perl distribution or mail your report to perlbug@perl.org .

If you are posting a bug with a non-standard port (see the answer to "What platforms is Perl available for?"), a binary distribution, or a non-standard module (such as Tk, CGI, etc), then please see the documentation that came with it to determine the correct place to post bugs.

Read the perlbug(1) man page (perl5.004 or later) for more information.

18.1.18 What is perl.com? Perl Mongers? pm.org? perl.org? cpan.org?

The Perl Home Page at http://www.perl.com/ is currently hosted by The O'Reilly Network, a subsidiary of O'Reilly and Associates.

Perl Mongers is an advocacy organization for the Perl language which maintains the web site http://www.perl.org/ as a general advocacy site for the Perl language.

Perl Mongers uses the pm.org domain for services related to Perl user groups, including the hosting of mailing lists and web sites. See the Perl user group web site at http://www.pm.org/ for more information about joining, starting, or requesting services for a Perl user group.

Perl Mongers also maintain the perl.org domain to provide general support services to the Perl community, including the hosting of mailing lists, web sites, and other services. The web site http://www.perl.org/ is a general advocacy site for the Perl language, and there are many other sub-domains for special topics, such as

```
    http://bugs.perl.org/
    http://history.perl.org/
    http://lists.perl.org/
    http://use.perl.org/
```

http://www.cpan.org/ is the Comprehensive Perl Archive Network, a replicated worlwide repository of Perl software, see the *What is CPAN?* question earlier in this document.

Chapter 19

perlfaq3

Programming Tools ($Revision: 1.37 $, $Date: 2003/11/24 19:55:50 $)

19.1 DESCRIPTION

This section of the FAQ answers questions related to programmer tools and programming support.

19.1.1 How do I do (anything)?

Have you looked at CPAN (see *perlfaq2*)? The chances are that someone has already written a module that can solve your problem. Have you read the appropriate manpages? Here's a brief index:

```
        Basics          perldata, perlvar, perlsyn, perlop, perlsub
        Execution       perlrun, perldebug
        Functions       perlfunc
        Objects         perlref, perlmod, perlobj, perltie
        Data Structures perlref, perllol, perldsc
        Modules         perlmod, perlmodlib, perlsub
        Regexes         perlre, perlfunc, perlop, perllocale
        Moving to perl5 perltrap, perl
        Linking w/C     perlxstut, perlxs, perlcall, perlguts, perlembed
        Various         http://www.cpan.org/misc/olddoc/FMTEYEWTK.tgz
                        (not a man-page but still useful, a collection
                         of various essays on Perl techniques)
```

A crude table of contents for the Perl manpage set is found in *perltoc*.

19.1.2 How can I use Perl interactively?

The typical approach uses the Perl debugger, described in the perldebug(1) manpage, on an “empty” program, like this:

```
    perl -de 42
```

Now just type in any legal Perl code, and it will be immediately evaluated. You can also examine the symbol table, get stack backtraces, check variable values, set breakpoints, and other operations typically found in symbolic debuggers.

19.1.3 Is there a Perl shell?

The psh (Perl sh) is currently at version 1.8. The Perl Shell is a shell that combines the interactive nature of a Unix shell with the power of Perl. The goal is a full featured shell that behaves as expected for normal shell activity and uses Perl syntax and functionality for control-flow statements and other things. You can get psh at http://www.focusresearch.com/gregor/psh/ .

Zoidberg is a similar project and provides a shell written in perl, configured in perl and operated in perl. It is intended as a login shell and development environment. It can be found at http://zoidberg.sf.net/ or your local CPAN mirror.

The Shell.pm module (distributed with Perl) makes Perl try commands which aren't part of the Perl language as shell commands. perlsh from the source distribution is simplistic and uninteresting, but may still be what you want.

19.1.4 How do I find which modules are installed on my system?

You can use the ExtUtils::Installed module to show all installed distributions, although it can take awhile to do its magic. The standard library which comes with Perl just shows up as "Perl" (although you can get those with Module::CoreList).

```
        use ExtUtils::Installed;

        my $inst    = ExtUtils::Installed->new();
        my @modules = $inst->modules();
```

If you want a list of all of the Perl module filenames, you can use File::Find::Rule.

```
        use File::Find::Rule;

        my @files = File::Find::Rule->file()->name( '*.pm' )->in( @INC );
```

If you do not have that module, you can do the same thing with File::Find which is part of the standard library.

```
    use File::Find;
    my @files;

    find sub { push @files, $File::Find::name if -f _ && /\.pm$/ },
         @INC;

        print join "\n", @files;
```

If you simply need to quickly check to see if a module is available, you can check for its documentation. If you can read the documentation the module is most likely installed. If you cannot read the documentation, the module might not have any (in rare cases).

```
        prompt% perldoc Module::Name
```

You can also try to include the module in a one-liner to see if perl finds it.

```
        perl -MModule::Name -e1
```

19.1.5 How do I debug my Perl programs?

Have you tried `use warnings` or used `-w`? They enable warnings to detect dubious practices.

Have you tried `use strict`? It prevents you from using symbolic references, makes you predeclare any subroutines that you call as bare words, and (probably most importantly) forces you to predeclare your variables with `my`, `our`, or `use vars`.

Did you check the return values of each and every system call? The operating system (and thus Perl) tells you whether they worked, and if not why.

```
open(FH, "> /etc/cantwrite")
  or die "Couldn't write to /etc/cantwrite: $!\n";
```

Did you read *perltrap*? It's full of gotchas for old and new Perl programmers and even has sections for those of you who are upgrading from languages like *awk* and *C*.

Have you tried the Perl debugger, described in *perldebug*? You can step through your program and see what it's doing and thus work out why what it's doing isn't what it should be doing.

19.1.6 How do I profile my Perl programs?

You should get the Devel::DProf module from the standard distribution (or separately on CPAN) and also use Benchmark.pm from the standard distribution. The Benchmark module lets you time specific portions of your code, while Devel::DProf gives detailed breakdowns of where your code spends its time.

Here's a sample use of Benchmark:

```
use Benchmark;

@junk = `cat /etc/motd`;
$count = 10_000;

timethese($count, {
          'map' => sub { my @a = @junk;
                         map { s/a/b/ } @a;
                         return @a },
          'for' => sub { my @a = @junk;
                         for (@a) { s/a/b/ };
                         return @a },
         });
```

This is what it prints (on one machine–your results will be dependent on your hardware, operating system, and the load on your machine):

```
Benchmark: timing 10000 iterations of for, map...
       for:  4 secs ( 3.97 usr  0.01 sys =  3.98 cpu)
       map:  6 secs ( 4.97 usr  0.00 sys =  4.97 cpu)
```

Be aware that a good benchmark is very hard to write. It only tests the data you give it and proves little about the differing complexities of contrasting algorithms.

19.1.7 How do I cross-reference my Perl programs?

The B::Xref module can be used to generate cross-reference reports for Perl programs.

```
  perl -MO=Xref[,OPTIONS] scriptname.plx
```

19.1.8 Is there a pretty-printer (formatter) for Perl?

Perltidy is a Perl script which indents and reformats Perl scripts to make them easier to read by trying to follow the rules of the *perlstyle*. If you write Perl scripts, or spend much time reading them, you will probably find it useful. It is available at http://perltidy.sourceforge.net

Of course, if you simply follow the guidelines in *perlstyle*, you shouldn't need to reformat. The habit of formatting your code as you write it will help prevent bugs. Your editor can and should help you with this. The perl-mode or newer cperl-mode for emacs can provide remarkable amounts of help with most (but not all) code, and even less programmable editors can provide significant assistance. Tom Christiansen and many other VI users swear by the following settings in vi and its clones:

```
    set ai sw=4
    map! ^O {^M}^[O^T
```

Put that in your *.exrc* file (replacing the caret characters with control characters) and away you go. In insert mode, ˆT is for indenting, ˆD is for undenting, and ˆO is for blockdenting– as it were. A more complete example, with comments, can be found at http://www.cpan.org/authors/id/TOMC/scripts/toms.exrc.gz

The a2ps http://www-inf.enst.fr/%7Edemaille/a2ps/black+white.ps.gz does lots of things related to generating nicely printed output of documents, as does enscript at http://people.ssh.fi/mtr/genscript/ .

19.1.9 Is there a ctags for Perl?

Recent versions of ctags do much more than older versions did. EXUBERANT CTAGS is available from http://ctags.sourceforge.net/ and does a good job of making tags files for perl code.

There is also a simple one at http://www.cpan.org/authors/id/TOMC/scripts/ptags.gz which may do the trick. It can be easy to hack this into what you want.

19.1.10 Is there an IDE or Windows Perl Editor?

Perl programs are just plain text, so any editor will do.

If you're on Unix, you already have an IDE–Unix itself. The UNIX philosophy is the philosophy of several small tools that each do one thing and do it well. It's like a carpenter's toolbox.

If you want an IDE, check the following:

Komodo

ActiveState's cross-platform (as of April 2001 Windows and Linux), multi-language IDE has Perl support, including a regular expression debugger and remote debugging (http://www.ActiveState.com/Products/Komodo/index.html). (Visual Perl, a Visual Studio.NET plug-in is currently (early 2001) in beta (http://www.ActiveState.com/Products/VisualPerl/index.html)).

The Object System

(http://www.castlelink.co.uk/object_system/) is a Perl web applications development IDE, apparently for any platform that runs Perl.

Open Perl IDE

(http://open-perl-ide.sourceforge.net/) Open Perl IDE is an integrated development environment for writing and debugging Perl scripts with ActiveState's ActivePerl distribution under Windows 95/98/NT/2000.

PerlBuilder

(http://www.solutionsoft.com/perl.htm) is an integrated development environment for Windows that supports Perl development.

visiPerl+

(http://helpconsulting.net/visiperl/) From Help Consulting, for Windows.

OptiPerl

(http://www.optiperl.com/) is a Windows IDE with simulated CGI environment, including debugger and syntax highlighting editor.

For editors: if you're on Unix you probably have vi or a vi clone already, and possibly an emacs too, so you may not need to download anything. In any emacs the cperl-mode (M-x cperl-mode) gives you perhaps the best available Perl editing mode in any editor.

If you are using Windows, you can use any editor that lets you work with plain text, such as NotePad or WordPad. Word processors, such as Microsoft Word or WordPerfect, typically do not work since they insert all sorts of behind-the-scenes information, although some allow you to save files as "Text Only". You can also download text editors designed specifically for programming, such as Textpad (http://www.textpad.com/) and UltraEdit (http://www.ultraedit.com/), among others.

If you are using MacOS, the same concerns apply. MacPerl (for Classic environments) comes with a simple editor. Popular external editors are BBEdit (http://www.bbedit.com/) or Alpha (http://www.kelehers.org/alpha/). MacOS X users can use Unix editors as well.

GNU Emacs

http://www.gnu.org/software/emacs/windows/ntemacs.html

MicroEMACS

http://www.microemacs.de/

XEmacs

http://www.xemacs.org/Download/index.html

Jed

http://space.mit.edu/˜davis/jed/

or a vi clone such as

Elvis

ftp://ftp.cs.pdx.edu/pub/elvis/ http://www.fh-wedel.de/elvis/

Vile

http://dickey.his.com/vile/vile.html

Vim

http://www.vim.org/

For vi lovers in general, Windows or elsewhere:

```
    http://www.thomer.com/thomer/vi/vi.html
```

nvi (http://www.bostic.com/vi/ , available from CPAN in src/misc/) is yet another vi clone, unfortunately not available for Windows, but in UNIX platforms you might be interested in trying it out, firstly because strictly speaking it is not a vi clone, it is the real vi, or the new incarnation of it, and secondly because you can embed Perl inside it to use Perl as the scripting language. nvi is not alone in this, though: at least also vim and vile offer an embedded Perl.

The following are Win32 multilanguage editor/IDESs that support Perl:

Codewright

http://www.starbase.com/

MultiEdit

http://www.MultiEdit.com/

SlickEdit

http://www.slickedit.com/

There is also a toyedit Text widget based editor written in Perl that is distributed with the Tk module on CPAN. The ptkdb (http://world.std.com/˜aep/ptkdb/) is a Perl/tk based debugger that acts as a development environment of sorts. Perl Composer (http://perlcomposer.sourceforge.net/) is an IDE for Perl/Tk GUI creation.

In addition to an editor/IDE you might be interested in a more powerful shell environment for Win32. Your options include

Bash

from the Cygwin package (http://sources.redhat.com/cygwin/)

Ksh

from the MKS Toolkit (http://www.mks.com/), or the Bourne shell of the U/WIN environment (http://www.research.att.com/sw/tools/uwin/)

Tcsh

ftp://ftp.astron.com/pub/tcsh/ , see also http://www.primate.wisc.edu/software/csh-tcsh-book/

Zsh

ftp://ftp.blarg.net/users/amol/zsh/ , see also http://www.zsh.org/

MKS and U/WIN are commercial (U/WIN is free for educational and research purposes), Cygwin is covered by the GNU Public License (but that shouldn't matter for Perl use). The Cygwin, MKS, and U/WIN all contain (in addition to the shells) a comprehensive set of standard UNIX toolkit utilities.

If you're transferring text files between Unix and Windows using FTP be sure to transfer them in ASCII mode so the ends of lines are appropriately converted.

On Mac OS the MacPerl Application comes with a simple 32k text editor that behaves like a rudimentary IDE. In contrast to the MacPerl Application the MPW Perl tool can make use of the MPW Shell itself as an editor (with no 32k limit).

BBEdit and BBEdit Lite

are text editors for Mac OS that have a Perl sensitivity mode (http://web.barebones.com/).

Alpha

is an editor, written and extensible in Tcl, that nonetheless has built in support for several popular markup and programming languages including Perl and HTML (http://alpha.olm.net/).

Pepper and Pe are programming language sensitive text editors for Mac OS X and BeOS respectively (http://www.hekkelman.com/).

19.1.11 Where can I get Perl macros for vi?

For a complete version of Tom Christiansen's vi configuration file, see http://www.cpan.org/authors/Tom_Christiansen/scripts/toms.exrc.gz , the standard benchmark file for vi emulators. The file runs best with nvi, the current version of vi out of Berkeley, which incidentally can be built with an embedded Perl interpreter–see http://www.cpan.org/src/misc/ .

19.1.12 Where can I get perl-mode for emacs?

Since Emacs version 19 patchlevel 22 or so, there have been both a perl-mode.el and support for the Perl debugger built in. These should come with the standard Emacs 19 distribution.

In the Perl source directory, you'll find a directory called "emacs", which contains a cperl-mode that color-codes keywords, provides context-sensitive help, and other nifty things.

Note that the perl-mode of emacs will have fits with `"main'foo"` (single quote), and mess up the indentation and highlighting. You are probably using `"main::foo"` in new Perl code anyway, so this shouldn't be an issue.

19.1.13 How can I use curses with Perl?

The Curses module from CPAN provides a dynamically loadable object module interface to a curses library. A small demo can be found at the directory http://www.cpan.org/authors/Tom_Christiansen/scripts/rep.gz ; this program repeats a command and updates the screen as needed, rendering **rep ps axu** similar to **top**.

19.1.14 How can I use X or Tk with Perl?

Tk is a completely Perl-based, object-oriented interface to the Tk toolkit that doesn't force you to use Tcl just to get at Tk. Sx is an interface to the Athena Widget set. Both are available from CPAN. See the directory http://www.cpan.org/modules/by-category/08_User_Interfaces/

Invaluable for Perl/Tk programming are the Perl/Tk FAQ at http://w4.lns.cornell.edu/%7Epvhp/ptk/ptkTOC.html , the Perl/Tk Reference Guide available at http://www.cpan.org/authors/Stephen_O_Lidie/ , and the online manpages at http://www-users.cs.umn.edu/%7Eamundson/perl/perltk/toc.html .

19.1.15 How can I generate simple menus without using CGI or Tk?

The http://www.cpan.org/authors/id/SKUNZ/perlmenu.v4.0.tar.gz module, which is curses-based, can help with this.

19.1.16 How can I make my Perl program run faster?

The best way to do this is to come up with a better algorithm. This can often make a dramatic difference. Jon Bentley's book *Programming Pearls* (that's not a misspelling!) has some good tips on optimization, too. Advice on benchmarking boils down to: benchmark and profile to make sure you're optimizing the right part, look for better algorithms instead of microtuning your code, and when all else fails consider just buying faster hardware. You will probably want to read the answer to the earlier question "How do I profile my Perl programs?" if you haven't done so already.

A different approach is to autoload seldom-used Perl code. See the AutoSplit and AutoLoader modules in the standard distribution for that. Or you could locate the bottleneck and think about writing just that part in C, the way we used to take bottlenecks in C code and write them in assembler. Similar to rewriting in C, modules that have critical sections can be written in C (for instance, the PDL module from CPAN).

If you're currently linking your perl executable to a shared *libc.so*, you can often gain a 10-25% performance benefit by rebuilding it to link with a static libc.a instead. This will make a bigger perl executable, but your Perl programs (and programmers) may thank you for it. See the *INSTALL* file in the source distribution for more information.

The undump program was an ancient attempt to speed up Perl program by storing the already-compiled form to disk. This is no longer a viable option, as it only worked on a few architectures, and wasn't a good solution anyway.

19.1.17 How can I make my Perl program take less memory?

When it comes to time-space tradeoffs, Perl nearly always prefers to throw memory at a problem. Scalars in Perl use more memory than strings in C, arrays take more than that, and hashes use even more. While there's still a lot to be done, recent releases have been addressing these issues. For example, as of 5.004, duplicate hash keys are shared amongst all hashes using them, so require no reallocation.

In some cases, using substr() or vec() to simulate arrays can be highly beneficial. For example, an array of a thousand booleans will take at least 20,000 bytes of space, but it can be turned into one 125-byte bit vector–a considerable memory savings. The standard Tie::SubstrHash module can also help for certain types of data structure. If you're working with specialist data structures (matrices, for instance) modules that implement these in C may use less memory than equivalent Perl modules.

Another thing to try is learning whether your Perl was compiled with the system malloc or with Perl's builtin malloc. Whichever one it is, try using the other one and see whether this makes a difference. Information about malloc is in the *INSTALL* file in the source distribution. You can find out whether you are using perl's malloc by typing `perl -V:usemymalloc`.

Of course, the best way to save memory is to not do anything to waste it in the first place. Good programming practices can go a long way toward this:

- Don't slurp!

  Don't read an entire file into memory if you can process it line by line. Or more concretely, use a loop like this:

  ```
  #
  # Good Idea
  #
  while (<FILE>) {
     # ...
  }
  ```

  instead of this:

  ```
  #
  # Bad Idea
  #
  @data = <FILE>;
  foreach (@data) {
      # ...
  }
  ```

  When the files you're processing are small, it doesn't much matter which way you do it, but it makes a huge difference when they start getting larger.

- Use map and grep selectively

  Remember that both map and grep expect a LIST argument, so doing this:

  ```
  @wanted = grep {/pattern/} <FILE>;
  ```

  will cause the entire file to be slurped. For large files, it's better to loop:

  ```
  while (<FILE>) {
          push(@wanted, $_) if /pattern/;
  }
  ```

- Avoid unnecessary quotes and stringification

  Don't quote large strings unless absolutely necessary:

  ```
  my $copy = "$large_string";
  ```

  makes 2 copies of $large_string (one for $copy and another for the quotes), whereas

  ```
  my $copy = $large_string;
  ```

  only makes one copy.

  Ditto for stringifying large arrays:

  ```
  {
          local $, = "\n";
          print @big_array;
  }
  ```

  is much more memory-efficient than either

  ```
  print join "\n", @big_array;
  ```

or

```
        {
                local $" = "\n";
                print "@big_array";
        }
```

- Pass by reference

  Pass arrays and hashes by reference, not by value. For one thing, it's the only way to pass multiple lists or hashes (or both) in a single call/return. It also avoids creating a copy of all the contents. This requires some judgment, however, because any changes will be propagated back to the original data. If you really want to mangle (er, modify) a copy, you'll have to sacrifice the memory needed to make one.

- Tie large variables to disk.

  For "big" data stores (i.e. ones that exceed available memory) consider using one of the DB modules to store it on disk instead of in RAM. This will incur a penalty in access time, but that's probably better than causing your hard disk to thrash due to massive swapping.

19.1.18 Is it safe to return a reference to local or lexical data?

Yes. Perl's garbage collection system takes care of this so everything works out right.

```
    sub makeone {
        my @a = ( 1 .. 10 );
        return \@a;
    }

    for ( 1 .. 10 ) {
        push @many, makeone();
    }

    print $many[4][5], "\n";

    print "@many\n";
```

19.1.19 How can I free an array or hash so my program shrinks?

You usually can't. On most operating systems, memory allocated to a program can never be returned to the system. That's why long-running programs sometimes re-exec themselves. Some operating systems (notably, systems that use mmap(2) for allocating large chunks of memory) can reclaim memory that is no longer used, but on such systems, perl must be configured and compiled to use the OS's malloc, not perl's.

However, judicious use of my() on your variables will help make sure that they go out of scope so that Perl can free up that space for use in other parts of your program. A global variable, of course, never goes out of scope, so you can't get its space automatically reclaimed, although undef()ing and/or delete()ing it will achieve the same effect. In general, memory allocation and de-allocation isn't something you can or should be worrying about much in Perl, but even this capability (preallocation of data types) is in the works.

19.1.20 How can I make my CGI script more efficient?

Beyond the normal measures described to make general Perl programs faster or smaller, a CGI program has additional issues. It may be run several times per second. Given that each time it runs it will need to be re-compiled and will often allocate a megabyte or more of system memory, this can be a killer. Compiling into C **isn't going to help you** because the process start-up overhead is where the bottleneck is.

There are two popular ways to avoid this overhead. One solution involves running the Apache HTTP server (available from http://www.apache.org/) with either of the mod_perl or mod_fastcgi plugin modules.

With mod_perl and the Apache::Registry module (distributed with mod_perl), httpd will run with an embedded Perl interpreter which pre-compiles your script and then executes it within the same address space without forking. The Apache extension also gives Perl access to the internal server API, so modules written in Perl can do just about anything a module written in C can. For more on mod_perl, see http://perl.apache.org/

With the FCGI module (from CPAN) and the mod_fastcgi module (available from http://www.fastcgi.com/) each of your Perl programs becomes a permanent CGI daemon process.

Both of these solutions can have far-reaching effects on your system and on the way you write your CGI programs, so investigate them with care.

See http://www.cpan.org/modules/by-category/15_World_Wide_Web_HTML_HTTP_CGI/ .

A non-free, commercial product, "The Velocity Engine for Perl", (http://www.binevolve.com/ or http://www.binevolve.com/velocigen/) might also be worth looking at. It will allow you to increase the performance of your Perl programs, running programs up to 25 times faster than normal CGI Perl when running in persistent Perl mode or 4 to 5 times faster without any modification to your existing CGI programs. Fully functional evaluation copies are available from the web site.

19.1.21 How can I hide the source for my Perl program?

Delete it. :-) Seriously, there are a number of (mostly unsatisfactory) solutions with varying levels of "security".

First of all, however, you *can't* take away read permission, because the source code has to be readable in order to be compiled and interpreted. (That doesn't mean that a CGI script's source is readable by people on the web, though–only by people with access to the filesystem.) So you have to leave the permissions at the socially friendly 0755 level.

Some people regard this as a security problem. If your program does insecure things and relies on people not knowing how to exploit those insecurities, it is not secure. It is often possible for someone to determine the insecure things and exploit them without viewing the source. Security through obscurity, the name for hiding your bugs instead of fixing them, is little security indeed.

You can try using encryption via source filters (Starting from Perl 5.8 the Filter::Simple and Filter::Util::Call modules are included in the standard distribution), but any decent programmer will be able to decrypt it. You can try using the byte code compiler and interpreter described below, but the curious might still be able to de-compile it. You can try using the native-code compiler described below, but crackers might be able to disassemble it. These pose varying degrees of difficulty to people wanting to get at your code, but none can definitively conceal it (true of every language, not just Perl).

It is very easy to recover the source of Perl programs. You simply feed the program to the perl interpreter and use the modules in the B:: hierarchy. The B::Deparse module should be able to defeat most attempts to hide source. Again, this is not unique to Perl.

If you're concerned about people profiting from your code, then the bottom line is that nothing but a restrictive license will give you legal security. License your software and pepper it with threatening statements like "This is unpublished proprietary software of XYZ Corp. Your access to it does not give you permission to use it blah blah blah." We are not lawyers, of course, so you should see a lawyer if you want to be sure your license's wording will stand up in court.

19.1.22 How can I compile my Perl program into byte code or C?

Malcolm Beattie has written a multifunction backend compiler, available from CPAN, that can do both these things. It is included in the perl5.005 release, but is still considered experimental. This means it's fun to play with if you're a programmer but not really for people looking for turn-key solutions.

Merely compiling into C does not in and of itself guarantee that your code will run very much faster. That's because except for lucky cases where a lot of native type inferencing is possible, the normal Perl run-time system is still present and so your program will take just as long to run and be just as big. Most programs save little more than compilation time, leaving execution no more than 10-30% faster. A few rare programs actually benefit significantly (even running several times faster), but this takes some tweaking of your code.

You'll probably be astonished to learn that the current version of the compiler generates a compiled form of your script whose executable is just as big as the original perl executable, and then some. That's because as currently written, all programs are prepared for a full eval() statement. You can tremendously reduce this cost by building a shared *libperl.so* library and linking against that. See the *INSTALL* podfile in the Perl source distribution for details. If you link your main perl binary with this, it will make it minuscule. For example, on one author's system, */usr/bin/perl* is only 11k in size!

In general, the compiler will do nothing to make a Perl program smaller, faster, more portable, or more secure. In fact, it can make your situation worse. The executable will be bigger, your VM system may take longer to load the whole thing, the binary is fragile and hard to fix, and compilation never stopped software piracy in the form of crackers, viruses, or bootleggers. The real advantage of the compiler is merely packaging, and once you see the size of what it makes (well, unless you use a shared *libperl.so*), you'll probably want a complete Perl install anyway.

19.1.23 How can I compile Perl into Java?

You can also integrate Java and Perl with the Perl Resource Kit from O'Reilly and Associates. See http://www.oreilly.com/catalog/prkunix/ .

Perl 5.6 comes with Java Perl Lingo, or JPL. JPL, still in development, allows Perl code to be called from Java. See jpl/README in the Perl source tree.

19.1.24 How can I get `#!perl` to work on [MS-DOS,NT,...]?

For OS/2 just use

```
    extproc perl -S -your_switches
```

as the first line in `*.cmd` file (`-S` due to a bug in cmd.exe's 'extproc' handling). For DOS one should first invent a corresponding batch file and codify it in `ALTERNATE_SHEBANG` (see the *dosish.h* file in the source distribution for more information).

The Win95/NT installation, when using the ActiveState port of Perl, will modify the Registry to associate the `.pl` extension with the perl interpreter. If you install another port, perhaps even building your own Win95/NT Perl from the standard sources by using a Windows port of gcc (e.g., with cygwin or mingw32), then you'll have to modify the Registry yourself. In addition to associating `.pl` with the interpreter, NT people can use: `SET PATHEXT=%PATHEXT%;.PL` to let them run the program `install-linux.pl` merely by typing `install-linux`.

Macintosh Perl programs will have the appropriate Creator and Type, so that double-clicking them will invoke the Perl application.

IMPORTANT!: Whatever you do, PLEASE don't get frustrated, and just throw the perl interpreter into your cgi-bin directory, in order to get your programs working for a web server. This is an EXTREMELY big security risk. Take the time to figure out how to do it correctly.

19.1.25 Can I write useful Perl programs on the command line?

Yes. Read *perlrun* for more information. Some examples follow. (These assume standard Unix shell quoting rules.)

```
    # sum first and last fields
    perl -lane 'print $F[0] + $F[-1]' *

    # identify text files
    perl -le 'for(@ARGV) {print if -f && -T _}' *
    # remove (most) comments from C program
    perl -0777 -pe 's{/\*.*?\*/}{}gs' foo.c

    # make file a month younger than today, defeating reaper daemons
    perl -e '$X=24*60*60; utime(time(),time() + 30 * $X,@ARGV)' *

    # find first unused uid
    perl -le '$i++ while getpwuid($i); print $i'

    # display reasonable manpath
    echo $PATH | perl -nl -072 -e '
        s![^/+]*$!man!&&-d&&!$s{$_}++&&push@m,$_;END{print"@m"}'
```

OK, the last one was actually an Obfuscated Perl Contest entry. :-)

19.1.26 Why don't Perl one-liners work on my DOS/Mac/VMS system?

The problem is usually that the command interpreters on those systems have rather different ideas about quoting than the Unix shells under which the one-liners were created. On some systems, you may have to change single-quotes to double ones, which you must *NOT* do on Unix or Plan9 systems. You might also have to change a single % to a %%.

For example:

```
    # Unix
    perl -e 'print "Hello world\n"'

    # DOS, etc.
    perl -e "print \"Hello world\n\""

    # Mac
    print "Hello world\n"
     (then Run "Myscript" or Shift-Command-R)

    # MPW
    perl -e 'print "Hello world\n"'

    # VMS
    perl -e "print ""Hello world\n"""
```

The problem is that none of these examples are reliable: they depend on the command interpreter. Under Unix, the first two often work. Under DOS, it's entirely possible that neither works. If 4DOS was the command shell, you'd probably have better luck like this:

```
  perl -e "print <Ctrl-x>"Hello world\n<Ctrl-x>""
```

Under the Mac, it depends which environment you are using. The MacPerl shell, or MPW, is much like Unix shells in its support for several quoting variants, except that it makes free use of the Mac's non-ASCII characters as control characters.

Using qq(), q(), and qx(), instead of "double quotes", 'single quotes', and `backticks`, may make one-liners easier to write.

There is no general solution to all of this. It is a mess.

[Some of this answer was contributed by Kenneth Albanowski.]

19.1.27 Where can I learn about CGI or Web programming in Perl?

For modules, get the CGI or LWP modules from CPAN. For textbooks, see the two especially dedicated to web stuff in the question on books. For problems and questions related to the web, like “Why do I get 500 Errors” or “Why doesn’t it run from the browser right when it runs fine on the command line”, see the troubleshooting guides and references in *perlfaq9* or in the CGI MetaFAQ:

```
        http://www.perl.org/CGI_MetaFAQ.html
```

19.1.28 Where can I learn about object-oriented Perl programming?

A good place to start is *perltoot*, and you can use *perlobj*, *perlboot*, *perltoot*, *perltooc*, and *perlbot* for reference. (If you are using really old Perl, you may not have all of these, try http://www.perldoc.com/ , but consider upgrading your perl.)

A good book on OO on Perl is the "Object-Oriented Perl" by Damian Conway from Manning Publications, http://www.manning.com/Conway/index.html

19.1.29 Where can I learn about linking C with Perl? [h2xs, xsubpp]

If you want to call C from Perl, start with *perlxstut*, moving on to *perlxs*, *xsubpp*, and *perlguts*. If you want to call Perl from C, then read *perlembed*, *perlcall*, and *perlguts*. Don’t forget that you can learn a lot from looking at how the authors of existing extension modules wrote their code and solved their problems.

19.1.30 I’ve read perlembed, perlguts, etc., but I can’t embed perl in my C program; what am I doing wrong?

Download the ExtUtils::Embed kit from CPAN and run ‘make test’. If the tests pass, read the pods again and again and again. If they fail, see *perlbug* and send a bug report with the output of `make test TEST_VERBOSE=1` along with `perl -V`.

19.1.31 When I tried to run my script, I got this message. What does it mean?

A complete list of Perl’s error messages and warnings with explanatory text can be found in *perldiag*. You can also use the splain program (distributed with Perl) to explain the error messages:

```
    perl program 2>diag.out
    splain [-v] [-p] diag.out
```

or change your program to explain the messages for you:

```
    use diagnostics;
```

or

```
    use diagnostics -verbose;
```

19.1.32 What’s MakeMaker?

This module (part of the standard Perl distribution) is designed to write a Makefile for an extension module from a Makefile.PL. For more information, see *ExtUtils::MakeMaker*.

Data Manipulation ($Revision: 1.54 $, $Date: 2003/11/30 00:50:08 $)

20.1 DESCRIPTION

This section of the FAQ answers questions related to manipulating numbers, dates, strings, arrays, hashes, and miscellaneous data issues.

20.2 Data: Numbers

20.2.1 Why am I getting long decimals (eg, 19.9499999999999) instead of the numbers I should be getting (eg, 19.95)?

Internally, your computer represents floating-point numbers in binary. Digital (as in powers of two) computers cannot store all numbers exactly. Some real numbers lose precision in the process. This is a problem with how computers store numbers and affects all computer languages, not just Perl.

perlnumber show the gory details of number representations and conversions.

To limit the number of decimal places in your numbers, you can use the printf or sprintf function. See the "Floating Point Arithmetic" for more details.

```
        printf "%.2f", 10/3;

        my $number = sprintf "%.2f", 10/3;
```

20.2.2 Why is int() broken?

Your int() is most probably working just fine. It's the numbers that aren't quite what you think.

First, see the above item "Why am I getting long decimals (eg, 19.9499999999999) instead of the numbers I should be getting (eg, 19.95)?".

For example, this

```
    print int(0.6/0.2-2), "\n";
```

will in most computers print 0, not 1, because even such simple numbers as 0.6 and 0.2 cannot be presented exactly by floating-point numbers. What you think in the above as 'three' is really more like 2.9999999999999995559.

20.2.3 Why isn't my octal data interpreted correctly?

Perl only understands octal and hex numbers as such when they occur as literals in your program. Octal literals in perl must start with a leading "0" and hexadecimal literals must start with a leading "0x". If they are read in from somewhere and assigned, no automatic conversion takes place. You must explicitly use oct() or hex() if you want the values converted to decimal. oct() interprets hex ("0x350"), octal ("0350" or even without the leading "0", like "377") and binary ("0b1010") numbers, while hex() only converts hexadecimal ones, with or without a leading "0x", like "0x255", "3A", "ff", or "deadbeef". The inverse mapping from decimal to octal can be done with either the "%o" or "%O" sprintf() formats.

This problem shows up most often when people try using chmod(), mkdir(), umask(), or sysopen(), which by widespread tradition typically take permissions in octal.

```
chmod(644,  $file); # WRONG
chmod(0644, $file); # right
```

Note the mistake in the first line was specifying the decimal literal 644, rather than the intended octal literal 0644. The problem can be seen with:

```
printf("%#o",644); # prints 01204
```

Surely you had not intended `chmod(01204, $file);` - did you? If you want to use numeric literals as arguments to chmod() et al. then please try to express them as octal constants, that is with a leading zero and with the following digits restricted to the set 0..7.

20.2.4 Does Perl have a round() function? What about ceil() and floor()? Trig functions?

Remember that int() merely truncates toward 0. For rounding to a certain number of digits, sprintf() or printf() is usually the easiest route.

```
printf("%.3f", 3.1415926535);       # prints 3.142
```

The POSIX module (part of the standard Perl distribution) implements ceil(), floor(), and a number of other mathematical and trigonometric functions.

```
use POSIX;
$ceil   = ceil(3.5);                        # 4
$floor  = floor(3.5);                       # 3
```

In 5.000 to 5.003 perls, trigonometry was done in the Math::Complex module. With 5.004, the Math::Trig module (part of the standard Perl distribution) implements the trigonometric functions. Internally it uses the Math::Complex module and some functions can break out from the real axis into the complex plane, for example the inverse sine of 2.

Rounding in financial applications can have serious implications, and the rounding method used should be specified precisely. In these cases, it probably pays not to trust whichever system rounding is being used by Perl, but to instead implement the rounding function you need yourself.

To see why, notice how you'll still have an issue on half-way-point alternation:

```
for ($i = 0; $i < 1.01; $i += 0.05) { printf "%.1f ",$i}

0.0 0.1 0.1 0.2 0.2 0.2 0.3 0.3 0.4 0.4 0.5 0.5 0.6 0.7 0.7
0.8 0.8 0.9 0.9 1.0 1.0
```

Don't blame Perl. It's the same as in C. IEEE says we have to do this. Perl numbers whose absolute values are integers under 2**31 (on 32 bit machines) will work pretty much like mathematical integers. Other numbers are not guaranteed.

20.2.5 How do I convert between numeric representations/bases/radixes?

As always with Perl there is more than one way to do it. Below are a few examples of approaches to making common conversions between number representations. This is intended to be representational rather than exhaustive.

Some of the examples below use the Bit::Vector module from CPAN. The reason you might choose Bit::Vector over the perl built in functions is that it works with numbers of ANY size, that it is optimized for speed on some operations, and for at least some programmers the notation might be familiar.

How do I convert hexadecimal into decimal

Using perl's built in conversion of 0x notation:

```
$dec = 0xDEADBEEF;
```

Using the hex function:

```
$dec = hex("DEADBEEF");
```

Using pack:

```
$dec = unpack("N", pack("H8", substr("0" x 8 . "DEADBEEF", -8)));
```

Using the CPAN module Bit::Vector:

```
use Bit::Vector;
$vec = Bit::Vector->new_Hex(32, "DEADBEEF");
$dec = $vec->to_Dec();
```

How do I convert from decimal to hexadecimal

Using sprintf:

```
$hex = sprintf("%X", 3735928559); # upper case A-F
$hex = sprintf("%x", 3735928559); # lower case a-f
```

Using unpack:

```
$hex = unpack("H*", pack("N", 3735928559));
```

Using Bit::Vector:

```
use Bit::Vector;
$vec = Bit::Vector->new_Dec(32, -559038737);
$hex = $vec->to_Hex();
```

And Bit::Vector supports odd bit counts:

```
use Bit::Vector;
$vec = Bit::Vector->new_Dec(33, 3735928559);
$vec->Resize(32); # suppress leading 0 if unwanted
$hex = $vec->to_Hex();
```

How do I convert from octal to decimal

Using Perl's built in conversion of numbers with leading zeros:

```
    $dec = 033653337357; # note the leading 0!
```

Using the oct function:

```
    $dec = oct("33653337357");
```

Using Bit::Vector:

```
    use Bit::Vector;
    $vec = Bit::Vector->new(32);
    $vec->Chunk_List_Store(3, split(//, reverse "33653337357"));
    $dec = $vec->to_Dec();
```

How do I convert from decimal to octal

Using sprintf:

```
    $oct = sprintf("%o", 3735928559);
```

Using Bit::Vector:

```
    use Bit::Vector;
    $vec = Bit::Vector->new_Dec(32, -559038737);
    $oct = reverse join('', $vec->Chunk_List_Read(3));
```

How do I convert from binary to decimal

Perl 5.6 lets you write binary numbers directly with the 0b notation:

```
    $number = 0b10110110;
```

Using oct:

```
    my $input = "10110110";
    $decimal = oct( "0b$input" );
```

Using pack and ord:

```
    $decimal = ord(pack('B8', '10110110'));
```

Using pack and unpack for larger strings:

```
    $int = unpack("N", pack("B32",
        substr("0" x 32 . "11110101011011011111011101111", -32)));
    $dec = sprintf("%d", $int);

    # substr() is used to left pad a 32 character string with zeros.
```

Using Bit::Vector:

```
    $vec = Bit::Vector->new_Bin(32, "11011110101011011011111011101111");
    $dec = $vec->to_Dec();
```

How do I convert from decimal to binary

Using sprintf (perl 5.6+):

```
    $bin = sprintf("%b", 3735928559);
```

Using unpack:

```
    $bin = unpack("B*", pack("N", 3735928559));
```

Using Bit::Vector:

```
    use Bit::Vector;
    $vec = Bit::Vector->new_Dec(32, -559038737);
    $bin = $vec->to_Bin();
```

The remaining transformations (e.g. hex -> oct, bin -> hex, etc.) are left as an exercise to the inclined reader.

20.2.6 Why doesn't & work the way I want it to?

The behavior of binary arithmetic operators depends on whether they're used on numbers or strings. The operators treat a string as a series of bits and work with that (the string `"3"` is the bit pattern `00110011`). The operators work with the binary form of a number (the number 3 is treated as the bit pattern `00000011`).

So, saying `11 & 3` performs the "and" operation on numbers (yielding 3). Saying `"11" & "3"` performs the "and" operation on strings (yielding `"1"`).

Most problems with & and | arise because the programmer thinks they have a number but really it's a string. The rest arise because the programmer says:

```
if ("\020\020" & "\101\101") {
    # ...
}
```

but a string consisting of two null bytes (the result of `"\020\020" & "\101\101"`) is not a false value in Perl. You need:

```
if ( ("\020\020" & "\101\101") !~ /[^\000]/) {
    # ...
}
```

20.2.7 How do I multiply matrices?

Use the Math::Matrix or Math::MatrixReal modules (available from CPAN) or the PDL extension (also available from CPAN).

20.2.8 How do I perform an operation on a series of integers?

To call a function on each element in an array, and collect the results, use:

```
@results = map { my_func($_) } @array;
```

For example:

```
@triple = map { 3 * $_ } @single;
```

To call a function on each element of an array, but ignore the results:

```
foreach $iterator (@array) {
    some_func($iterator);
}
```

To call a function on each integer in a (small) range, you **can** use:

```
    @results = map { some_func($_) } (5 .. 25);
```

but you should be aware that the `..` operator creates an array of all integers in the range. This can take a lot of memory for large ranges. Instead use:

```
    @results = ();
    for ($i=5; $i < 500_005; $i++) {
        push(@results, some_func($i));
    }
```

This situation has been fixed in Perl5.005. Use of `..` in a `for` loop will iterate over the range, without creating the entire range.

```
    for my $i (5 .. 500_005) {
        push(@results, some_func($i));
    }
```

will not create a list of 500,000 integers.

20.2.9 How can I output Roman numerals?

Get the http://www.cpan.org/modules/by-module/Roman module.

20.2.10 Why aren't my random numbers random?

If you're using a version of Perl before 5.004, you must call `srand` once at the start of your program to seed the random number generator.

```
         BEGIN { srand() if $] < 5.004 }
```

5.004 and later automatically call `srand` at the beginning. Don't call `srand` more than once—you make your numbers less random, rather than more.

Computers are good at being predictable and bad at being random (despite appearances caused by bugs in your programs :-). see the *random* article in the "Far More Than You Ever Wanted To Know" collection in http://www.cpan.org/misc/olddoc/FMTEYEWTK.tgz , courtesy of Tom Phoenix, talks more about this. John von Neumann said, "Anyone who attempts to generate random numbers by deterministic means is, of course, living in a state of sin."

If you want numbers that are more random than `rand` with `srand` provides, you should also check out the Math::TrulyRandom module from CPAN. It uses the imperfections in your system's timer to generate random numbers, but this takes quite a while. If you want a better pseudorandom generator than comes with your operating system, look at "Numerical Recipes in C" at http://www.nr.com/ .

20.2.11 How do I get a random number between X and Y?

`rand($x)` returns a number such that `0 <= rand($x) < $x`. Thus what you want to have perl figure out is a random number in the range from 0 to the difference between your *X* and *Y*.

That is, to get a number between 10 and 15, inclusive, you want a random number between 0 and 5 that you can then add to 10.

```
    my $number = 10 + int rand( 15-10+1 );
```

Hence you derive the following simple function to abstract that. It selects a random integer between the two given integers (inclusive), For example: `random_int_in(50,120)`.

```
sub random_int_in ($$) {
  my($min, $max) = @_;
   # Assumes that the two arguments are integers themselves!
  return $min if $min == $max;
  ($min, $max) = ($max, $min)  if  $min > $max;
  return $min + int rand(1 + $max - $min);
}
```

20.3 Data: Dates

20.3.1 How do I find the day or week of the year?

The localtime function returns the day of the week. Without an argument localtime uses the current time.

```
$day_of_year = (localtime)[7];
```

The POSIX module can also format a date as the day of the year or week of the year.

```
use POSIX qw/strftime/;
my $day_of_year  = strftime "%j", localtime;
my $week_of_year = strftime "%W", localtime;
```

To get the day of year for any date, use the Time::Local module to get a time in epoch seconds for the argument to localtime.

```
use POSIX qw/strftime/;
use Time::Local;
my $week_of_year = strftime "%W",
        localtime( timelocal( 0, 0, 0, 18, 11, 1987 ) );
```

The Date::Calc module provides two functions for to calculate these.

```
use Date::Calc;
my $day_of_year  = Day_of_Year(  1987, 12, 18 );
my $week_of_year = Week_of_Year( 1987, 12, 18 );
```

20.3.2 How do I find the current century or millennium?

Use the following simple functions:

```
sub get_century    {
    return int((((localtime(shift || time))[5] + 1999))/100);
}
sub get_millennium {
    return 1+int((((localtime(shift || time))[5] + 1899))/1000);
}
```

On some systems, the POSIX module's strftime() function has been extended in a non-standard way to use a `%C` format, which they sometimes claim is the "century". It isn't, because on most such systems, this is only the first two digits of the four-digit year, and thus cannot be used to reliably determine the current century or millennium.

20.3.3 How can I compare two dates and find the difference?

If you're storing your dates as epoch seconds then simply subtract one from the other. If you've got a structured date (distinct year, day, month, hour, minute, seconds values), then for reasons of accessibility, simplicity, and efficiency, merely use either timelocal or timegm (from the Time::Local module in the standard distribution) to reduce structured dates to epoch seconds. However, if you don't know the precise format of your dates, then you should probably use either of the Date::Manip and Date::Calc modules from CPAN before you go hacking up your own parsing routine to handle arbitrary date formats.

20.3.4 How can I take a string and turn it into epoch seconds?

If it's a regular enough string that it always has the same format, you can split it up and pass the parts to `timelocal` in the standard Time::Local module. Otherwise, you should look into the Date::Calc and Date::Manip modules from CPAN.

20.3.5 How can I find the Julian Day?

Use the Time::JulianDay module (part of the Time-modules bundle available from CPAN.)

Before you immerse yourself too deeply in this, be sure to verify that it is the *Julian* Day you really want. Are you interested in a way of getting serial days so that you just can tell how many days they are apart or so that you can do also other date arithmetic? If you are interested in performing date arithmetic, this can be done using modules Date::Manip or Date::Calc.

There is too many details and much confusion on this issue to cover in this FAQ, but the term is applied (correctly) to a calendar now supplanted by the Gregorian Calendar, with the Julian Calendar failing to adjust properly for leap years on centennial years (among other annoyances). The term is also used (incorrectly) to mean: [1] days in the Gregorian Calendar; and [2] days since a particular starting time or 'epoch', usually 1970 in the Unix world and 1980 in the MS-DOS/Windows world. If you find that it is not the first meaning that you really want, then check out the Date::Manip and Date::Calc modules. (Thanks to David Cassell for most of this text.)

20.3.6 How do I find yesterday's date?

If you only need to find the date (and not the same time), you can use the Date::Calc module.

```
        use Date::Calc qw(Today Add_Delta_Days);

        my @date = Add_Delta_Days( Today(), -1 );

        print "@date\n";
```

Most people try to use the time rather than the calendar to figure out dates, but that assumes that your days are twenty-four hours each. For most people, there are two days a year when they aren't: the switch to and from summer time throws this off. Russ Allbery offers this solution.

```
    sub yesterday {
                my $now  = defined $_[0] ? $_[0] : time;
                my $then = $now - 60 * 60 * 24;
                my $ndst = (localtime $now)[8] > 0;
                my $tdst = (localtime $then)[8] > 0;
                $then - ($tdst - $ndst) * 60 * 60;
                }
```

Should give you "this time yesterday" in seconds since epoch relative to the first argument or the current time if no argument is given and suitable for passing to localtime or whatever else you need to do with it. $ndst is whether we're currently in daylight savings time; $tdst is whether the point 24 hours ago was in daylight savings time. If $tdst and $ndst are the same, a boundary wasn't crossed, and the correction will subtract 0. If $tdst is 1 and $ndst is 0, subtract an hour more from yesterday's time since we gained an extra hour while going off daylight savings time. If $tdst is 0 and $ndst is 1, subtract a negative hour (add an hour) to yesterday's time since we lost an hour.

All of this is because during those days when one switches off or onto DST, a "day" isn't 24 hours long; it's either 23 or 25.

The explicit settings of $ndst and $tdst are necessary because localtime only says it returns the system tm struct, and the system tm struct at least on Solaris doesn't guarantee any particular positive value (like, say, 1) for isdst, just a positive value. And that value can potentially be negative, if DST information isn't available (this sub just treats those cases like no DST).

Note that between 2am and 3am on the day after the time zone switches off daylight savings time, the exact hour of "yesterday" corresponding to the current hour is not clearly defined. Note also that if used between 2am and 3am the day after the change to daylight savings time, the result will be between 3am and 4am of the previous day; it's arguable whether this is correct.

This sub does not attempt to deal with leap seconds (most things don't).

20.3.7 Does Perl have a Year 2000 problem? Is Perl Y2K compliant?

Short answer: No, Perl does not have a Year 2000 problem. Yes, Perl is Y2K compliant (whatever that means). The programmers you've hired to use it, however, probably are not.

Long answer: The question belies a true understanding of the issue. Perl is just as Y2K compliant as your pencil–no more, and no less. Can you use your pencil to write a non-Y2K-compliant memo? Of course you can. Is that the pencil's fault? Of course it isn't.

The date and time functions supplied with Perl (gmtime and localtime) supply adequate information to determine the year well beyond 2000 (2038 is when trouble strikes for 32-bit machines). The year returned by these functions when used in a list context is the year minus 1900. For years between 1910 and 1999 this *happens* to be a 2-digit decimal number. To avoid the year 2000 problem simply do not treat the year as a 2-digit number. It isn't.

When gmtime() and localtime() are used in scalar context they return a timestamp string that contains a fully-expanded year. For example, `$timestamp = gmtime(1005613200)` sets $timestamp to "Tue Nov 13 01:00:00 2001". There's no year 2000 problem here.

That doesn't mean that Perl can't be used to create non-Y2K compliant programs. It can. But so can your pencil. It's the fault of the user, not the language. At the risk of inflaming the NRA: "Perl doesn't break Y2K, people do." See http://language.perl.com/news/y2k.html for a longer exposition.

20.4 Data: Strings

20.4.1 How do I validate input?

The answer to this question is usually a regular expression, perhaps with auxiliary logic. See the more specific questions (numbers, mail addresses, etc.) for details.

20.4.2 How do I unescape a string?

It depends just what you mean by "escape". URL escapes are dealt with in *perlfaq9*. Shell escapes with the backslash (\) character are removed with

```
    s/\\(.)/$1/g;
```

This won't expand `"\n"` or `"\t"` or any other special escapes.

20.4.3 How do I remove consecutive pairs of characters?

To turn "abbcccd" into "abccd":

```
s/(.)\1/$1/g;       # add /s to include newlines
```

Here's a solution that turns "abbcccd" to "abcd":

```
y///cs;     # y == tr, but shorter :-)
```

20.4.4 How do I expand function calls in a string?

This is documented in *perlref*. In general, this is fraught with quoting and readability problems, but it is possible. To interpolate a subroutine call (in list context) into a string:

```
print "My sub returned @{[mysub(1,2,3)]} that time.\n";
```

See also "How can I expand variables in text strings?" in this section of the FAQ.

20.4.5 How do I find matching/nesting anything?

This isn't something that can be done in one regular expression, no matter how complicated. To find something between two single characters, a pattern like `/x([^x]*)x/` will get the intervening bits in $1. For multiple ones, then something more like `/alpha(.*?)omega/` would be needed. But none of these deals with nested patterns. For balanced expressions using `(`, `{`, `[` or `<` as delimiters, use the CPAN module Regexp::Common, or see (??{ code }) in *perlre*. For other cases, you'll have to write a parser.

If you are serious about writing a parser, there are a number of modules or oddities that will make your life a lot easier. There are the CPAN modules Parse::RecDescent, Parse::Yapp, and Text::Balanced; and the byacc program. Starting from perl 5.8 the Text::Balanced is part of the standard distribution.

One simple destructive, inside-out approach that you might try is to pull out the smallest nesting parts one at a time:

```
while (s/BEGIN((?:(?!BEGIN)(?!END).)*)END//gs) {
    # do something with $1
}
```

A more complicated and sneaky approach is to make Perl's regular expression engine do it for you. This is courtesy Dean Inada, and rather has the nature of an Obfuscated Perl Contest entry, but it really does work:

```
# $_ contains the string to parse
# BEGIN and END are the opening and closing markers for the
# nested text.

@( = ('(','');
@) = (')','');
($re=$_)=~s/((BEGIN)|(END)|.)/$)[!$3]\Q$1\E$([!$2]/gs;
@$ = (eval{/$re/},$@!~/unmatched/i);
print join("\n",@$[0..$#$]) if( $$[-1] );
```

20.4.6 How do I reverse a string?

Use reverse() in scalar context, as documented in reverse in *perlfunc*.

```
$reversed = reverse $string;
```

20.4.7 How do I expand tabs in a string?

You can do it yourself:

```
1 while $string =~ s/\t+/' ' x (length($&) * 8 - length($`) % 8)/e;
```

Or you can just use the Text::Tabs module (part of the standard Perl distribution).

```
use Text::Tabs;
@expanded_lines = expand(@lines_with_tabs);
```

20.4.8 How do I reformat a paragraph?

Use Text::Wrap (part of the standard Perl distribution):

```
use Text::Wrap;
print wrap("\t", '  ', @paragraphs);
```

The paragraphs you give to Text::Wrap should not contain embedded newlines. Text::Wrap doesn't justify the lines (flush-right).

Or use the CPAN module Text::Autoformat. Formatting files can be easily done by making a shell alias, like so:

```
alias fmt="perl -i -MText::Autoformat -n0777 \
    -e 'print autoformat $_, {all=>1}' $*"
```

See the documentation for Text::Autoformat to appreciate its many capabilities.

20.4.9 How can I access or change N characters of a string?

You can access the first characters of a string with substr(). To get the first character, for example, start at position 0 and grab the string of length 1.

```
    $string = "Just another Perl Hacker";
$first_char = substr( $string, 0, 1 );  #  'J'
```

To change part of a string, you can use the optional fourth argument which is the replacement string.

```
substr( $string, 13, 4, "Perl 5.8.0" );
```

You can also use substr() as an lvalue.

```
substr( $string, 13, 4 ) =  "Perl 5.8.0";
```

20.4.10 How do I change the Nth occurrence of something?

You have to keep track of N yourself. For example, let's say you want to change the fifth occurrence of "whoever" or "whomever" into "whosoever" or "whomsoever", case insensitively. These all assume that $_ contains the string to be altered.

```
$count = 0;
s{((whom?)ever)}{
    ++$count == 5           # is it the 5th?
        ? "${2}soever"      # yes, swap
        : $1                # renege and leave it there
}ige;
```

In the more general case, you can use the /g modifier in a while loop, keeping count of matches.

```
$WANT = 3;
$count = 0;
$_ = "One fish two fish red fish blue fish";
while (/(\w+)\s+fish\b/gi) {
    if (++$count == $WANT) {
        print "The third fish is a $1 one.\n";
    }
}
```

That prints out: "The third fish is a red one." You can also use a repetition count and repeated pattern like this:

```
/(?:\w+\s+fish\s+){2}(\w+)\s+fish/i;
```

20.4.11 How can I count the number of occurrences of a substring within a string?

There are a number of ways, with varying efficiency. If you want a count of a certain single character (X) within a string, you can use the tr/// function like so:

```
$string = "ThisXlineXhasXsomeXx'sXinXit";
$count = ($string =~ tr/X//);
print "There are $count X characters in the string";
```

This is fine if you are just looking for a single character. However, if you are trying to count multiple character substrings within a larger string, tr/// won't work. What you can do is wrap a while() loop around a global pattern match. For example, let's count negative integers:

```
$string = "-9 55 48 -2 23 -76 4 14 -44";
while ($string =~ /-\d+/g) { $count++ }
print "There are $count negative numbers in the string";
```

Another version uses a global match in list context, then assigns the result to a scalar, producing a count of the number of matches.

```
    $count = () = $string =~ /-\d+/g;
```

20.4.12 How do I capitalize all the words on one line?

To make the first letter of each word upper case:

```
        $line =~ s/\b(\w)/\U$1/g;
```

This has the strange effect of turning "`don't do it`" into "`Don'T Do It`". Sometimes you might want this. Other times you might need a more thorough solution (Suggested by brian d foy):

```
    $string =~ s/ (
                 (^\w)    #at the beginning of the line
                   |      # or
                 (\s\w)   #preceded by whitespace
                   )
                /\U$1/xg;
    $string =~ /([\w']+)/\u\L$1/g;
```

To make the whole line upper case:

```
        $line = uc($line);
```

To force each word to be lower case, with the first letter upper case:

```
        $line =~ s/(\w+)/\u\L$1/g;
```

You can (and probably should) enable locale awareness of those characters by placing a `use locale` pragma in your program. See *perllocale* for endless details on locales.

This is sometimes referred to as putting something into "title case", but that's not quite accurate. Consider the proper capitalization of the movie *Dr. Strangelove or: How I Learned to Stop Worrying and Love the Bomb*, for example.

Damian Conway's *Text::Autoformat* module provides some smart case transformations:

```
    use Text::Autoformat;
    my $x = "Dr. Strangelove or: How I Learned to Stop ".
      "Worrying and Love the Bomb";

    print $x, "\n";
    for my $style (qw( sentence title highlight ))
    {
        print autoformat($x, { case => $style }), "\n";
    }
```

20.4.13 How can I split a [character] delimited string except when inside [character]?

Several modules can handle this sort of pasing—Text::Balanced, Text::CVS, Text::CVS_XS, and Text::ParseWords, among others.

Take the example case of trying to split a string that is comma-separated into its different fields. You can't use `split(/,/)` because you shouldn't split if the comma is inside quotes. For example, take a data line like this:

```
    SAR001,"","Cimetrix, Inc","Bob Smith","CAM",N,8,1,0,7,"Error, Core Dumped"
```

Due to the restriction of the quotes, this is a fairly complex problem. Thankfully, we have Jeffrey Friedl, author of *Mastering Regular Expressions*, to handle these for us. He suggests (assuming your string is contained in $text):

```
 @new = ();
 push(@new, $+) while $text =~ m{
     "([^\"\\]*(?:\\.[^\"\\]*)*)",?  # groups the phrase inside the quotes
   | ([^,]+),?
   | ,
 }gx;
 push(@new, undef) if substr($text,-1,1) eq ',';
```

If you want to represent quotation marks inside a quotation-mark-delimited field, escape them with backslashes (eg, `"like \"this\""`.

Alternatively, the Text::ParseWords module (part of the standard Perl distribution) lets you say:

```
use Text::ParseWords;
@new = quotewords(",", 0, $text);
```

There's also a Text::CSV (Comma-Separated Values) module on CPAN.

20.4.14 How do I strip blank space from the beginning/end of a string?

Although the simplest approach would seem to be

```
$string =~ s/^\s*(.*?)\s*$/$1/;
```

not only is this unnecessarily slow and destructive, it also fails with embedded newlines. It is much faster to do this operation in two steps:

```
$string =~ s/^\s+//;
$string =~ s/\s+$//;
```

Or more nicely written as:

```
for ($string) {
    s/^\s+//;
    s/\s+$//;
}
```

This idiom takes advantage of the `foreach` loop's aliasing behavior to factor out common code. You can do this on several strings at once, or arrays, or even the values of a hash if you use a slice:

```
# trim whitespace in the scalar, the array,
# and all the values in the hash
foreach ($scalar, @array, @hash{keys %hash}) {
    s/^\s+//;
    s/\s+$//;
}
```

20.4.15 How do I pad a string with blanks or pad a number with zeroes?

In the following examples, `$pad_len` is the length to which you wish to pad the string, `$text` or `$num` contains the string to be padded, and `$pad_char` contains the padding character. You can use a single character string constant instead of the `$pad_char` variable if you know what it is in advance. And in the same way you can use an integer in place of `$pad_len` if you know the pad length in advance.

The simplest method uses the `sprintf` function. It can pad on the left or right with blanks and on the left with zeroes and it will not truncate the result. The `pack` function can only pad strings on the right with blanks and it will truncate the result to a maximum length of `$pad_len`.

```
# Left padding a string with blanks (no truncation):
    $padded = sprintf("%${pad_len}s", $text);
    $padded = sprintf("%*s", $pad_len, $text);  # same thing

# Right padding a string with blanks (no truncation):
    $padded = sprintf("%-${pad_len}s", $text);
    $padded = sprintf("%-*s", $pad_len, $text); # same thing

# Left padding a number with 0 (no truncation):
    $padded = sprintf("%0${pad_len}d", $num);
    $padded = sprintf("%0*d", $pad_len, $num); # same thing

# Right padding a string with blanks using pack (will truncate):
$padded = pack("A$pad_len",$text);
```

If you need to pad with a character other than blank or zero you can use one of the following methods. They all generate a pad string with the `x` operator and combine that with `$text`. These methods do not truncate `$text`.

Left and right padding with any character, creating a new string:

```
$padded = $pad_char x ( $pad_len - length( $text ) ) . $text;
$padded = $text . $pad_char x ( $pad_len - length( $text ) );
```

Left and right padding with any character, modifying `$text` directly:

```
substr( $text, 0, 0 ) = $pad_char x ( $pad_len - length( $text ) );
$text .= $pad_char x ( $pad_len - length( $text ) );
```

20.4.16 How do I extract selected columns from a string?

Use substr() or unpack(), both documented in *perlfunc*. If you prefer thinking in terms of columns instead of widths, you can use this kind of thing:

```
# determine the unpack format needed to split Linux ps output
# arguments are cut columns
my $fmt = cut2fmt(8, 14, 20, 26, 30, 34, 41, 47, 59, 63, 67, 72);

sub cut2fmt {
    my(@positions) = @_;
    my $template  = '';
    my $lastpos   = 1;
    for my $place (@positions) {
        $template .= "A" . ($place - $lastpos) . " ";
        $lastpos   = $place;
    }
    $template .= "A*";
    return $template;
}
```

20.4.17 How do I find the soundex value of a string?

Use the standard Text::Soundex module distributed with Perl. Before you do so, you may want to determine whether 'soundex' is in fact what you think it is. Knuth's soundex algorithm compresses words into a small space, and so it does not necessarily distinguish between two words which you might want to appear separately. For example, the last names 'Knuth' and 'Kant' are both mapped to the soundex code K530. If Text::Soundex does not do what you are looking for, you might want to consider the String::Approx module available at CPAN.

20.4.18 How can I expand variables in text strings?

Let’s assume that you have a string like:

```
    $text = 'this has a $foo in it and a $bar';
```

If those were both global variables, then this would suffice:

```
    $text =~ s/\$(\w+)/${$1}/g;  # no /e needed
```

But since they are probably lexicals, or at least, they could be, you’d have to do this:

```
    $text =~ s/(\$\w+)/$1/eeg;
    die if $@;                  # needed /ee, not /e
```

It’s probably better in the general case to treat those variables as entries in some special hash. For example:

```
    %user_defs = (
        foo  => 23,
        bar  => 19,
    );
    $text =~ s/\$(\w+)/$user_defs{$1}/g;
```

See also “How do I expand function calls in a string?” in this section of the FAQ.

20.4.19 What’s wrong with always quoting "$ vars"?

The problem is that those double-quotes force stringification– coercing numbers and references into strings–even when you don’t want them to be strings. Think of it this way: double-quote expansion is used to produce new strings. If you already have a string, why do you need more?

If you get used to writing odd things like these:

```
    print "$var";       # BAD
    $new = "$old";      # BAD
    somefunc("$var");   # BAD
```

You’ll be in trouble. Those should (in 99.8% of the cases) be the simpler and more direct:

```
    print $var;
    $new = $old;
    somefunc($var);
```

Otherwise, besides slowing you down, you’re going to break code when the thing in the scalar is actually neither a string nor a number, but a reference:

```
    func(\@array);
    sub func {
        my $aref = shift;
        my $oref = "$aref";  # WRONG
    }
```

You can also get into subtle problems on those few operations in Perl that actually do care about the difference between a string and a number, such as the magical ++ autoincrement operator or the syscall() function.

Stringification also destroys arrays.

```
    @lines = `command`;
    print "@lines";             # WRONG - extra blanks
    print @lines;               # right
```

20.4.20 Why don't my <<HERE documents work?

Check for these three things:

There must be no space after the << part.

There (probably) should be a semicolon at the end.

You can't (easily) have any space in front of the tag.

If you want to indent the text in the here document, you can do this:

```
    # all in one
    ($VAR = <<HERE_TARGET) =~ s/^\s+//gm;
        your text
        goes here
    HERE_TARGET
```

But the HERE_TARGET must still be flush against the margin. If you want that indented also, you'll have to quote in the indentation.

```
    ($quote = <<'    FINIS') =~ s/^\s+//gm;
            ...we will have peace, when you and all your works have
            perished--and the works of your dark master to whom you
            would deliver us. You are a liar, Saruman, and a corrupter
            of men's hearts.  --Theoden in /usr/src/perl/taint.c
        FINIS
    $quote =~ s/\s+--/\n--/;
```

A nice general-purpose fixer-upper function for indented here documents follows. It expects to be called with a here document as its argument. It looks to see whether each line begins with a common substring, and if so, strips that substring off. Otherwise, it takes the amount of leading whitespace found on the first line and removes that much off each subsequent line.

```
    sub fix {
        local $_ = shift;
        my ($white, $leader);  # common whitespace and common leading string
        if (/^\s*(?:([^\w\s]+)(\s*).*\n)(?:\s*\1\2?.*\n)+$/) {
            ($white, $leader) = ($2, quotemeta($1));
        } else {
            ($white, $leader) = (/^(\s+)/, '');
        }
        s/^\s*?$leader(?:$white)?//gm;
        return $_;
    }
```

This works with leading special strings, dynamically determined:

```
    $remember_the_main = fix<<'    MAIN_INTERPRETER_LOOP';
        @@@ int
        @@@ runops() {
        @@@     SAVEI32(runlevel);
        @@@     runlevel++;
        @@@     while ( op = (*op->op_ppaddr)() );
        @@@     TAINT_NOT;
        @@@     return 0;
        @@@ }
    MAIN_INTERPRETER_LOOP
```

Or with a fixed amount of leading whitespace, with remaining indentation correctly preserved:

```
$poem = fix<<EVER_ON_AND_ON;
   Now far ahead the Road has gone,
      And I must follow, if I can,
   Pursuing it with eager feet,
      Until it joins some larger way
   Where many paths and errands meet.
      And whither then? I cannot say.
            --Bilbo in /usr/src/perl/pp_ctl.c
EVER_ON_AND_ON
```

20.5 Data: Arrays

20.5.1 What is the difference between a list and an array?

An array has a changeable length. A list does not. An array is something you can push or pop, while a list is a set of values. Some people make the distinction that a list is a value while an array is a variable. Subroutines are passed and return lists, you put things into list context, you initialize arrays with lists, and you foreach() across a list. `@` variables are arrays, anonymous arrays are arrays, arrays in scalar context behave like the number of elements in them, subroutines access their arguments through the array `@_`, and push/pop/shift only work on arrays.

As a side note, there's no such thing as a list in scalar context. When you say

```
$scalar = (2, 5, 7, 9);
```

you're using the comma operator in scalar context, so it uses the scalar comma operator. There never was a list there at all! This causes the last value to be returned: 9.

20.5.2 What is the difference between $ array[1] and @array[1]?

The former is a scalar value; the latter an array slice, making it a list with one (scalar) value. You should use $ when you want a scalar value (most of the time) and @ when you want a list with one scalar value in it (very, very rarely; nearly never, in fact).

Sometimes it doesn't make a difference, but sometimes it does. For example, compare:

```
$good[0] = `some program that outputs several lines`;
```

with

```
@bad[0]  = `same program that outputs several lines`;
```

The `use warnings` pragma and the **-w** flag will warn you about these matters.

20.5.3 How can I remove duplicate elements from a list or array?

There are several possible ways, depending on whether the array is ordered and whether you wish to preserve the ordering.

a)

If @in is sorted, and you want @out to be sorted: (this assumes all true values in the array)

```
$prev = "not equal to $in[0]";
@out = grep($_ ne $prev && ($prev = $_, 1), @in);
```

This is nice in that it doesn't use much extra memory, simulating uniq(1)'s behavior of removing only adjacent duplicates. The ", 1" guarantees that the expression is true (so that grep picks it up) even if the $_ is 0, "", or undef.

b)

If you don't know whether @in is sorted:

```
undef %saw;
@out = grep(!$saw{$_}++, @in);
```

c)

Like (b), but @in contains only small integers:

```
@out = grep(!$saw[$_]++, @in);
```

d)

A way to do (b) without any loops or greps:

```
undef %saw;
@saw{@in} = ();
@out = sort keys %saw;  # remove sort if undesired
```

e)

Like (d), but @in contains only small positive integers:

```
undef @ary;
@ary[@in] = @in;
@out = grep {defined} @ary;
```

But perhaps you should have been using a hash all along, eh?

20.5.4 How can I tell whether a certain element is contained in a list or array?

Hearing the word "in" is an *in*dication that you probably should have used a hash, not a list or array, to store your data. Hashes are designed to answer this question quickly and efficiently. Arrays aren't.

That being said, there are several ways to approach this. If you are going to make this query many times over arbitrary string values, the fastest way is probably to invert the original array and maintain a hash whose keys are the first array's values.

```
@blues = qw/azure cerulean teal turquoise lapis-lazuli/;
%is_blue = ();
for (@blues) { $is_blue{$_} = 1 }
```

Now you can check whether $is_blue{$some_color}. It might have been a good idea to keep the blues all in a hash in the first place.

If the values are all small integers, you could use a simple indexed array. This kind of an array will take up less space:

```
@primes = (2, 3, 5, 7, 11, 13, 17, 19, 23, 29, 31);
@is_tiny_prime = ();
for (@primes) { $is_tiny_prime[$_] = 1 }
# or simply  @istiny_prime[@primes] = (1) x @primes;
```

Now you check whether $is_tiny_prime[$some_number].

If the values in question are integers instead of strings, you can save quite a lot of space by using bit strings instead:

```
@articles = ( 1..10, 150..2000, 2017 );
undef $read;
for (@articles) { vec($read,$_,1) = 1 }
```

Now check whether `vec($read,$n,1)` is true for some `$n`.

Please do not use

```
($is_there) = grep $_ eq $whatever, @array;
```

or worse yet

```
($is_there) = grep /$whatever/, @array;
```

These are slow (checks every element even if the first matches), inefficient (same reason), and potentially buggy (what if there are regex characters in $whatever?). If you're only testing once, then use:

```
$is_there = 0;
foreach $elt (@array) {
    if ($elt eq $elt_to_find) {
        $is_there = 1;
        last;
    }
}
if ($is_there) { ... }
```

20.5.5 How do I compute the difference of two arrays? How do I compute the intersection of two arrays?

Use a hash. Here's code to do both and more. It assumes that each element is unique in a given array:

```
@union = @intersection = @difference = ();
%count = ();
foreach $element (@array1, @array2) { $count{$element}++ }
foreach $element (keys %count) {
    push @union, $element;
    push @{ $count{$element} > 1 ? \@intersection : \@difference }, $element;
}
```

Note that this is the *symmetric difference*, that is, all elements in either A or in B but not in both. Think of it as an xor operation.

20.5.6 How do I test whether two arrays or hashes are equal?

The following code works for single-level arrays. It uses a stringwise comparison, and does not distinguish defined versus undefined empty strings. Modify if you have other needs.

```
$are_equal = compare_arrays(\@frogs, \@toads);

sub compare_arrays {
    my ($first, $second) = @_;
    no warnings;  # silence spurious -w undef complaints
    return 0 unless @$first == @$second;
    for (my $i = 0; $i < @$first; $i++) {
        return 0 if $first->[$i] ne $second->[$i];
    }
    return 1;
}
```

For multilevel structures, you may wish to use an approach more like this one. It uses the CPAN module FreezeThaw:

```
use FreezeThaw qw(cmpStr);
@a = @b = ( "this", "that", [ "more", "stuff" ] );

printf "a and b contain %s arrays\n",
    cmpStr(\@a, \@b) == 0
        ? "the same"
        : "different";
```

This approach also works for comparing hashes. Here we'll demonstrate two different answers:

```
use FreezeThaw qw(cmpStr cmpStrHard);

%a = %b = ( "this" => "that", "extra" => [ "more", "stuff" ] );
$a{EXTRA} = \%b;
$b{EXTRA} = \%a;

printf "a and b contain %s hashes\n",
    cmpStr(\%a, \%b) == 0 ? "the same" : "different";

printf "a and b contain %s hashes\n",
    cmpStrHard(\%a, \%b) == 0 ? "the same" : "different";
```

The first reports that both those the hashes contain the same data, while the second reports that they do not. Which you prefer is left as an exercise to the reader.

20.5.7 How do I find the first array element for which a condition is true?

To find the first array element which satisfies a condition, you can use the first() function in the List::Util module, which comes with Perl 5.8. This example finds the first element that contains "Perl".

```
        use List::Util qw(first);

        my $element = first { /Perl/ } @array;
```

If you cannot use List::Util, you can make your own loop to do the same thing. Once you find the element, you stop the loop with last.

```
        my $found;
        foreach my $element ( @array )
                {
                if( /Perl/ ) { $found = $element; last }
                }
```

If you want the array index, you can iterate through the indices and check the array element at each index until you find one that satisfies the condition.

```
        my( $found, $index ) = ( undef, -1 );
    for( $i = 0; $i < @array; $i++ )
        {
        if( $array[$i] =~ /Perl/ )
                {
                $found = $array[$i];
                $index = $i;
                last;
                }
        }
```

20.5.8 How do I handle linked lists?

In general, you usually don't need a linked list in Perl, since with regular arrays, you can push and pop or shift and unshift at either end, or you can use splice to add and/or remove arbitrary number of elements at arbitrary points. Both pop and shift are both O(1) operations on Perl's dynamic arrays. In the absence of shifts and pops, push in general needs to reallocate on the order every log(N) times, and unshift will need to copy pointers each time.

If you really, really wanted, you could use structures as described in *perldsc* or *perltoot* and do just what the algorithm book tells you to do. For example, imagine a list node like this:

```
$node = {
    VALUE => 42,
    LINK  => undef,
};
```

You could walk the list this way:

```
print "List: ";
for ($node = $head;  $node; $node = $node->{LINK}) {
    print $node->{VALUE}, " ";
}
print "\n";
```

You could add to the list this way:

```
my ($head, $tail);
$tail = append($head, 1);       # grow a new head
for $value ( 2 .. 10 ) {
    $tail = append($tail, $value);
}

sub append {
    my($list, $value) = @_;
    my $node = { VALUE => $value };
    if ($list) {
        $node->{LINK} = $list->{LINK};
        $list->{LINK} = $node;
    } else {
        $_[0] = $node;      # replace caller's version
    }
    return $node;
}
```

But again, Perl's built-in are virtually always good enough.

20.5.9 How do I handle circular lists?

Circular lists could be handled in the traditional fashion with linked lists, or you could just do something like this with an array:

```
unshift(@array, pop(@array));  # the last shall be first
push(@array, shift(@array));   # and vice versa
```

20.5.10 How do I shuffle an array randomly?

If you either have Perl 5.8.0 or later installed, or if you have Scalar-List-Utils 1.03 or later installed, you can say:

```
use List::Util 'shuffle';

    @shuffled = shuffle(@list);
```

If not, you can use a Fisher-Yates shuffle.

```
sub fisher_yates_shuffle {
    my $deck = shift;  # $deck is a reference to an array
    my $i = @$deck;
    while ($i--) {
        my $j = int rand ($i+1);
        @$deck[$i,$j] = @$deck[$j,$i];
    }
}

# shuffle my mpeg collection
#
my @mpeg = <audio/*/*.mp3>;
fisher_yates_shuffle( \@mpeg );    # randomize @mpeg in place
print @mpeg;
```

Note that the above implementation shuffles an array in place, unlike the List::Util::shuffle() which takes a list and returns a new shuffled list.

You've probably seen shuffling algorithms that work using splice, randomly picking another element to swap the current element with

```
srand;
@new = ();
@old = 1 .. 10;  # just a demo
while (@old) {
    push(@new, splice(@old, rand @old, 1));
}
```

This is bad because splice is already O(N), and since you do it N times, you just invented a quadratic algorithm; that is, O(N**2). This does not scale, although Perl is so efficient that you probably won't notice this until you have rather largish arrays.

20.5.11 How do I process/modify each element of an array?

Use for/foreach:

```
for (@lines) {
    s/foo/bar/;     # change that word
    y/XZ/ZX/;       # swap those letters
}
```

Here's another; let's compute spherical volumes:

```
for (@volumes = @radii) {   # @volumes has changed parts
    $_ **= 3;
    $_ *= (4/3) * 3.14159;  # this will be constant folded
}
```

which can also be done with map() which is made to transform one list into another:

```
        @volumes = map {$_ ** 3 * (4/3) * 3.14159} @radii;
```

If you want to do the same thing to modify the values of the hash, you can use the `values` function. As of Perl 5.6 the values are not copied, so if you modify $orbit (in this case), you modify the value.

```
    for $orbit ( values %orbits ) {
        ($orbit **= 3) *= (4/3) * 3.14159;
    }
```

Prior to perl 5.6 `values` returned copies of the values, so older perl code often contains constructions such as `@orbits{keys %orbits}` instead of `values %orbits` where the hash is to be modified.

20.5.12 How do I select a random element from an array?

Use the rand() function (see rand in *perlfunc*):

```
    $index   = rand @array;
    $element = $array[$index];
```

Or, simply: my $element = $array[rand @array];

20.5.13 How do I permute N elements of a list?

Use the List::Permutor module on CPAN. If the list is actually an array, try the Algorithm::Permute module (also on CPAN). It's written in XS code and is very efficient.

```
        use Algorithm::Permute;
        my @array = 'a'..'d';
        my $p_iterator = Algorithm::Permute->new ( \@array );
        while (my @perm = $p_iterator->next) {
           print "next permutation: (@perm)\n";
        }
```

For even faster execution, you could do:

```
   use Algorithm::Permute;
   my @array = 'a'..'d';
   Algorithm::Permute::permute {
      print "next permutation: (@array)\n";
   } @array;
```

Here's a little program that generates all permutations of all the words on each line of input. The algorithm embodied in the permute() function is discussed in Volume 4 (still unpublished) of Knuth's *The Art of Computer Programming* and will work on any list:

```
        #!/usr/bin/perl -n
        # Fischer-Kause ordered permutation generator
        sub permute (&@) {
                my $code = shift;
                my @idx = 0..$#_;
                while ( $code->(@_[@idx]) ) {
                        my $p = $#idx;
                        --$p while $idx[$p-1] > $idx[$p];
                        my $q = $p or return;
                        push @idx, reverse splice @idx, $p;
                        ++$q while $idx[$p-1] > $idx[$q];
                        @idx[$p-1,$q]=@idx[$q,$p-1];
                }
        }

        permute {print"@_\n"} split;
```

20.5.14 How do I sort an array by (anything)?

Supply a comparison function to sort() (described in sort in *perlfunc*):

```
    @list = sort { $a <=> $b } @list;
```

The default sort function is cmp, string comparison, which would sort `(1, 2, 10)` into `(1, 10, 2)`. <=>, used above, is the numerical comparison operator.

If you have a complicated function needed to pull out the part you want to sort on, then don't do it inside the sort function. Pull it out first, because the sort BLOCK can be called many times for the same element. Here's an example of how to pull out the first word after the first number on each item, and then sort those words case-insensitively.

```
    @idx = ();
    for (@data) {
        ($item) = /\d+\s*(\S+)/;
        push @idx, uc($item);
    }
    @sorted = @data[ sort { $idx[$a] cmp $idx[$b] } 0 .. $#idx ];
```

which could also be written this way, using a trick that's come to be known as the Schwartzian Transform:

```
    @sorted = map  { $_->[0] }
              sort { $a->[1] cmp $b->[1] }
              map  { [ $_, uc( (/\d+\s*(\S+)/)[0]) ] } @data;
```

If you need to sort on several fields, the following paradigm is useful.

```
    @sorted = sort { field1($a) <=> field1($b) ||
                     field2($a) cmp field2($b) ||
                     field3($a) cmp field3($b)
                   }     @data;
```

This can be conveniently combined with precalculation of keys as given above.

See the *sort* article in the "Far More Than You Ever Wanted To Know" collection in http://www.cpan.org/misc/olddoc/FMTEYEWTK.tgz for more about this approach.

See also the question below on sorting hashes.

20.5.15 How do I manipulate arrays of bits?

Use pack() and unpack(), or else vec() and the bitwise operations.

For example, this sets $vec to have bit N set if $ints[N] was set:

```
    $vec = '';
    foreach(@ints) { vec($vec,$_,1) = 1 }
```

Here's how, given a vector in $vec, you can get those bits into your @ints array:

```
    sub bitvec_to_list {
        my $vec = shift;
        my @ints;
        # Find null-byte density then select best algorithm
        if ($vec =~ tr/\0// / length $vec > 0.95) {
            use integer;
            my $i;
            # This method is faster with mostly null-bytes
            while($vec =~ /[^\0]/g ) {
                $i = -9 + 8 * pos $vec;
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
                push @ints, $i if vec($vec, ++$i, 1);
            }
        } else {
            # This method is a fast general algorithm
            use integer;
            my $bits = unpack "b*", $vec;
            push @ints, 0 if $bits =~ s/^(\d)// && $1;
            push @ints, pos $bits while($bits =~ /1/g);
        }
        return \@ints;
    }
```

This method gets faster the more sparse the bit vector is. (Courtesy of Tim Bunce and Winfried Koenig.)

You can make the while loop a lot shorter with this suggestion from Benjamin Goldberg:

```
        while($vec =~ /[^\0]+/g ) {
           push @ints, grep vec($vec, $_, 1), $-[0] * 8 .. $+[0] * 8;
        }
```

Or use the CPAN module Bit::Vector:

```
    $vector = Bit::Vector->new($num_of_bits);
    $vector->Index_List_Store(@ints);
    @ints = $vector->Index_List_Read();
```

Bit::Vector provides efficient methods for bit vector, sets of small integers and "big int" math.

Here's a more extensive illustration using vec():

```
# vec demo
$vector = "\xff\x0f\xef\xfe";
print "Ilya's string \\xff\\x0f\\xef\\xfe represents the number ",
    unpack("N", $vector), "\n";
$is_set = vec($vector, 23, 1);
print "Its 23rd bit is ", $is_set ? "set" : "clear", ".\n";
pvec($vector);

set_vec(1,1,1);
set_vec(3,1,1);
set_vec(23,1,1);

set_vec(3,1,3);
set_vec(3,2,3);
set_vec(3,4,3);
set_vec(3,4,7);
set_vec(3,8,3);
set_vec(3,8,7);

set_vec(0,32,17);
set_vec(1,32,17);

sub set_vec {
    my ($offset, $width, $value) = @_;
    my $vector = '';
    vec($vector, $offset, $width) = $value;
    print "offset=$offset width=$width value=$value\n";
    pvec($vector);
}

sub pvec {
    my $vector = shift;
    my $bits = unpack("b*", $vector);
    my $i = 0;
    my $BASE = 8;

    print "vector length in bytes: ", length($vector), "\n";
    @bytes = unpack("A8" x length($vector), $bits);
    print "bits are: @bytes\n\n";
}
```

20.5.16 Why does defined() return true on empty arrays and hashes?

The short story is that you should probably only use defined on scalars or functions, not on aggregates (arrays and hashes). See defined in *perlfunc* in the 5.004 release or later of Perl for more detail.

20.6 Data: Hashes (Associative Arrays)

20.6.1 How do I process an entire hash?

Use the each() function (see each in *perlfunc*) if you don't care whether it's sorted:

```
while ( ($key, $value) = each %hash) {
    print "$key = $value\n";
}
```

If you want it sorted, you'll have to use foreach() on the result of sorting the keys as shown in an earlier question.

20.6.2 What happens if I add or remove keys from a hash while iterating over it?

Don't do that. :-)

[lwall] In Perl 4, you were not allowed to modify a hash at all while iterating over it. In Perl 5 you can delete from it, but you still can't add to it, because that might cause a doubling of the hash table, in which half the entries get copied up to the new top half of the table, at which point you've totally bamboozled the iterator code. Even if the table doesn't double, there's no telling whether your new entry will be inserted before or after the current iterator position.

Either treasure up your changes and make them after the iterator finishes or use keys to fetch all the old keys at once, and iterate over the list of keys.

20.6.3 How do I look up a hash element by value?

Create a reverse hash:

```
    %by_value = reverse %by_key;
    $key = $by_value{$value};
```

That's not particularly efficient. It would be more space-efficient to use:

```
    while (($key, $value) = each %by_key) {
        $by_value{$value} = $key;
    }
```

If your hash could have repeated values, the methods above will only find one of the associated keys. This may or may not worry you. If it does worry you, you can always reverse the hash into a hash of arrays instead:

```
     while (($key, $value) = each %by_key) {
         push @{$key_list_by_value{$value}}, $key;
     }
```

20.6.4 How can I know how many entries are in a hash?

If you mean how many keys, then all you have to do is use the keys() function in a scalar context:

```
    $num_keys = keys %hash;
```

The keys() function also resets the iterator, which means that you may see strange results if you use this between uses of other hash operators such as each().

20.6.5 How do I sort a hash (optionally by value instead of key)?

Internally, hashes are stored in a way that prevents you from imposing an order on key-value pairs. Instead, you have to sort a list of the keys or values:

```
    @keys = sort keys %hash;    # sorted by key
    @keys = sort {
                    $hash{$a} cmp $hash{$b}
            } keys %hash;       # and by value
```

Here we'll do a reverse numeric sort by value, and if two keys are identical, sort by length of key, or if that fails, by straight ASCII comparison of the keys (well, possibly modified by your locale–see *perllocale*).

```
    @keys = sort {
                $hash{$b} <=> $hash{$a}
                          ||
                length($b) <=> length($a)
                          ||
                      $a cmp $b
    } keys %hash;
```

20.6.6 How can I always keep my hash sorted?

You can look into using the DB_File module and tie() using the $DB_BTREE hash bindings as documented in DB_File/"In Memory Databases". The Tie::IxHash module from CPAN might also be instructive.

20.6.7 What's the difference between "delete" and "undef" with hashes?

Hashes contain pairs of scalars: the first is the key, the second is the value. The key will be coerced to a string, although the value can be any kind of scalar: string, number, or reference. If a key $key is present in %hash, `exists($hash{$key})` will return true. The value for a given key can be `undef`, in which case `$hash{$key}` will be `undef` while `exists $hash{$key}` will return true. This corresponds to (`$key`, `undef`) being in the hash.

Pictures help... here's the %hash table:

```
  keys  values
+------+------+
|  a   |  3   |
|  x   |  7   |
|  d   |  0   |
|  e   |  2   |
+------+------+
```

And these conditions hold

```
$hash{'a'}                       is true
$hash{'d'}                       is false
defined $hash{'d'}               is true
defined $hash{'a'}               is true
exists $hash{'a'}                is true (Perl5 only)
grep ($_ eq 'a', keys %hash)     is true
```

If you now say

```
undef $hash{'a'}
```

your table now reads:

```
  keys  values
+------+------+
|  a   | undef|
|  x   |  7   |
|  d   |  0   |
|  e   |  2   |
+------+------+
```

and these conditions now hold; changes in caps:

```
$hash{'a'}                       is FALSE
$hash{'d'}                       is false
defined $hash{'d'}               is true
defined $hash{'a'}               is FALSE
exists $hash{'a'}                is true (Perl5 only)
grep ($_ eq 'a', keys %hash)     is true
```

Notice the last two: you have an undef value, but a defined key!

Now, consider this:

```
        delete $hash{'a'}
```

your table now reads:

```
          keys  values
        +------+------+
        |  x   |  7   |
        |  d   |  0   |
        |  e   |  2   |
        +------+------+
```

and these conditions now hold; changes in caps:

```
        $hash{'a'}                       is false
        $hash{'d'}                       is false
        defined $hash{'d'}               is true
        defined $hash{'a'}               is false
        exists $hash{'a'}                is FALSE (Perl5 only)
        grep ($_ eq 'a', keys %hash)     is FALSE
```

See, the whole entry is gone!

20.6.8 Why don't my tied hashes make the defined/exists distinction?

This depends on the tied hash's implementation of EXISTS(). For example, there isn't the concept of undef with hashes that are tied to DBM* files. It also means that exists() and defined() do the same thing with a DBM* file, and what they end up doing is not what they do with ordinary hashes.

20.6.9 How do I reset an each() operation part-way through?

Using `keys %hash` in scalar context returns the number of keys in the hash *and* resets the iterator associated with the hash. You may need to do this if you use `last` to exit a loop early so that when you re-enter it, the hash iterator has been reset.

20.6.10 How can I get the unique keys from two hashes?

First you extract the keys from the hashes into lists, then solve the "removing duplicates" problem described above. For example:

```
    %seen = ();
    for $element (keys(%foo), keys(%bar)) {
        $seen{$element}++;
    }
    @uniq = keys %seen;
```

Or more succinctly:

```
    @uniq = keys %{{%foo,%bar}};
```

Or if you really want to save space:

```
    %seen = ();
    while (defined ($key = each %foo)) {
        $seen{$key}++;
    }
    while (defined ($key = each %bar)) {
        $seen{$key}++;
    }
    @uniq = keys %seen;
```

20.6.11 How can I store a multidimensional array in a DBM file?

Either stringify the structure yourself (no fun), or else get the MLDBM (which uses Data::Dumper) module from CPAN and layer it on top of either DB_File or GDBM_File.

20.6.12 How can I make my hash remember the order I put elements into it?

Use the Tie::IxHash from CPAN.

```
use Tie::IxHash;
tie my %myhash, 'Tie::IxHash';
for (my $i=0; $i<20; $i++) {
    $myhash{$i} = 2*$i;
}
my @keys = keys %myhash;
# @keys = (0,1,2,3,...)
```

20.6.13 Why does passing a subroutine an undefined element in a hash create it?

If you say something like:

```
somefunc($hash{"nonesuch key here"});
```

Then that element "autovivifies"; that is, it springs into existence whether you store something there or not. That's because functions get scalars passed in by reference. If somefunc() modifies `$_[0]`, it has to be ready to write it back into the caller's version.

This has been fixed as of Perl5.004.

Normally, merely accessing a key's value for a nonexistent key does *not* cause that key to be forever there. This is different than awk's behavior.

20.6.14 How can I make the Perl equivalent of a C structure/C++ class/hash or array of hashes or arrays?

Usually a hash ref, perhaps like this:

```
$record = {
    NAME   => "Jason",
    EMPNO  => 132,
    TITLE  => "deputy peon",
    AGE    => 23,
    SALARY => 37_000,
    PALS   => [ "Norbert", "Rhys", "Phineas"],
};
```

References are documented in *perlref* and the upcoming *perlreftut*. Examples of complex data structures are given in *perldsc* and *perllol*. Examples of structures and object-oriented classes are in *perltoot*.

20.6.15 How can I use a reference as a hash key?

You can't do this directly, but you could use the standard Tie::RefHash module distributed with Perl.

20.7 Data: Misc

20.7.1 How do I handle binary data correctly?

Perl is binary clean, so this shouldn't be a problem. For example, this works fine (assuming the files are found):

```
if (‘cat /vmunix‘ =~ /gzip/) {
    print "Your kernel is GNU-zip enabled!\n";
}
```

On less elegant (read: Byzantine) systems, however, you have to play tedious games with "text" versus "binary" files. See binmode in *perlfunc* or *perlopentut*.

If you're concerned about 8-bit ASCII data, then see *perllocale*.

If you want to deal with multibyte characters, however, there are some gotchas. See the section on Regular Expressions.

20.7.2 How do I determine whether a scalar is a number/whole/integer/float?

Assuming that you don't care about IEEE notations like "NaN" or "Infinity", you probably just want to use a regular expression.

```
if (/\D/)            { print "has nondigits\n" }
if (/^\d+$/)         { print "is a whole number\n" }
if (/^-?\d+$/)       { print "is an integer\n" }
if (/^[+-]?\d+$/)    { print "is a +/- integer\n" }
if (/^-?\d+\.?\d*$/) { print "is a real number\n" }
if (/^-?(?:\d+(?:\.\d*)?|\.\d+)$/) { print "is a decimal number\n" }
if (/^([+-]?)(?=\d|\.\d)\d*(\.\d*)?([Ee]([+-]?\d+))?$/)
                     { print "a C float\n" }
```

There are also some commonly used modules for the task. *Scalar::Util* (distributed with 5.8) provides access to perl's internal function `looks_like_number` for determining whether a variable looks like a number. *Data::Types* exports functions that validate data types using both the above and other regular expressions. Thirdly, there is `Regexp::Common` which has regular expressions to match various types of numbers. Those three modules are available from the CPAN.

If you're on a POSIX system, Perl supports the `POSIX::strtod` function. Its semantics are somewhat cumbersome, so here's a `getnum` wrapper function for more convenient access. This function takes a string and returns the number it found, or `undef` for input that isn't a C float. The `is_numeric` function is a front end to `getnum` if you just want to say, "Is this a float?"

```
sub getnum {
    use POSIX qw(strtod);
    my $str = shift;
    $str =~ s/^\s+//;
    $str =~ s/\s+$//;
    $! = 0;
    my($num, $unparsed) = strtod($str);
    if (($str eq ’’) || ($unparsed != 0) || $!) {
        return undef;
    } else {
        return $num;
    }
}

sub is_numeric { defined getnum($_[0]) }
```

Or you could check out the *String::Scanf* module on the CPAN instead. The POSIX module (part of the standard Perl distribution) provides the `strtod` and `strtol` for converting strings to double and longs, respectively.

20.7.3 How do I keep persistent data across program calls?

For some specific applications, you can use one of the DBM modules. See AnyDBM_File. More generically, you should consult the FreezeThaw or Storable modules from CPAN. Starting from Perl 5.8 Storable is part of the standard distribution. Here's one example using Storable's `store` and `retrieve` functions:

```
    use Storable;
    store(\%hash, "filename");

    # later on...
    $href = retrieve("filename");        # by ref
    %hash = %{ retrieve("filename") };   # direct to hash
```

20.7.4 How do I print out or copy a recursive data structure?

The Data::Dumper module on CPAN (or the 5.005 release of Perl) is great for printing out data structures. The Storable module on CPAN (or the 5.8 release of Perl), provides a function called `dclone` that recursively copies its argument.

```
    use Storable qw(dclone);
    $r2 = dclone($r1);
```

Where $r1 can be a reference to any kind of data structure you'd like. It will be deeply copied. Because `dclone` takes and returns references, you'd have to add extra punctuation if you had a hash of arrays that you wanted to copy.

```
    %newhash = %{ dclone(\%oldhash) };
```

20.7.5 How do I define methods for every class/object?

Use the UNIVERSAL class (see *UNIVERSAL*).

20.7.6 How do I verify a credit card checksum?

Get the Business::CreditCard module from CPAN.

20.7.7 How do I pack arrays of doubles or floats for XS code?

The kgbpack.c code in the PGPLOT module on CPAN does just this. If you're doing a lot of float or double processing, consider using the PDL module from CPAN instead–it makes number-crunching easy.

perlfaq5

Files and Formats ($Revision: 1.30 $, $Date: 2003/11/23 08:07:46 $)

21.1 DESCRIPTION

This section deals with I/O and the "f" issues: filehandles, flushing, formats, and footers.

21.1.1 How do I flush/unbuffer an output filehandle? Why must I do this?

Perl does not support truly unbuffered output (except insofar as you can `syswrite(OUT, $char, 1)`), although it does support is "command buffering", in which a physical write is performed after every output command.

The C standard I/O library (stdio) normally buffers characters sent to devices so that there isn't a system call for each byte. In most stdio implementations, the type of output buffering and the size of the buffer varies according to the type of device. Perl's print() and write() functions normally buffer output, while syswrite() bypasses buffering all together.

If you want your output to be sent immediately when you execute print() or write() (for instance, for some network protocols), you must set the handle's autoflush flag. This flag is the Perl variable $| and when it is set to a true value, Perl will flush the handle's buffer after each print() or write(). Setting $| affects buffering only for the currently selected default file handle. You choose this handle with the one argument select() call (see $| in *perlvar* and select in *perlfunc*).

Use select() to choose the desired handle, then set its per-filehandle variables.

```
    $old_fh = select(OUTPUT_HANDLE);
    $| = 1;
    select($old_fh);
```

Some idioms can handle this in a single statement:

```
    select((select(OUTPUT_HANDLE), $| = 1)[0]);

    $| = 1, select $_ for select OUTPUT_HANDLE;
```

Some modules offer object-oriented access to handles and their variables, although they may be overkill if this is the only thing you do with them. You can use IO::Handle:

```
    use IO::Handle;
    open(DEV, ">/dev/printer");   # but is this?
    DEV->autoflush(1);
```

or IO::Socket:

```
    use IO::Socket;               # this one is kinda a pipe?
        my $sock = IO::Socket::INET->new( 'www.example.com:80' ) ;

    $sock->autoflush();
```

21.1.2 How do I change one line in a file/delete a line in a file/insert a line in the middle of a file/append to the beginning of a file?

Use the Tie::File module, which is included in the standard distribution since Perl 5.8.0.

21.1.3 How do I count the number of lines in a file?

One fairly efficient way is to count newlines in the file. The following program uses a feature of tr///, as documented in *perlop*. If your text file doesn't end with a newline, then it's not really a proper text file, so this may report one fewer line than you expect.

```
    $lines = 0;
    open(FILE, $filename) or die "Can't open `$filename': $!";
    while (sysread FILE, $buffer, 4096) {
        $lines += ($buffer =~ tr/\n//);
    }
    close FILE;
```

This assumes no funny games with newline translations.

21.1.4 How can I use Perl's `-i` option from within a program?

`-i` sets the value of Perl's `$^I` variable, which in turn affects the behavior of <>; see *perlrun* for more details. By modifying the appropriate variables directly, you can get the same behavior within a larger program. For example:

```
     # ...
     {
        local($^I, @ARGV) = ('.orig', glob("*.c"));
        while (<>) {
           if ($. == 1) {
               print "This line should appear at the top of each file\n";
           }
           s/\b(p)earl\b/${1}erl/i;        # Correct typos, preserving case
           print;
           close ARGV if eof;              # Reset $.
        }
     }
     # $^I and @ARGV return to their old values here
```

This block modifies all the `.c` files in the current directory, leaving a backup of the original data from each file in a new `.c.orig` file.

21.1.5 How do I make a temporary file name?

Use the File::Temp module, see *File::Temp* for more information.

```
  use File::Temp qw/ tempfile tempdir /;

  $dir = tempdir( CLEANUP => 1 );
  ($fh, $filename) = tempfile( DIR => $dir );

  # or if you don't need to know the filename

  $fh = tempfile( DIR => $dir );
```

The File::Temp has been a standard module since Perl 5.6.1. If you don't have a modern enough Perl installed, use the `new_tmpfile` class method from the IO::File module to get a filehandle opened for reading and writing. Use it if you don't need to know the file's name:

```
    use IO::File;
    $fh = IO::File->new_tmpfile()
        or die "Unable to make new temporary file: $!";
```

If you're committed to creating a temporary file by hand, use the process ID and/or the current time-value. If you need to have many temporary files in one process, use a counter:

```
    BEGIN {
        use Fcntl;
        my $temp_dir = -d '/tmp' ? '/tmp' : $ENV{TMPDIR} || $ENV{TEMP};
        my $base_name = sprintf("%s/%d-%d-0000", $temp_dir, $$, time());
        sub temp_file {
            local *FH;
            my $count = 0;
            until (defined(fileno(FH)) || $count++ > 100) {
                $base_name =~ s/-(\d+)$/"-" . (1 + $1)/e;
                # O_EXCL is required for security reasons.
                sysopen(FH, $base_name, O_WRONLY|O_EXCL|O_CREAT);
            }
            if (defined(fileno(FH))
                return (*FH, $base_name);
            } else {
                return ();
            }
        }
    }
```

21.1.6 How can I manipulate fixed-record-length files?

The most efficient way is using pack() and unpack(). This is faster than using substr() when taking many, many strings. It is slower for just a few.

Here is a sample chunk of code to break up and put back together again some fixed-format input lines, in this case from the output of a normal, Berkeley-style ps:

```
    # sample input line:
    #   15158 p5  T      0:00 perl /home/tchrist/scripts/now-what
    my $PS_T = 'A6 A4 A7 A5 A*';
    open my $ps, '-|', 'ps';
    print scalar <$ps>;
    my @fields = qw( pid tt stat time command );
    while (<$ps>) {
        my %process;
        @process{@fields} = unpack($PS_T, $_);
        for my $field ( @fields ) {
            print "$field: <$process{$field}>\n";
        }
        print 'line=', pack($PS_T, @process{@fields} ), "\n";
    }
```

We've used a hash slice in order to easily handle the fields of each row. Storing the keys in an array means it's easy to operate on them as a group or loop over them with for. It also avoids polluting the program with global variables and using symbolic references.

21.1.7 How can I make a filehandle local to a subroutine? How do I pass filehandles between subroutines? How do I make an array of filehandles?

As of perl5.6, open() autovivifies file and directory handles as references if you pass it an uninitialized scalar variable. You can then pass these references just like any other scalar, and use them in the place of named handles.

```
        open my    $fh, $file_name;

        open local $fh, $file_name;

        print $fh "Hello World!\n";

        process_file( $fh );
```

Before perl5.6, you had to deal with various typeglob idioms which you may see in older code.

```
        open FILE, "> $filename";
        process_typeglob(   *FILE );
        process_reference( \*FILE );

        sub process_typeglob  { local *FH = shift; print FH  "Typeglob!" }
        sub process_reference { local $fh = shift; print $fh "Reference!" }
```

If you want to create many anonymous handles, you should check out the Symbol or IO::Handle modules.

21.1.8 How can I use a filehandle indirectly?

An indirect filehandle is using something other than a symbol in a place that a filehandle is expected. Here are ways to get indirect filehandles:

```
    $fh =   SOME_FH;       # bareword is strict-subs hostile
    $fh =  "SOME_FH";      # strict-refs hostile; same package only
    $fh =  *SOME_FH;       # typeglob
    $fh = \*SOME_FH;       # ref to typeglob (bless-able)
    $fh =  *SOME_FH{IO};   # blessed IO::Handle from *SOME_FH typeglob
```

Or, you can use the `new` method from one of the IO::* modules to create an anonymous filehandle, store that in a scalar variable, and use it as though it were a normal filehandle.

```
    use IO::Handle;                     # 5.004 or higher
    $fh = IO::Handle->new();
```

Then use any of those as you would a normal filehandle. Anywhere that Perl is expecting a filehandle, an indirect filehandle may be used instead. An indirect filehandle is just a scalar variable that contains a filehandle. Functions like `print`, `open`, `seek`, or the <FH> diamond operator will accept either a named filehandle or a scalar variable containing one:

```
    ($ifh, $ofh, $efh) = (*STDIN, *STDOUT, *STDERR);
    print $ofh "Type it: ";
    $got = <$ifh>
    print $efh "What was that: $got";
```

If you're passing a filehandle to a function, you can write the function in two ways:

```
    sub accept_fh {
        my $fh = shift;
        print $fh "Sending to indirect filehandle\n";
    }
```

Or it can localize a typeglob and use the filehandle directly:

```
    sub accept_fh {
        local *FH = shift;
        print  FH "Sending to localized filehandle\n";
    }
```

Both styles work with either objects or typeglobs of real filehandles. (They might also work with strings under some circumstances, but this is risky.)

```
    accept_fh(*STDOUT);
    accept_fh($handle);
```

In the examples above, we assigned the filehandle to a scalar variable before using it. That is because only simple scalar variables, not expressions or subscripts of hashes or arrays, can be used with built-ins like `print`, `printf`, or the diamond operator. Using something other than a simple scalar variable as a filehandle is illegal and won't even compile:

```
    @fd = (*STDIN, *STDOUT, *STDERR);
    print $fd[1] "Type it: ";                          # WRONG
    $got = <$fd[0]>                                    # WRONG
    print $fd[2] "What was that: $got";                # WRONG
```

With `print` and `printf`, you get around this by using a block and an expression where you would place the filehandle:

```
    print  { $fd[1] } "funny stuff\n";
    printf { $fd[1] } "Pity the poor %x.\n", 3_735_928_559;
    # Pity the poor deadbeef.
```

That block is a proper block like any other, so you can put more complicated code there. This sends the message out to one of two places:

```
    $ok = -x "/bin/cat";
    print { $ok ? $fd[1] : $fd[2] } "cat stat $ok\n";
    print { $fd[ 1+ ($ok || 0) ]  } "cat stat $ok\n";
```

This approach of treating `print` and `printf` like object methods calls doesn't work for the diamond operator. That's because it's a real operator, not just a function with a comma-less argument. Assuming you've been storing typeglobs in your structure as we did above, you can use the built-in function named `readline` to read a record just as <> does. Given the initialization shown above for @fd, this would work, but only because readline() requires a typeglob. It doesn't work with objects or strings, which might be a bug we haven't fixed yet.

```
    $got = readline($fd[0]);
```

Let it be noted that the flakiness of indirect filehandles is not related to whether they're strings, typeglobs, objects, or anything else. It's the syntax of the fundamental operators. Playing the object game doesn't help you at all here.

21.1.9 How can I set up a footer format to be used with write()?

There's no builtin way to do this, but *perlform* has a couple of techniques to make it possible for the intrepid hacker.

21.1.10 How can I write() into a string?

See Accessing Formatting Internals in *perlform* for an swrite() function.

21.1.11 How can I output my numbers with commas added?

This subroutine will add commas to your number:

```
        sub commify {
           local $_  = shift;
           1 while s/^([-+]?\d+)(\d{3})/$1,$2/;
           return $_;
           }
```

This regex from Benjamin Goldberg will add commas to numbers:

```
   s/(^[-+]?\d+?(?=(?>(?:\d{3})+)(?!\d))|\G\d{3}(?=\d))/$1,/g;
```

It is easier to see with comments:

```
   s/(
       ^[-+]?            # beginning of number.
       \d{1,3}?          # first digits before first comma
       (?=               # followed by, (but not included in the match) :
          (?>(?:\d{3})+) # some positive multiple of three digits.
          (?!\d)         # an *exact* multiple, not x * 3 + 1 or whatever.
       )
      |                  # or:
       \G\d{3}           # after the last group, get three digits
       (?=\d)            # but they have to have more digits after them.
   )/$1,/xg;
```

21.1.12 How can I translate tildes (˜) in a filename?

Use the <> (glob()) operator, documented in *perlfunc*. Older versions of Perl require that you have a shell installed that groks tildes. Recent perl versions have this feature built in. The File::KGlob module (available from CPAN) gives more portable glob functionality.

Within Perl, you may use this directly:

```
        $filename =~ s{
          ^ ~             # find a leading tilde
          (               # save this in $1
              [^/]        # a non-slash character
                    *     # repeated 0 or more times (0 means me)
          )
        }{
          $1
              ? (getpwnam($1))[7]
              : ( $ENV{HOME} || $ENV{LOGDIR} )
        }ex;
```

21.1.13 How come when I open a file read-write it wipes it out?

Because you're using something like this, which truncates the file and *then* gives you read-write access:

```
open(FH, "+> /path/name");          # WRONG (almost always)
```

Whoops. You should instead use this, which will fail if the file doesn't exist.

```
open(FH, "+< /path/name");          # open for update
```

Using ">" always clobbers or creates. Using "<" never does either. The "+" doesn't change this.
Here are examples of many kinds of file opens. Those using sysopen() all assume

```
use Fcntl;
```

To open file for reading:

```
open(FH, "< $path")                                 || die $!;
sysopen(FH, $path, O_RDONLY)                        || die $!;
```

To open file for writing, create new file if needed or else truncate old file:

```
open(FH, "> $path") || die $!;
sysopen(FH, $path, O_WRONLY|O_TRUNC|O_CREAT)        || die $!;
sysopen(FH, $path, O_WRONLY|O_TRUNC|O_CREAT, 0666)  || die $!;
```

To open file for writing, create new file, file must not exist:

```
sysopen(FH, $path, O_WRONLY|O_EXCL|O_CREAT)         || die $!;
sysopen(FH, $path, O_WRONLY|O_EXCL|O_CREAT, 0666)   || die $!;
```

To open file for appending, create if necessary:

```
open(FH, ">> $path") || die $!;
sysopen(FH, $path, O_WRONLY|O_APPEND|O_CREAT)       || die $!;
sysopen(FH, $path, O_WRONLY|O_APPEND|O_CREAT, 0666) || die $!;
```

To open file for appending, file must exist:

```
sysopen(FH, $path, O_WRONLY|O_APPEND)               || die $!;
```

To open file for update, file must exist:

```
open(FH, "+< $path")                                || die $!;
sysopen(FH, $path, O_RDWR)                          || die $!;
```

To open file for update, create file if necessary:

```
sysopen(FH, $path, O_RDWR|O_CREAT)                  || die $!;
sysopen(FH, $path, O_RDWR|O_CREAT, 0666)            || die $!;
```

To open file for update, file must not exist:

```
sysopen(FH, $path, O_RDWR|O_EXCL|O_CREAT)           || die $!;
sysopen(FH, $path, O_RDWR|O_EXCL|O_CREAT, 0666)     || die $!;
```

To open a file without blocking, creating if necessary:

```
sysopen(FH, "/foo/somefile", O_WRONLY|O_NDELAY|O_CREAT)
        or die "can't open /foo/somefile: $!":
```

Be warned that neither creation nor deletion of files is guaranteed to be an atomic operation over NFS. That is, two processes might both successfully create or unlink the same file! Therefore O_EXCL isn't as exclusive as you might wish.
See also the new *perlopentut* if you have it (new for 5.6).

21.1.14 Why do I sometimes get an "Argument list too long" when I use <*>?

The <> operator performs a globbing operation (see above). In Perl versions earlier than v5.6.0, the internal glob() operator forks csh(1) to do the actual glob expansion, but csh can't handle more than 127 items and so gives the error message `Argument list too long`. People who installed tcsh as csh won't have this problem, but their users may be surprised by it.

To get around this, either upgrade to Perl v5.6.0 or later, do the glob yourself with readdir() and patterns, or use a module like File::KGlob, one that doesn't use the shell to do globbing.

21.1.15 Is there a leak/bug in glob()?

Due to the current implementation on some operating systems, when you use the glob() function or its angle-bracket alias in a scalar context, you may cause a memory leak and/or unpredictable behavior. It's best therefore to use glob() only in list context.

21.1.16 How can I open a file with a leading ">" or trailing blanks?

Normally perl ignores trailing blanks in filenames, and interprets certain leading characters (or a trailing "|") to mean something special.

The three argument form of open() lets you specify the mode separately from the filename. The open() function treats special mode characters and whitespace in the filename as literals

```
        open FILE, "<", "  file  ";  # filename is "   file   "
        open FILE, ">", ">file";     # filename is ">file"
```

It may be a lot clearer to use sysopen(), though:

```
    use Fcntl;
    $badpath = "<<<something really wicked   ";
    sysopen (FH, $badpath, O_WRONLY | O_CREAT | O_TRUNC)
        or die "can't open $badpath: $!";
```

21.1.17 How can I reliably rename a file?

If your operating system supports a proper mv(1) utility or its functional equivalent, this works:

```
    rename($old, $new) or system("mv", $old, $new);
```

It may be more portable to use the File::Copy module instead. You just copy to the new file to the new name (checking return values), then delete the old one. This isn't really the same semantically as a rename(), which preserves meta-information like permissions, timestamps, inode info, etc.

Newer versions of File::Copy export a move() function.

21.1.18 How can I lock a file?

Perl's builtin flock() function (see *perlfunc* for details) will call flock(2) if that exists, fcntl(2) if it doesn't (on perl version 5.004 and later), and lockf(3) if neither of the two previous system calls exists. On some systems, it may even use a different form of native locking. Here are some gotchas with Perl's flock():

1. Produces a fatal error if none of the three system calls (or their close equivalent) exists.
2. lockf(3) does not provide shared locking, and requires that the filehandle be open for writing (or appending, or read/writing).

3. Some versions of flock() can't lock files over a network (e.g. on NFS file systems), so you'd need to force the use of fcntl(2) when you build Perl. But even this is dubious at best. See the flock entry of *perlfunc* and the *INSTALL* file in the source distribution for information on building Perl to do this.

   Two potentially non-obvious but traditional flock semantics are that it waits indefinitely until the lock is granted, and that its locks are *merely advisory*. Such discretionary locks are more flexible, but offer fewer guarantees. This means that files locked with flock() may be modified by programs that do not also use flock(). Cars that stop for red lights get on well with each other, but not with cars that don't stop for red lights. See the perlport manpage, your port's specific documentation, or your system-specific local manpages for details. It's best to assume traditional behavior if you're writing portable programs. (If you're not, you should as always feel perfectly free to write for your own system's idiosyncrasies (sometimes called "features"). Slavish adherence to portability concerns shouldn't get in the way of your getting your job done.)

   For more information on file locking, see also File Locking in *perlopentut* if you have it (new for 5.6).

21.1.19 Why can't I just open(FH, ">file.lock")?

A common bit of code **NOT TO USE** is this:

```
    sleep(3) while -e "file.lock";      # PLEASE DO NOT USE
    open(LCK, "> file.lock");           # THIS BROKEN CODE
```

This is a classic race condition: you take two steps to do something which must be done in one. That's why computer hardware provides an atomic test-and-set instruction. In theory, this "ought" to work:

```
    sysopen(FH, "file.lock", O_WRONLY|O_EXCL|O_CREAT)
                or die "can't open  file.lock: $!";
```

except that lamentably, file creation (and deletion) is not atomic over NFS, so this won't work (at least, not every time) over the net. Various schemes involving link() have been suggested, but these tend to involve busy-wait, which is also subdesirable.

21.1.20 I still don't get locking. I just want to increment the number in the file. How can I do this?

Didn't anyone ever tell you web-page hit counters were useless? They don't count number of hits, they're a waste of time, and they serve only to stroke the writer's vanity. It's better to pick a random number; they're more realistic.

Anyway, this is what you can do if you can't help yourself.

```
    use Fcntl qw(:DEFAULT :flock);
    sysopen(FH, "numfile", O_RDWR|O_CREAT)       or die "can't open numfile: $!";
    flock(FH, LOCK_EX)                           or die "can't flock numfile: $!";
    $num = <FH> || 0;
    seek(FH, 0, 0)                               or die "can't rewind numfile: $!";
    truncate(FH, 0)                              or die "can't truncate numfile: $!";
    (print FH $num+1, "\n")                      or die "can't write numfile: $!";
    close FH                                     or die "can't close numfile: $!";
```

Here's a much better web-page hit counter:

```
    $hits = int( (time() - 850_000_000) / rand(1_000) );
```

If the count doesn't impress your friends, then the code might. :-)

21.1.21 All I want to do is append a small amount of text to the end of a file. Do I still have to use locking?

If you are on a system that correctly implements flock() and you use the example appending code from "perldoc -f flock" everything will be OK even if the OS you are on doesn't implement append mode correctly (if such a system exists.) So if you are happy to restrict yourself to OSs that implement flock() (and that's not really much of a restriction) then that is what you should do.

If you know you are only going to use a system that does correctly implement appending (i.e. not Win32) then you can omit the seek() from the above code.

If you know you are only writing code to run on an OS and filesystem that does implement append mode correctly (a local filesystem on a modern Unix for example), and you keep the file in block-buffered mode and you write less than one buffer-full of output between each manual flushing of the buffer then each bufferload is almost guaranteed to be written to the end of the file in one chunk without getting intermingled with anyone else's output. You can also use the syswrite() function which is simply a wrapper around your systems write(2) system call.

There is still a small theoretical chance that a signal will interrupt the system level write() operation before completion. There is also a possibility that some STDIO implementations may call multiple system level write()s even if the buffer was empty to start. There may be some systems where this probability is reduced to zero.

21.1.22 How do I randomly update a binary file?

If you're just trying to patch a binary, in many cases something as simple as this works:

```
    perl -i -pe 's{window manager}{window mangler}g' /usr/bin/emacs
```

However, if you have fixed sized records, then you might do something more like this:

```
    $RECSIZE = 220; # size of record, in bytes
    $recno   = 37;  # which record to update
    open(FH, "+<somewhere") || die "can't update somewhere: $!";
    seek(FH, $recno * $RECSIZE, 0);
    read(FH, $record, $RECSIZE) == $RECSIZE || die "can't read record $recno: $!";
    # munge the record
    seek(FH, -$RECSIZE, 1);
    print FH $record;
    close FH;
```

Locking and error checking are left as an exercise for the reader. Don't forget them or you'll be quite sorry.

21.1.23 How do I get a file's timestamp in perl?

If you want to retrieve the time at which the file was last read, written, or had its meta-data (owner, etc) changed, you use the **-M**, **-A**, or **-C** file test operations as documented in *perlfunc*. These retrieve the age of the file (measured against the start-time of your program) in days as a floating point number. Some platforms may not have all of these times. See *perlport* for details. To retrieve the "raw" time in seconds since the epoch, you would call the stat function, then use localtime(), gmtime(), or POSIX::strftime() to convert this into human-readable form.

Here's an example:

```
    $write_secs = (stat($file))[9];
    printf "file %s updated at %s\n", $file,
        scalar localtime($write_secs);
```

If you prefer something more legible, use the File::stat module (part of the standard distribution in version 5.004 and later):

```
    # error checking left as an exercise for reader.
    use File::stat;
    use Time::localtime;
    $date_string = ctime(stat($file)->mtime);
    print "file $file updated at $date_string\n";
```

The POSIX::strftime() approach has the benefit of being, in theory, independent of the current locale. See *perllocale* for details.

21.1.24 How do I set a file's timestamp in perl?

You use the utime() function documented in utime in *perlfunc*. By way of example, here's a little program that copies the read and write times from its first argument to all the rest of them.

```
    if (@ARGV < 2) {
        die "usage: cptimes timestamp_file other_files ...\n";
    }
    $timestamp = shift;
    ($atime, $mtime) = (stat($timestamp))[8,9];
    utime $atime, $mtime, @ARGV;
```

Error checking is, as usual, left as an exercise for the reader.

Note that utime() currently doesn't work correctly with Win95/NT ports. A bug has been reported. Check it carefully before using utime() on those platforms.

21.1.25 How do I print to more than one file at once?

To connect one filehandle to several output filehandles, you can use the IO::Tee or Tie::FileHandle::Multiplex modules.

If you only have to do this once, you can print individually to each filehandle.

```
    for $fh (FH1, FH2, FH3) { print $fh "whatever\n" }
```

21.1.26 How can I read in an entire file all at once?

You can use the File::Slurp module to do it in one step.

```
        use File::Slurp;

        $all_of_it = read_file($filename); # entire file in scalar
    @all_lines = read_file($filename); # one line perl element
```

The customary Perl approach for processing all the lines in a file is to do so one line at a time:

```
    open (INPUT, $file)         || die "can't open $file: $!";
    while (<INPUT>) {
        chomp;
        # do something with $_
    }
    close(INPUT)                || die "can't close $file: $!";
```

This is tremendously more efficient than reading the entire file into memory as an array of lines and then processing it one element at a time, which is often–if not almost always–the wrong approach. Whenever you see someone do this:

```
    @lines = <INPUT>;
```

you should think long and hard about why you need everything loaded at once. It's just not a scalable solution. You might also find it more fun to use the standard Tie::File module, or the DB_File module's $DB_RECNO bindings, which allow you to tie an array to a file so that accessing an element the array actually accesses the corresponding line in the file.

You can read the entire filehandle contents into a scalar.

```
    {
        local(*INPUT, $/);
        open (INPUT, $file)     || die "can't open $file: $!";
        $var = <INPUT>;
    }
```

That temporarily undefs your record separator, and will automatically close the file at block exit. If the file is already open, just use this:

```
    $var = do { local $/; <INPUT> };
```

For ordinary files you can also use the read function.

```
        read( INPUT, $var, -s INPUT );
```

The third argument tests the byte size of the data on the INPUT filehandle and reads that many bytes into the buffer $var.

21.1.27 How can I read in a file by paragraphs?

Use the `$/` variable (see *perlvar* for details). You can either set it to `""` to eliminate empty paragraphs (`"abc\n\n\n\ndef"`, for instance, gets treated as two paragraphs and not three), or `"\n\n"` to accept empty paragraphs.

Note that a blank line must have no blanks in it. Thus `"fred\n \nstuff\n\n"` is one paragraph, but `"fred\n\nstuff\n\n"` is two.

21.1.28 How can I read a single character from a file? From the keyboard?

You can use the builtin `getc()` function for most filehandles, but it won't (easily) work on a terminal device. For STDIN, either use the Term::ReadKey module from CPAN or use the sample code in getc in *perlfunc*.

If your system supports the portable operating system programming interface (POSIX), you can use the following code, which you'll note turns off echo processing as well.

```
    #!/usr/bin/perl -w
    use strict;
    $| = 1;
    for (1..4) {
        my $got;
        print "gimme: ";
        $got = getone();
        print "--> $got\n";
    }
    exit;

    BEGIN {
        use POSIX qw(:termios_h);

        my ($term, $oterm, $echo, $noecho, $fd_stdin);
        $fd_stdin = fileno(STDIN);

        $term     = POSIX::Termios->new();
        $term->getattr($fd_stdin);
        $oterm     = $term->getlflag();

        $echo     = ECHO | ECHOK | ICANON;
        $noecho   = $oterm & ~$echo;

        sub cbreak {
            $term->setlflag($noecho);
            $term->setcc(VTIME, 1);
            $term->setattr($fd_stdin, TCSANOW);
        }

        sub cooked {
            $term->setlflag($oterm);
            $term->setcc(VTIME, 0);
            $term->setattr($fd_stdin, TCSANOW);
        }

        sub getone {
            my $key = '';
            cbreak();
            sysread(STDIN, $key, 1);
            cooked();
            return $key;
        }

    }

    END { cooked() }
```

The Term::ReadKey module from CPAN may be easier to use. Recent versions include also support for non-portable systems as well.

```
    use Term::ReadKey;
    open(TTY, "</dev/tty");
    print "Gimme a char: ";
    ReadMode "raw";
    $key = ReadKey 0, *TTY;
    ReadMode "normal";
    printf "\nYou said %s, char number %03d\n",
        $key, ord $key;
```

21.1.29 How can I tell whether there's a character waiting on a filehandle?

The very first thing you should do is look into getting the Term::ReadKey extension from CPAN. As we mentioned earlier, it now even has limited support for non-portable (read: not open systems, closed, proprietary, not POSIX, not Unix, etc) systems.

You should also check out the Frequently Asked Questions list in comp.unix.* for things like this: the answer is essentially the same. It's very system dependent. Here's one solution that works on BSD systems:

```
    sub key_ready {
        my($rin, $nfd);
        vec($rin, fileno(STDIN), 1) = 1;
        return $nfd = select($rin,undef,undef,0);
    }
```

If you want to find out how many characters are waiting, there's also the FIONREAD ioctl call to be looked at. The *h2ph* tool that comes with Perl tries to convert C include files to Perl code, which can be `require`d. FIONREAD ends up defined as a function in the *sys/ioctl.ph* file:

```
    require 'sys/ioctl.ph';

    $size = pack("L", 0);
    ioctl(FH, FIONREAD(), $size)    or die "Couldn't call ioctl: $!\n";
    $size = unpack("L", $size);
```

If *h2ph* wasn't installed or doesn't work for you, you can *grep* the include files by hand:

```
    % grep FIONREAD /usr/include/*/*
    /usr/include/asm/ioctls.h:#define FIONREAD      0x541B
```

Or write a small C program using the editor of champions:

```
    % cat > fionread.c
    #include <sys/ioctl.h>
    main() {
        printf("%#08x\n", FIONREAD);
    }
    ^D
    % cc -o fionread fionread.c
    % ./fionread
    0x4004667f
```

And then hard code it, leaving porting as an exercise to your successor.

```
    $FIONREAD = 0x4004667f;         # XXX: opsys dependent

    $size = pack("L", 0);
    ioctl(FH, $FIONREAD, $size)     or die "Couldn't call ioctl: $!\n";
    $size = unpack("L", $size);
```

FIONREAD requires a filehandle connected to a stream, meaning that sockets, pipes, and tty devices work, but *not* files.

21.1.30 How do I do a `tail -f` in perl?

First try

```
    seek(GWFILE, 0, 1);
```

The statement `seek(GWFILE, 0, 1)` doesn't change the current position, but it does clear the end-of-file condition on the handle, so that the next <GWFILE> makes Perl try again to read something.

If that doesn't work (it relies on features of your stdio implementation), then you need something more like this:

```
        for (;;) {
          for ($curpos = tell(GWFILE); <GWFILE>; $curpos = tell(GWFILE)) {
            # search for some stuff and put it into files
          }
          # sleep for a while
          seek(GWFILE, $curpos, 0);  # seek to where we had been
        }
```

If this still doesn't work, look into the POSIX module. POSIX defines the clearerr() method, which can remove the end of file condition on a filehandle. The method: read until end of file, clearerr(), read some more. Lather, rinse, repeat.

There's also a File::Tail module from CPAN.

21.1.31 How do I dup() a filehandle in Perl?

If you check open in *perlfunc*, you'll see that several of the ways to call open() should do the trick. For example:

```
    open(LOG, ">>/foo/logfile");
    open(STDERR, ">&LOG");
```

Or even with a literal numeric descriptor:

```
   $fd = $ENV{MHCONTEXTFD};
   open(MHCONTEXT, "<&=$fd");   # like fdopen(3S)
```

Note that "<&STDIN" makes a copy, but "<&=STDIN" make an alias. That means if you close an aliased handle, all aliases become inaccessible. This is not true with a copied one.

Error checking, as always, has been left as an exercise for the reader.

21.1.32 How do I close a file descriptor by number?

This should rarely be necessary, as the Perl close() function is to be used for things that Perl opened itself, even if it was a dup of a numeric descriptor as with MHCONTEXT above. But if you really have to, you may be able to do this:

```
    require 'sys/syscall.ph';
    $rc = syscall(&SYS_close, $fd + 0);  # must force numeric
    die "can't sysclose $fd: $!" unless $rc == -1;
```

Or, just use the fdopen(3S) feature of open():

```
    {
        local *F;
        open F, "<&=$fd" or die "Cannot reopen fd=$fd: $!";
        close F;
    }
```

21.1.33 Why can't I use "C:\temp\foo" in DOS paths? Why doesn't ‘C:\temp\foo.exe‘ work?

Whoops! You just put a tab and a formfeed into that filename! Remember that within double quoted strings ("like\this"), the backslash is an escape character. The full list of these is in Quote and Quote-like Operators in *perlop*. Unsurprisingly, you don't have a file called "c:(tab)emp(formfeed)oo" or "c:(tab)emp(formfeed)oo.exe" on your legacy DOS filesystem.

Either single-quote your strings, or (preferably) use forward slashes. Since all DOS and Windows versions since something like MS-DOS 2.0 or so have treated / and \ the same in a path, you might as well use the one that doesn't clash with Perl–or the POSIX shell, ANSI C and C++, awk, Tcl, Java, or Python, just to mention a few. POSIX paths are more portable, too.

21.1.34 Why doesn't glob("*.*") get all the files?

Because even on non-Unix ports, Perl's glob function follows standard Unix globbing semantics. You'll need `glob("*")` to get all (non-hidden) files. This makes glob() portable even to legacy systems. Your port may include proprietary globbing functions as well. Check its documentation for details.

21.1.35 Why does Perl let me delete read-only files? Why does `-i` clobber protected files? Isn't this a bug in Perl?

This is elaborately and painstakingly described in the *file-dir-perms* article in the "Far More Than You Ever Wanted To Know" collection in http://www.cpan.org/misc/olddoc/FMTEYEWTK.tgz .

The executive summary: learn how your filesystem works. The permissions on a file say what can happen to the data in that file. The permissions on a directory say what can happen to the list of files in that directory. If you delete a file, you're removing its name from the directory (so the operation depends on the permissions of the directory, not of the file). If you try to write to the file, the permissions of the file govern whether you're allowed to.

21.1.36 How do I select a random line from a file?

Here's an algorithm from the Camel Book:

```
    srand;
    rand($.) < 1 && ($line = $_) while <>;
```

This has a significant advantage in space over reading the whole file in. You can find a proof of this method in *The Art of Computer Programming*, Volume 2, Section 3.4.2, by Donald E. Knuth.

You can use the File::Random module which provides a function for that algorithm:

```
        use File::Random qw/random_line/;
        my $line = random_line($filename);
```

Another way is to use the Tie::File module, which treats the entire file as an array. Simply access a random array element.

21.1.37 Why do I get weird spaces when I print an array of lines?

Saying

```
    print "@lines\n";
```

joins together the elements of `@lines` with a space between them. If `@lines` were `("little", "fluffy", "clouds")` then the above statement would print

```
    little fluffy clouds
```

but if each element of `@lines` was a line of text, ending a newline character `("little\n", "fluffy\n", "clouds\n")` then it would print:

```
    little
     fluffy
     clouds
```

If your array contains lines, just print them:

```
    print @lines;
```

perlfaq6

Regular Expressions ($Revision: 1.20 $, $Date: 2003/01/03 20:05:28 $)

22.1 DESCRIPTION

This section is surprisingly small because the rest of the FAQ is littered with answers involving regular expressions. For example, decoding a URL and checking whether something is a number are handled with regular expressions, but those answers are found elsewhere in this document (in *perlfaq9*: “How do I decode or create those %-encodings on the web” and *perlfaq4*: “How do I determine whether a scalar is a number/whole/integer/float”, to be precise).

22.1.1 How can I hope to use regular expressions without creating illegible and unmaintainable code?

Three techniques can make regular expressions maintainable and understandable.

Comments Outside the Regex

Describe what you’re doing and how you’re doing it, using normal Perl comments.

```
# turn the line into the first word, a colon, and the
# number of characters on the rest of the line
s/^(\w+)(.*)/ lc($1) . ":" . length($2) /meg;
```

Comments Inside the Regex

The `/x` modifier causes whitespace to be ignored in a regex pattern (except in a character class), and also allows you to use normal comments there, too. As you can imagine, whitespace and comments help a lot.

`/x` lets you turn this:

```
s{<(?:[^>'"]*|".*?"|'.*?')+>}{}gs;
```

into this:

```
s{ <                    # opening angle bracket
    (?:                 # Non-backreffing grouping paren
         [^>'"] *       # 0 or more things that are neither > nor ' nor "
            |           #    or else
         ".*?"          # a section between double quotes (stingy match)
            |           #    or else
         '.*?'          # a section between single quotes (stingy match)
    ) +                 #   all occurring one or more times
   >                    # closing angle bracket
}{}gsx;                 # replace with nothing, i.e. delete
```

It’s still not quite so clear as prose, but it is very useful for describing the meaning of each part of the pattern.

Different Delimiters

While we normally think of patterns as being delimited with `/` characters, they can be delimited by almost any character. *perlre* describes this. For example, the `s///` above uses braces as delimiters. Selecting another delimiter can avoid quoting the delimiter within the pattern:

```
s/\/usr\/local/\/usr\/share/g;      # bad delimiter choice
s#/usr/local#/usr/share#g;          # better
```

22.1.2 I’m having trouble matching over more than one line. What’s wrong?

Either you don’t have more than one line in the string you’re looking at (probably), or else you aren’t using the correct modifier(s) on your pattern (possibly).

There are many ways to get multiline data into a string. If you want it to happen automatically while reading input, you’ll want to set $/ (probably to ” for paragraphs or `undef` for the whole file) to allow you to read more than one line at a time.

Read *perlre* to help you decide which of `/s` and `/m` (or both) you might want to use: `/s` allows dot to include newline, and `/m` allows caret and dollar to match next to a newline, not just at the end of the string. You do need to make sure that you’ve actually got a multiline string in there.

For example, this program detects duplicate words, even when they span line breaks (but not paragraph ones). For this example, we don’t need `/s` because we aren’t using dot in a regular expression that we want to cross line boundaries. Neither do we need `/m` because we aren’t wanting caret or dollar to match at any point inside the record next to newlines. But it’s imperative that $/ be set to something other than the default, or else we won’t actually ever have a multiline record read in.

```
$/ = '';            # read in more whole paragraph, not just one line
while ( <> ) {
    while ( /\b([\w'-]+)(\s+\1)+\b/gi ) {   # word starts alpha
        print "Duplicate $1 at paragraph $.\n";
    }
}
```

Here’s code that finds sentences that begin with "From " (which would be mangled by many mailers):

```
$/ = '';            # read in more whole paragraph, not just one line
while ( <> ) {
    while ( /^From /gm ) { # /m makes ^ match next to \n
        print "leading from in paragraph $.\n";
    }
}
```

Here’s code that finds everything between START and END in a paragraph:

```
undef $/;           # read in whole file, not just one line or paragraph
while ( <> ) {
    while ( /START(.*?)END/sgm ) { # /s makes . cross line boundaries
        print "$1\n";
    }
}
```

22.1.3 How can I pull out lines between two patterns that are themselves on different lines?

You can use Perl's somewhat exotic `..` operator (documented in *perlop*):

```
    perl -ne 'print if /START/ .. /END/' file1 file2 ...
```

If you wanted text and not lines, you would use

```
    perl -0777 -ne 'print "$1\n" while /START(.*?)END/gs' file1 file2 ...
```

But if you want nested occurrences of `START` through `END`, you'll run up against the problem described in the question in this section on matching balanced text.

Here's another example of using `..`:

```
    while (<>) {
        $in_header =   1  .. /^$/;
        $in_body   = /^$/ .. eof();
        # now choose between them
    } continue {
        reset if eof();         # fix $.
    }
```

22.1.4 I put a regular expression into $ / but it didn't work. What's wrong?

Up to Perl 5.8.0, $/ has to be a string. This may change in 5.10, but don't get your hopes up. Until then, you can use these examples if you really need to do this.

Use the four argument form of sysread to continually add to a buffer. After you add to the buffer, you check if you have a complete line (using your regular expression).

```
       local $_ = "";
       while( sysread FH, $_, 8192, length ) {
          while( s/^((?s).*?)your_pattern/ ) {
             my $record = $1;
             # do stuff here.
          }
       }

 You can do the same thing with foreach and a match using the
 c flag and the \G anchor, if you do not mind your entire file
 being in memory at the end.

       local $_ = "";
       while( sysread FH, $_, 8192, length ) {
          foreach my $record ( m/\G((?s).*?)your_pattern/gc ) {
             # do stuff here.
          }
          substr( $_, 0, pos ) = "" if pos;
       }
```

22.1.5 How do I substitute case insensitively on the LHS while preserving case on the RHS?

Here’s a lovely Perlish solution by Larry Rosler. It exploits properties of bitwise xor on ASCII strings.

```
    $_= "this is a TEsT case";

    $old = 'test';
    $new = 'success';

    s{(\Q$old\E)}
     { uc $new | (uc $1 ^ $1) .
        (uc(substr $1, -1) ^ substr $1, -1) x
            (length($new) - length $1)
     }egi;

    print;
```

And here it is as a subroutine, modeled after the above:

```
    sub preserve_case($$) {
        my ($old, $new) = @_;
        my $mask = uc $old ^ $old;

        uc $new | $mask .
            substr($mask, -1) x (length($new) - length($old))
    }

    $a = "this is a TEsT case";
    $a =~ s/(test)/preserve_case($1, "success")/egi;
    print "$a\n";
```

This prints:

```
    this is a SUcCESS case
```

As an alternative, to keep the case of the replacement word if it is longer than the original, you can use this code, by Jeff Pinyan:

```
  sub preserve_case {
    my ($from, $to) = @_;
    my ($lf, $lt) = map length, @_;

    if ($lt < $lf) { $from = substr $from, 0, $lt }
    else { $from .= substr $to, $lf }

    return uc $to | ($from ^ uc $from);
  }
```

This changes the sentence to "this is a SUcCess case."

Just to show that C programmers can write C in any programming language, if you prefer a more C-like solution, the following script makes the substitution have the same case, letter by letter, as the original. (It also happens to run about 240% slower than the Perlish solution runs.) If the substitution has more characters than the string being substituted, the case of the last character is used for the rest of the substitution.

```
    # Original by Nathan Torkington, massaged by Jeffrey Friedl
    #
    sub preserve_case($$)
    {
        my ($old, $new) = @_;
        my ($state) = 0; # 0 = no change; 1 = lc; 2 = uc
        my ($i, $oldlen, $newlen, $c) = (0, length($old), length($new));
        my ($len) = $oldlen < $newlen ? $oldlen : $newlen;

        for ($i = 0; $i < $len; $i++) {
            if ($c = substr($old, $i, 1), $c =~ /[\W\d_]/) {
                $state = 0;
            } elsif (lc $c eq $c) {
                substr($new, $i, 1) = lc(substr($new, $i, 1));
                $state = 1;
            } else {
                substr($new, $i, 1) = uc(substr($new, $i, 1));
                $state = 2;
            }
        }
        # finish up with any remaining new (for when new is longer than old)
        if ($newlen > $oldlen) {
            if ($state == 1) {
                substr($new, $oldlen) = lc(substr($new, $oldlen));
            } elsif ($state == 2) {
                substr($new, $oldlen) = uc(substr($new, $oldlen));
            }
        }
        return $new;
    }
```

22.1.6 How can I make `\w` match national character sets?

Put `use locale;` in your script. The \w character class is taken from the current locale.

See *perllocale* for details.

22.1.7 How can I match a locale-smart version of `/[a-zA-Z]/`?

You can use the POSIX character class syntax `/[[:alpha:]]/` documented in *perlre*.

No matter which locale you are in, the alphabetic characters are the characters in \w without the digits and the underscore. As a regex, that looks like `/[^\W\d_]/`. Its complement, the non-alphabetics, is then everything in \W along with the digits and the underscore, or `/[\W\d_]/`.

22.1.8 How can I quote a variable to use in a regex?

The Perl parser will expand $variable and @variable references in regular expressions unless the delimiter is a single quote. Remember, too, that the right-hand side of a `s///` substitution is considered a double-quoted string (see *perlop* for more details). Remember also that any regex special characters will be acted on unless you precede the substitution with \Q. Here's an example:

```
    $string = "Placido P. Octopus";
    $regex  = "P.";
    $string =~ s/$regex/Polyp/;
    # $string is now "Polypacido P. Octopus"
```

Because `.` is special in regular expressions, and can match any single character, the regex `P.` here has matched the <Pl> in the original string.

To escape the special meaning of `.`, we use `\Q`:

```
    $string = "Placido P. Octopus";
    $regex  = "P.";

    $string =~ s/\Q$regex/Polyp/;
    # $string is now "Placido Polyp Octopus"
```

The use of `\Q` causes the <.> in the regex to be treated as a regular character, so that `P.` matches a `P` followed by a dot.

22.1.9 What is /o really for?

Using a variable in a regular expression match forces a re-evaluation (and perhaps recompilation) each time the regular expression is encountered. The `/o` modifier locks in the regex the first time it's used. This always happens in a constant regular expression, and in fact, the pattern was compiled into the internal format at the same time your entire program was.

Use of `/o` is irrelevant unless variable interpolation is used in the pattern, and if so, the regex engine will neither know nor care whether the variables change after the pattern is evaluated the *very first* time.

`/o` is often used to gain an extra measure of efficiency by not performing subsequent evaluations when you know it won't matter (because you know the variables won't change), or more rarely, when you don't want the regex to notice if they do.

For example, here's a "paragrep" program:

```
    $/ = '';  # paragraph mode
    $pat = shift;
    while (<>) {
        print if /$pat/o;
    }
```

22.1.10 How do I use a regular expression to strip C style comments from a file?

While this actually can be done, it's much harder than you'd think. For example, this one-liner

```
    perl -0777 -pe 's{/\*.*?\*/}{}gs' foo.c
```

will work in many but not all cases. You see, it's too simple-minded for certain kinds of C programs, in particular, those with what appear to be comments in quoted strings. For that, you'd need something like this, created by Jeffrey Friedl and later modified by Fred Curtis.

```
    $/ = undef;
    $_ = <>;
    s#/\*[^*]*\*+([^/*][^*]*\*+)*/|("(\\.|[^"\\])*"|'(\\.|[^'\\])*'|.[^/"'\\]*)#$2#gs
    print;
```

This could, of course, be more legibly written with the `/x` modifier, adding whitespace and comments. Here it is expanded, courtesy of Fred Curtis.

```
    s{
       /\*         ##  Start of /* ... */ comment
       [^*]*\*+    ##  Non-* followed by 1-or-more *'s
       (
         [^/*][^*]*\*+
       )*          ##  0-or-more things which don't start with /
                   ##    but do end with '*'
       /           ##  End of /* ... */ comment

     |         ##     OR  various things which aren't comments:

       (
         "           ##  Start of " ... " string
         (
           \\.           ##  Escaped char
         |               ##    OR
           [^"\\]        ##  Non "\
         )*
         "           ##  End of " ... " string

       |         ##     OR

         '           ##  Start of ' ... ' string
         (
           \\.           ##  Escaped char
         |               ##    OR
           [^'\\]        ##  Non '\
         )*
         '           ##  End of ' ... ' string

       |         ##     OR

         .           ##  Anything other char
         [^/"'\\]*   ##  Chars which doesn't start a comment, string or escape
       )
     }{$2}gxs;
```

A slight modification also removes C++ comments:

```
    s#/\*[^*]*\*+([^/*][^*]*\*+)*/|//[^\n]*|("(\\.|[^"\\])*"|'(\\.|[^'\\])*'|.[^/"'\\]*)#$2#gs;
```

22.1.11 Can I use Perl regular expressions to match balanced text?

Historically, Perl regular expressions were not capable of matching balanced text. As of more recent versions of perl including 5.6.1 experimental features have been added that make it possible to do this. Look at the documentation for the (??{ }) construct in recent perlre manual pages to see an example of matching balanced parentheses. Be sure to take special notice of the warnings present in the manual before making use of this feature.

CPAN contains many modules that can be useful for matching text depending on the context. Damian Conway provides some useful patterns in Regexp::Common. The module Text::Balanced provides a general solution to this problem.

One of the common applications of balanced text matching is working with XML and HTML. There are many modules available that support these needs. Two examples are HTML::Parser and XML::Parser. There are many others.

An elaborate subroutine (for 7-bit ASCII only) to pull out balanced and possibly nested single chars, like ` and ', { and }, or (and) can be found in http://www.cpan.org/authors/id/TOMC/scripts/pull_quotes.gz .

The C::Scan module from CPAN also contains such subs for internal use, but they are undocumented.

22.1.12 What does it mean that regexes are greedy? How can I get around it?

Most people mean that greedy regexes match as much as they can. Technically speaking, it's actually the quantifiers (?, *, +, {}) that are greedy rather than the whole pattern; Perl prefers local greed and immediate gratification to overall greed. To get non-greedy versions of the same quantifiers, use (??, *?, +?, {}?).

An example:

```
        $s1 = $s2 = "I am very very cold";
        $s1 =~ s/ve.*y //;      # I am cold
        $s2 =~ s/ve.*?y //;     # I am very cold
```

Notice how the second substitution stopped matching as soon as it encountered "y ". The *? quantifier effectively tells the regular expression engine to find a match as quickly as possible and pass control on to whatever is next in line, like you would if you were playing hot potato.

22.1.13 How do I process each word on each line?

Use the split function:

```
    while (<>) {
        foreach $word ( split ) {
            # do something with $word here
        }
    }
```

Note that this isn't really a word in the English sense; it's just chunks of consecutive non-whitespace characters.

To work with only alphanumeric sequences (including underscores), you might consider

```
    while (<>) {
        foreach $word (m/(\w+)/g) {
            # do something with $word here
        }
    }
```

22.1.14 How can I print out a word-frequency or line-frequency summary?

To do this, you have to parse out each word in the input stream. We'll pretend that by word you mean chunk of alphabetics, hyphens, or apostrophes, rather than the non-whitespace chunk idea of a word given in the previous question:

```
    while (<>) {
        while ( /(\b[^\W_\d][\w'-]+\b)/g ) {   # misses "`sheep'"
            $seen{$1}++;
        }
    }
    while ( ($word, $count) = each %seen ) {
        print "$count $word\n";
    }
```

If you wanted to do the same thing for lines, you wouldn't need a regular expression:

```
    while (<>) {
        $seen{$_}++;
    }
    while ( ($line, $count) = each %seen ) {
        print "$count $line";
    }
```

If you want these output in a sorted order, see *perlfaq4*: "How do I sort a hash (optionally by value instead of key)?".

22.1.15 How can I do approximate matching?

See the module String::Approx available from CPAN.

22.1.16 How do I efficiently match many regular expressions at once?

The following is extremely inefficient:

```
# slow but obvious way
@popstates = qw(CO ON MI WI MN);
while (defined($line = <>)) {
    for $state (@popstates) {
        if ($line =~ /\b$state\b/i) {
            print $line;
            last;
        }
    }
}
```

That's because Perl has to recompile all those patterns for each of the lines of the file. As of the 5.005 release, there's a much better approach, one which makes use of the new `qr//` operator:

```
# use spiffy new qr// operator, with /i flag even
use 5.005;
@popstates = qw(CO ON MI WI MN);
@poppats   = map { qr/\b$_\b/i } @popstates;
while (defined($line = <>)) {
    for $patobj (@poppats) {
        print $line if $line =~ /$patobj/;
    }
}
```

22.1.17 Why don't word-boundary searches with `\b` work for me?

Two common misconceptions are that `\b` is a synonym for `\s+` and that it's the edge between whitespace characters and non-whitespace characters. Neither is correct. `\b` is the place between a `\w` character and a `\W` character (that is, `\b` is the edge of a "word"). It's a zero-width assertion, just like `^`, `$`, and all the other anchors, so it doesn't consume any characters. *perlre* describes the behavior of all the regex metacharacters.

Here are examples of the incorrect application of `\b`, with fixes:

```
"two words" =~ /(\w+)\b(\w+)/;          # WRONG
"two words" =~ /(\w+)\s+(\w+)/;         # right

" =matchless= text" =~ /\b=(\w+)=\b/;   # WRONG
" =matchless= text" =~ /=(\w+)=/;       # right
```

Although they may not do what you thought they did, `\b` and `\B` can still be quite useful. For an example of the correct use of `\b`, see the example of matching duplicate words over multiple lines.

An example of using `\B` is the pattern `\Bis\B`. This will find occurrences of "is" on the insides of words only, as in "thistle", but not "this" or "island".

22.1.18 Why does using $ &, $ ‘, or $ ’ slow my program down?

Once Perl sees that you need one of these variables anywhere in the program, it provides them on each and every pattern match. The same mechanism that handles these provides for the use of $1, $2, etc., so you pay the same price for each regex that contains capturing parentheses. If you never use $&, etc., in your script, then regexes *without* capturing parentheses won't be penalized. So avoid $&, $', and $‘ if you can, but if you can't, once you've used them at all, use them at will because you've already paid the price. Remember that some algorithms really appreciate them. As of the 5.005 release. the $& variable is no longer "expensive" the way the other two are.

22.1.19 What good is \G in a regular expression?

You use the \G anchor to start the next match on the same string where the last match left off. The regular expression engine cannot skip over any characters to find the next match with this anchor, so \G is similar to the beginning of string anchor, ^. The \G anchor is typically used with the g flag. It uses the value of pos() as the position to start the next match. As the match operator makes successive matches, it updates pos() with the position of the next character past the last match (or the first character of the next match, depending on how you like to look at it). Each string has its own pos() value.

Suppose you want to match all of consective pairs of digits in a string like "1122a44" and stop matching when you encounter non-digits. You want to match 11 and 22 but the letter <a> shows up between 22 and 44 and you want to stop at a. Simply matching pairs of digits skips over the a and still matches 44.

```
        $_ = "1122a44";
        my @pairs = m/(\d\d)/g;   # qw( 11 22 44 )
```

If you use the \G anchor, you force the match after 22 to start with the a. The regular expression cannot match there since it does not find a digit, so the next match fails and the match operator returns the pairs it already found.

```
        $_ = "1122a44";
        my @pairs = m/\G(\d\d)/g; # qw( 11 22 )
```

You can also use the \G anchor in scalar context. You still need the g flag.

```
        $_ = "1122a44";
        while( m/\G(\d\d)/g )
                {
                print "Found $1\n";
                }
```

After the match fails at the letter a, perl resets pos() and the next match on the same string starts at the beginning.

```
        $_ = "1122a44";
        while( m/\G(\d\d)/g )
                {
                print "Found $1\n";
                }

        print "Found $1 after while" if m/(\d\d)/g; # finds "11"
```

You can disable pos() resets on fail with the c flag. Subsequent matches start where the last successful match ended (the value of pos()) even if a match on the same string as failed in the meantime. In this case, the match after the while() loop starts at the a (where the last match stopped), and since it does not use any anchor it can skip over the a to find "44".

```
        $_ = "1122a44";
        while( m/\G(\d\d)/gc )
                {
                print "Found $1\n";
                }
        print "Found $1 after while" if m/(\d\d)/g; # finds "44"
```

Typically you use the \G anchor with the c flag when you want to try a different match if one fails, such as in a tokenizer. Jeffrey Friedl offers this example which works in 5.004 or later.

```
    while (<>) {
      chomp;
      PARSER: {
           m/ \G( \d+\b    )/gcx   && do { print "number: $1\n";  redo; };
           m/ \G( \w+      )/gcx   && do { print "word:   $1\n";  redo; };
           m/ \G( \s+      )/gcx   && do { print "space:  $1\n";  redo; };
           m/ \G( [^\w\d]+ )/gcx   && do { print "other:  $1\n";  redo; };
      }
    }
```

For each line, the PARSER loop first tries to match a series of digits followed by a word boundary. This match has to start at the place the last match left off (or the beginning of the string on the first match). Since `m/ \G( \d+\b )/gcx` uses the c flag, if the string does not match that regular expression, perl does not reset pos() and the next match starts at the same position to try a different pattern.

22.1.20 Are Perl regexes DFAs or NFAs? Are they POSIX compliant?

While it's true that Perl's regular expressions resemble the DFAs (deterministic finite automata) of the egrep(1) program, they are in fact implemented as NFAs (non-deterministic finite automata) to allow backtracking and backreferencing. And they aren't POSIX-style either, because those guarantee worst-case behavior for all cases. (It seems that some people prefer guarantees of consistency, even when what's guaranteed is slowness.) See the book "Mastering Regular Expressions" (from O'Reilly) by Jeffrey Friedl for all the details you could ever hope to know on these matters (a full citation appears in *perlfaq2*).

22.1.21 What's wrong with using grep in a void context?

The problem is that grep builds a return list, regardless of the context. This means you're making Perl go to the trouble of building a list that you then just throw away. If the list is large, you waste both time and space. If your intent is to iterate over the list, then use a for loop for this purpose.

In perls older than 5.8.1, map suffers from this problem as well. But since 5.8.1, this has been fixed, and map is context aware - in void context, no lists are constructed.

22.1.22 How can I match strings with multibyte characters?

Starting from Perl 5.6 Perl has had some level of multibyte character support. Perl 5.8 or later is recommended. Supported multibyte character repertoires include Unicode, and legacy encodings through the Encode module. See *perluniintro*, *perlunicode*, and *Encode*.

If you are stuck with older Perls, you can do Unicode with the `Unicode::String` module, and character conversions using the `Unicode::Map8` and `Unicode::Map` modules. If you are using Japanese encodings, you might try using the jperl 5.005_03.

Finally, the following set of approaches was offered by Jeffrey Friedl, whose article in issue #5 of The Perl Journal talks about this very matter.

Let's suppose you have some weird Martian encoding where pairs of ASCII uppercase letters encode single Martian letters (i.e. the two bytes "CV" make a single Martian letter, as do the two bytes "SG", "VS", "XX", etc.). Other bytes represent single characters, just like ASCII.

So, the string of Martian "I am CVSGXX!" uses 12 bytes to encode the nine characters 'I', ' ', 'a', 'm', ' ', 'CV', 'SG', 'XX', '!'.

Now, say you want to search for the single character `/GX/`. Perl doesn't know about Martian, so it'll find the two bytes "GX" in the "I am CVSGXX!" string, even though that character isn't there: it just looks like it is because "SG" is next to "XX", but there's no real "GX". This is a big problem.

Here are a few ways, all painful, to deal with it:

```
$martian =~ s/([A-Z][A-Z])/ $1 /g; # Make sure adjacent ‘‘martian’’
                                   # bytes are no longer adjacent.
print "found GX!\n" if $martian =~ /GX/;
```

Or like this:

```
@chars = $martian =~ m/([A-Z][A-Z]|[^A-Z])/g;
# above is conceptually similar to:     @chars = $text =~ m/(.)/g;
#
foreach $char (@chars) {
    print "found GX!\n", last if $char eq 'GX';
}
```

Or like this:

```
while ($martian =~ m/\G([A-Z][A-Z]|.)/gs) {  # \G probably unneeded
    print "found GX!\n", last if $1 eq 'GX';
}
```

Here’s another, slightly less painful, way to do it from Benjamin Goldberg:

```
     $martian =~ m/
        (?!<[A-Z])
        (?:[A-Z][A-Z])*?
        GX
     /x;
```

This succeeds if the "martian" character GX is in the string, and fails otherwise. If you don’t like using (?!<), you can replace (?!<[A-Z]) with (?:^|[^A-Z]).

It does have the drawback of putting the wrong thing in $-[0] and $+[0], but this usually can be worked around.

22.1.23 How do I match a pattern that is supplied by the user?

Well, if it’s really a pattern, then just use

```
chomp($pattern = <STDIN>);
if ($line =~ /$pattern/) { }
```

Alternatively, since you have no guarantee that your user entered a valid regular expression, trap the exception this way:

```
if (eval { $line =~ /$pattern/ }) { }
```

If all you really want to search for a string, not a pattern, then you should either use the index() function, which is made for string searching, or if you can’t be disabused of using a pattern match on a non-pattern, then be sure to use `\Q`...`\E`, documented in *perlre*.

```
$pattern = <STDIN>;

open (FILE, $input) or die "Couldn't open input $input: $!; aborting";
while (<FILE>) {
    print if /\Q$pattern\E/;
}
close FILE;
```

General Perl Language Issues ($Revision: 1.15 $, $Date: 2003/07/24 02:17:21 $)

23.1 DESCRIPTION

This section deals with general Perl language issues that don't clearly fit into any of the other sections.

23.1.1 Can I get a BNF/yacc/RE for the Perl language?

There is no BNF, but you can paw your way through the yacc grammar in perly.y in the source distribution if you're particularly brave. The grammar relies on very smart tokenizing code, so be prepared to venture into toke.c as well.

In the words of Chaim Frenkel: "Perl's grammar can not be reduced to BNF. The work of parsing perl is distributed between yacc, the lexer, smoke and mirrors."

23.1.2 What are all these $ @%&* punctuation signs, and how do I know when to use them?

They are type specifiers, as detailed in *perldata*:

```
    $ for scalar values (number, string or reference)
    @ for arrays
    % for hashes (associative arrays)
    & for subroutines (aka functions, procedures, methods)
    * for all types of that symbol name.  In version 4 you used them like
      pointers, but in modern perls you can just use references.
```

There are couple of other symbols that you're likely to encounter that aren't really type specifiers:

```
    <> are used for inputting a record from a filehandle.
    \  takes a reference to something.
```

Note that <FILE> is *neither* the type specifier for files nor the name of the handle. It is the <> operator applied to the handle FILE. It reads one line (well, record–see $/ in *perlvar*) from the handle FILE in scalar context, or *all* lines in list context. When performing open, close, or any other operation besides <> on files, or even when talking about the handle, do *not* use the brackets. These are correct: `eof(FH)`, `seek(FH, 0, 2)` and "copying from STDIN to FILE".

23.1.3 Do I always/never have to quote my strings or use semicolons and commas?

Normally, a bareword doesn't need to be quoted, but in most cases probably should be (and must be under `use strict`). But a hash key consisting of a simple word (that isn't the name of a defined subroutine) and the left-hand operand to the => operator both count as though they were quoted:

```
    This                    is like this
    ------------            ---------------
    $foo{line}              $foo{"line"}
    bar => stuff            "bar" => stuff
```

The final semicolon in a block is optional, as is the final comma in a list. Good style (see *perlstyle*) says to put them in except for one-liners:

```
    if ($whoops) { exit 1 }
    @nums = (1, 2, 3);

    if ($whoops) {
        exit 1;
    }
    @lines = (
        "There Beren came from mountains cold",
        "And lost he wandered under leaves",
    );
```

23.1.4 How do I skip some return values?

One way is to treat the return values as a list and index into it:

```
        $dir = (getpwnam($user))[7];
```

Another way is to use undef as an element on the left-hand-side:

```
    ($dev, $ino, undef, undef, $uid, $gid) = stat($file);
```

You can also use a list slice to select only the elements that you need:

```
        ($dev, $ino, $uid, $gid) = ( stat($file) )[0,1,4,5];
```

23.1.5 How do I temporarily block warnings?

If you are running Perl 5.6.0 or better, the `use warnings` pragma allows fine control of what warning are produced. See *perllexwarn* for more details.

```
    {
        no warnings;           # temporarily turn off warnings
        $a = $b + $c;          # I know these might be undef
    }
```

If you have an older version of Perl, the `$^W` variable (documented in *perlvar*) controls runtime warnings for a block:

```
    {
        local $^W = 0;         # temporarily turn off warnings
        $a = $b + $c;          # I know these might be undef
    }
```

Note that like all the punctuation variables, you cannot currently use my() on `$^W`, only local().

23.1.6 What's an extension?

An extension is a way of calling compiled C code from Perl. Reading *perlxstut* is a good place to learn more about extensions.

23.1.7 Why do Perl operators have different precedence than C operators?

Actually, they don't. All C operators that Perl copies have the same precedence in Perl as they do in C. The problem is with operators that C doesn't have, especially functions that give a list context to everything on their right, eg. print, chmod, exec, and so on. Such functions are called "list operators" and appear as such in the precedence table in *perlop*.

A common mistake is to write:

```
    unlink $file || die "snafu";
```

This gets interpreted as:

```
    unlink ($file || die "snafu");
```

To avoid this problem, either put in extra parentheses or use the super low precedence `or` operator:

```
    (unlink $file) || die "snafu";
    unlink $file or die "snafu";
```

The "English" operators (`and`, `or`, `xor`, and `not`) deliberately have precedence lower than that of list operators for just such situations as the one above.

Another operator with surprising precedence is exponentiation. It binds more tightly even than unary minus, making `-2**2` product a negative not a positive four. It is also right-associating, meaning that `2**3**2` is two raised to the ninth power, not eight squared.

Although it has the same precedence as in C, Perl's `?:` operator produces an lvalue. This assigns $x to either $a or $b, depending on the trueness of $maybe:

```
    ($maybe ? $a : $b) = $x;
```

23.1.8 How do I declare/create a structure?

In general, you don't "declare" a structure. Just use a (probably anonymous) hash reference. See *perlref* and *perldsc* for details. Here's an example:

```
    $person = {};                   # new anonymous hash
    $person->{AGE}  = 24;           # set field AGE to 24
    $person->{NAME} = "Nat";        # set field NAME to "Nat"
```

If you're looking for something a bit more rigorous, try *perltoot*.

23.1.9 How do I create a module?

A module is a package that lives in a file of the same name. For example, the Hello::There module would live in Hello/There.pm. For details, read *perlmod*. You'll also find *Exporter* helpful. If you're writing a C or mixed-language module with both C and Perl, then you should study *perlxstut*.

The `h2xs` program will create stubs for all the important stuff for you:

```
  % h2xs -XA -n My::Module
```

The `-X` switch tells `h2xs` that you are not using `XS` extension code. The `-A` switch tells `h2xs` that you are not using the AutoLoader, and the `-n` switch specifies the name of the module. See *h2xs* for more details.

23.1.10 How do I create a class?

See *perltoot* for an introduction to classes and objects, as well as *perlobj* and *perlbot*.

23.1.11 How can I tell if a variable is tainted?

You can use the tainted() function of the Scalar::Util module, available from CPAN (or included with Perl since release 5.8.0). See also Laundering and Detecting Tainted Data in *perlsec*.

23.1.12 What's a closure?

Closures are documented in *perlref*.

Closure is a computer science term with a precise but hard-to-explain meaning. Closures are implemented in Perl as anonymous subroutines with lasting references to lexical variables outside their own scopes. These lexicals magically refer to the variables that were around when the subroutine was defined (deep binding).

Closures make sense in any programming language where you can have the return value of a function be itself a function, as you can in Perl. Note that some languages provide anonymous functions but are not capable of providing proper closures: the Python language, for example. For more information on closures, check out any textbook on functional programming. Scheme is a language that not only supports but encourages closures.

Here's a classic function-generating function:

```
sub add_function_generator {
  return sub { shift + shift };
}

$add_sub = add_function_generator();
$sum = $add_sub->(4,5);                # $sum is 9 now.
```

The closure works as a *function template* with some customization slots left out to be filled later. The anonymous subroutine returned by add_function_generator() isn't technically a closure because it refers to no lexicals outside its own scope.

Contrast this with the following make_adder() function, in which the returned anonymous function contains a reference to a lexical variable outside the scope of that function itself. Such a reference requires that Perl return a proper closure, thus locking in for all time the value that the lexical had when the function was created.

```
sub make_adder {
    my $addpiece = shift;
    return sub { shift + $addpiece };
}

$f1 = make_adder(20);
$f2 = make_adder(555);
```

Now `&$f1($n)` is always 20 plus whatever $n you pass in, whereas `&$f2($n)` is always 555 plus whatever $n you pass in. The $addpiece in the closure sticks around.

Closures are often used for less esoteric purposes. For example, when you want to pass in a bit of code into a function:

```
my $line;
timeout( 30, sub { $line = <STDIN> } );
```

If the code to execute had been passed in as a string, `'$line = <STDIN>'`, there would have been no way for the hypothetical timeout() function to access the lexical variable $line back in its caller's scope.

23.1.13 What is variable suicide and how can I prevent it?

Variable suicide is when you (temporarily or permanently) lose the value of a variable. It is caused by scoping through my() and local() interacting with either closures or aliased foreach() iterator variables and subroutine arguments. It used to be easy to inadvertently lose a variable's value this way, but now it's much harder. Take this code:

```
my $f = "foo";
sub T {
  while ($i++ < 3) { my $f = $f; $f .= "bar"; print $f, "\n" }
}
T;
print "Finally $f\n";
```

The $f that has "bar" added to it three times should be a new `$f` (`my $f` should create a new local variable each time through the loop). It isn't, however. This was a bug, now fixed in the latest releases (tested against 5.004_05, 5.005_03, and 5.005_56).

23.1.14 How can I pass/return a {Function, FileHandle, Array, Hash, Method, Regex}?

With the exception of regexes, you need to pass references to these objects. See Pass by Reference in *perlsub* for this particular question, and *perlref* for information on references.

See "Passing Regexes", below, for information on passing regular expressions.

Passing Variables and Functions

Regular variables and functions are quite easy to pass: just pass in a reference to an existing or anonymous variable or function:

```
func( \$some_scalar );

func( \@some_array  );
func( [ 1 .. 10 ]   );

func( \%some_hash   );
func( { this => 10, that => 20 }   );

func( \&some_func   );
func( sub { $_[0] ** $_[1] }   );
```

Passing Filehandles

As of Perl 5.6, you can represent filehandles with scalar variables which you treat as any other scalar.

```
open my $fh, $filename or die "Cannot open $filename! $!";
func( $fh );

sub func {
        my $passed_fh = shift;

        my $line = <$fh>;
        }
```

Before Perl 5.6, you had to use the `*FH` or `\*FH` notations. These are "typeglobs"–see Typeglobs and Filehandles in *perldata* and especially Pass by Reference in *perlsub* for more information.

Passing Regexes

To pass regexes around, you'll need to be using a release of Perl sufficiently recent as to support the `qr//` construct, pass around strings and use an exception-trapping eval, or else be very, very clever.

Here's an example of how to pass in a string to be regex compared using `qr//`:

```
sub compare($$) {
    my ($val1, $regex) = @_;
    my $retval = $val1 =~ /$regex/;
    return $retval;
}
$match = compare("old McDonald", qr/d.*D/i);
```

Notice how `qr//` allows flags at the end. That pattern was compiled at compile time, although it was executed later. The nifty `qr//` notation wasn't introduced until the 5.005 release. Before that, you had to approach this problem much less intuitively. For example, here it is again if you don't have `qr//`:

```
sub compare($$) {
    my ($val1, $regex) = @_;
    my $retval = eval { $val1 =~ /$regex/ };
    die if $@;
    return $retval;
}

$match = compare("old McDonald", q/($?i)d.*D/);
```

Make sure you never say something like this:

```
return eval "\$val =~ /$regex/";   # WRONG
```

or someone can sneak shell escapes into the regex due to the double interpolation of the eval and the double-quoted string. For example:

```
$pattern_of_evil = 'danger ${ system("rm -rf * &") } danger';

eval "\$string =~ /$pattern_of_evil/";
```

Those preferring to be very, very clever might see the O'Reilly book, *Mastering Regular Expressions*, by Jeffrey Friedl. Page 273's Build_MatchMany_Function() is particularly interesting. A complete citation of this book is given in *perlfaq2*.

Passing Methods

To pass an object method into a subroutine, you can do this:

```
call_a_lot(10, $some_obj, "methname")
sub call_a_lot {
    my ($count, $widget, $trick) = @_;
    for (my $i = 0; $i < $count; $i++) {
        $widget->$trick();
    }
}
```

Or, you can use a closure to bundle up the object, its method call, and arguments:

```
        my $whatnot =  sub { $some_obj->obfuscate(@args) };
        func($whatnot);
        sub func {
            my $code = shift;
            &$code();
        }
```

You could also investigate the can() method in the UNIVERSAL class (part of the standard perl distribution).

23.1.15 How do I create a static variable?

As with most things in Perl, TMTOWTDI. What is a "static variable" in other languages could be either a function-private variable (visible only within a single function, retaining its value between calls to that function), or a file-private variable (visible only to functions within the file it was declared in) in Perl.

Here's code to implement a function-private variable:

```
    BEGIN {
        my $counter = 42;
        sub prev_counter { return --$counter }
        sub next_counter { return $counter++ }
    }
```

Now prev_counter() and next_counter() share a private variable $counter that was initialized at compile time.

To declare a file-private variable, you'll still use a my(), putting the declaration at the outer scope level at the top of the file. Assume this is in file Pax.pm:

```
    package Pax;
    my $started = scalar(localtime(time()));

    sub begun { return $started }
```

When `use Pax` or `require Pax` loads this module, the variable will be initialized. It won't get garbage-collected the way most variables going out of scope do, because the begun() function cares about it, but no one else can get it. It is not called $Pax::started because its scope is unrelated to the package. It's scoped to the file. You could conceivably have several packages in that same file all accessing the same private variable, but another file with the same package couldn't get to it.

See Persistent Private Variables in *perlsub* for details.

23.1.16 What's the difference between dynamic and lexical (static) scoping? Between local() and my()?

`local($x)` saves away the old value of the global variable `$x` and assigns a new value for the duration of the subroutine *which is visible in other functions called from that subroutine*. This is done at run-time, so is called dynamic scoping. local() always affects global variables, also called package variables or dynamic variables.

`my($x)` creates a new variable that is only visible in the current subroutine. This is done at compile-time, so it is called lexical or static scoping. my() always affects private variables, also called lexical variables or (improperly) static(ly scoped) variables.

For instance:

```
    sub visible {
        print "var has value $var\n";
    }
    sub dynamic {
        local $var = 'local';   # new temporary value for the still-global
        visible();              #   variable called $var
    }

    sub lexical {
        my $var = 'private';    # new private variable, $var
        visible();              # (invisible outside of sub scope)
    }

    $var = 'global';

    visible();                  # prints global
    dynamic();                  # prints local
    lexical();                  # prints global
```

Notice how at no point does the value "private" get printed. That's because $var only has that value within the block of the lexical() function, and it is hidden from called subroutine.

In summary, local() doesn't make what you think of as private, local variables. It gives a global variable a temporary value. my() is what you're looking for if you want private variables.

See Private Variables via my() in *perlsub* and Temporary Values via local() in *perlsub* for excruciating details.

23.1.17 How can I access a dynamic variable while a similarly named lexical is in scope?

If you know your package, you can just mention it explicitly, as in $Some_Pack::var. Note that the notation $::var is **not** the dynamic $var in the current package, but rather the one in the "main" package, as though you had written $main::var.

```
        use vars '$var';
        local $var = "global";
        my    $var = "lexical";

        print "lexical is $var\n";
        print "global  is $main::var\n";
```

Alternatively you can use the compiler directive our() to bring a dynamic variable into the current lexical scope.

```
        require 5.006; # our() did not exist before 5.6
        use vars '$var';

        local $var = "global";
        my $var    = "lexical";

        print "lexical is $var\n";

        {
          our $var;
          print "global  is $var\n";
        }
```

23.1.18 What's the difference between deep and shallow binding?

In deep binding, lexical variables mentioned in anonymous subroutines are the same ones that were in scope when the subroutine was created. In shallow binding, they are whichever variables with the same names happen to be in scope when the subroutine is called. Perl always uses deep binding of lexical variables (i.e., those created with my()). However, dynamic variables (aka global, local, or package variables) are effectively shallowly bound. Consider this just one more reason not to use them. See the answer to §23.1.12.

23.1.19 Why doesn't "my($ foo) = <FILE>;" work right?

`my()` and `local()` give list context to the right hand side of =. The <FH> read operation, like so many of Perl's functions and operators, can tell which context it was called in and behaves appropriately. In general, the scalar() function can help. This function does nothing to the data itself (contrary to popular myth) but rather tells its argument to behave in whatever its scalar fashion is. If that function doesn't have a defined scalar behavior, this of course doesn't help you (such as with sort()).

To enforce scalar context in this particular case, however, you need merely omit the parentheses:

```
    local($foo) = <FILE>;           # WRONG
    local($foo) = scalar(<FILE>);   # ok
    local $foo  = <FILE>;           # right
```

You should probably be using lexical variables anyway, although the issue is the same here:

```
    my($foo) = <FILE>;  # WRONG
    my $foo  = <FILE>;  # right
```

23.1.20 How do I redefine a builtin function, operator, or method?

Why do you want to do that? :-)

If you want to override a predefined function, such as open(), then you'll have to import the new definition from a different module. See Overriding Built-in Functions in *perlsub*. There's also an example in Class::Template in *perltoot*.

If you want to overload a Perl operator, such as + or `**`, then you'll want to use the `use overload` pragma, documented in *overload*.

If you're talking about obscuring method calls in parent classes, see Overridden Methods in *perltoot*.

23.1.21 What's the difference between calling a function as &foo and foo()?

When you call a function as `&foo`, you allow that function access to your current @_ values, and you bypass prototypes. The function doesn't get an empty @_–it gets yours! While not strictly speaking a bug (it's documented that way in *perlsub*), it would be hard to consider this a feature in most cases.

When you call your function as `&foo()`, then you *do* get a new @_, but prototyping is still circumvented.

Normally, you want to call a function using `foo()`. You may only omit the parentheses if the function is already known to the compiler because it already saw the definition (`use` but not `require`), or via a forward reference or `use subs` declaration. Even in this case, you get a clean @_ without any of the old values leaking through where they don't belong.

23.1.22 How do I create a switch or case statement?

This is explained in more depth in the *perlsyn*. Briefly, there's no official case statement, because of the variety of tests possible in Perl (numeric comparison, string comparison, glob comparison, regex matching, overloaded comparisons, ...). Larry couldn't decide how best to do this, so he left it out, even though it's been on the wish list since perl1.

Starting from Perl 5.8 to get switch and case one can use the Switch extension and say:

```
        use Switch;
```

after which one has switch and case. It is not as fast as it could be because it's not really part of the language (it's done using source filters) but it is available, and it's very flexible.

But if one wants to use pure Perl, the general answer is to write a construct like this:

```
    for ($variable_to_test) {
        if    (/pat1/)  { }     # do something
        elsif (/pat2/)  { }     # do something else
        elsif (/pat3/)  { }     # do something else
        else            { }     # default
    }
```

Here's a simple example of a switch based on pattern matching, this time lined up in a way to make it look more like a switch statement. We'll do a multiway conditional based on the type of reference stored in $whatchamacallit:

```
    SWITCH: for (ref $whatchamacallit) {

        /^$/            && die "not a reference";

        /SCALAR/        && do {
                                print_scalar($$ref);
                                last SWITCH;
                        };

        /ARRAY/         && do {
                                print_array(@$ref);
                                last SWITCH;
                        };

        /HASH/          && do {
                                print_hash(%$ref);
                                last SWITCH;
                        };

        /CODE/          && do {
                                warn "can't print function ref";
                                last SWITCH;
                        };

        # DEFAULT

        warn "User defined type skipped";

    }
```

See perlsyn/"Basic BLOCKs and Switch Statements" for many other examples in this style.

Sometimes you should change the positions of the constant and the variable. For example, let's say you wanted to test which of many answers you were given, but in a case-insensitive way that also allows abbreviations. You can use the following technique if the strings all start with different characters or if you want to arrange the matches so that one takes precedence over another, as "SEND" has precedence over "STOP" here:

```
    chomp($answer = <>);
    if    ("SEND"  =~ /^\Q$answer/i) { print "Action is send\n"  }
    elsif ("STOP"  =~ /^\Q$answer/i) { print "Action is stop\n"  }
    elsif ("ABORT" =~ /^\Q$answer/i) { print "Action is abort\n" }
    elsif ("LIST"  =~ /^\Q$answer/i) { print "Action is list\n"  }
    elsif ("EDIT"  =~ /^\Q$answer/i) { print "Action is edit\n"  }
```

A totally different approach is to create a hash of function references.

```
    my %commands = (
        "happy" => \&joy,
        "sad",  => \&sullen,
        "done"  => sub { die "See ya!" },
        "mad"   => \&angry,
    );

    print "How are you? ";
    chomp($string = <STDIN>);
    if ($commands{$string}) {
        $commands{$string}->();
    } else {
        print "No such command: $string\n";
    }
```

23.1.23 How can I catch accesses to undefined variables, functions, or methods?

The AUTOLOAD method, discussed in Autoloading in *perlsub* and AUTOLOAD: Proxy Methods in *perltoot*, lets you capture calls to undefined functions and methods.

When it comes to undefined variables that would trigger a warning under `use warnings`, you can promote the warning to an error.

```
        use warnings FATAL => qw(uninitialized);
```

23.1.24 Why can't a method included in this same file be found?

Some possible reasons: your inheritance is getting confused, you've misspelled the method name, or the object is of the wrong type. Check out *perltoot* for details about any of the above cases. You may also use `print ref($object)` to find out the class `$object` was blessed into.

Another possible reason for problems is because you've used the indirect object syntax (eg, `find Guru "Samy"`) on a class name before Perl has seen that such a package exists. It's wisest to make sure your packages are all defined before you start using them, which will be taken care of if you use the `use` statement instead of `require`. If not, make sure to use arrow notation (eg., `Guru->find("Samy")`) instead. Object notation is explained in *perlobj*.

Make sure to read about creating modules in *perlmod* and the perils of indirect objects in Method Invocation in *perlobj*.

23.1.25 How can I find out my current package?

If you're just a random program, you can do this to find out what the currently compiled package is:

```
    my $packname = __PACKAGE__;
```

But, if you're a method and you want to print an error message that includes the kind of object you were called on (which is not necessarily the same as the one in which you were compiled):

```
    sub amethod {
        my $self  = shift;
        my $class = ref($self) || $self;
        warn "called me from a $class object";
    }
```

23.1.26 How can I comment out a large block of perl code?

You can use embedded POD to discard it. Enclose the blocks you want to comment out in POD markers, for example `=for nobody` and `=cut` (which marks ends of POD blocks).

```
    # program is here

    =for nobody

    all of this stuff

    here will be ignored
    by everyone

    =cut

    # program continues
```

The pod directives cannot go just anywhere. You must put a pod directive where the parser is expecting a new statement, not just in the middle of an expression or some other arbitrary grammar production.

See *perlpod* for more details.

23.1.27 How do I clear a package?

Use this code, provided by Mark-Jason Dominus:

```
    sub scrub_package {
        no strict 'refs';
        my $pack = shift;
        die "Shouldn't delete main package"
            if $pack eq "" || $pack eq "main";
        my $stash = *{$pack . '::'}{HASH};
        my $name;
        foreach $name (keys %$stash) {
            my $fullname = $pack . '::' . $name;
            # Get rid of everything with that name.
            undef $$fullname;
            undef @$fullname;
            undef %$fullname;
            undef &$fullname;
            undef *$fullname;
        }
    }
```

Or, if you're using a recent release of Perl, you can just use the Symbol::delete_package() function instead.

23.1.28 How can I use a variable as a variable name?

Beginners often think they want to have a variable contain the name of a variable.

```
    $fred    = 23;
    $varname = "fred";
    ++$$varname;         # $fred now 24
```

This works *sometimes*, but it is a very bad idea for two reasons.

The first reason is that this technique *only works on global variables*. That means that if $fred is a lexical variable created with my() in the above example, the code wouldn't work at all: you'd accidentally access the global and skip right over the private lexical altogether. Global variables are bad because they can easily collide accidentally and in general make for non-scalable and confusing code.

Symbolic references are forbidden under the `use strict` pragma. They are not true references and consequently are not reference counted or garbage collected.

The other reason why using a variable to hold the name of another variable is a bad idea is that the question often stems from a lack of understanding of Perl data structures, particularly hashes. By using symbolic references, you are just using the package's symbol-table hash (like `%main::`) instead of a user-defined hash. The solution is to use your own hash or a real reference instead.

```
    $USER_VARS{"fred"} = 23;
    $varname = "fred";
    $USER_VARS{$varname}++;  # not $$varname++
```

There we're using the %USER_VARS hash instead of symbolic references. Sometimes this comes up in reading strings from the user with variable references and wanting to expand them to the values of your perl program's variables. This is also a bad idea because it conflates the program-addressable namespace and the user-addressable one. Instead of reading a string and expanding it to the actual contents of your program's own variables:

```
    $str = 'this has a $fred and $barney in it';
    $str =~ s/(\$\w+)/$1/eeg;             # need double eval
```

it would be better to keep a hash around like %USER_VARS and have variable references actually refer to entries in that hash:

```
    $str =~ s/\$(\w+)/$USER_VARS{$1}/g;   # no /e here at all
```

That's faster, cleaner, and safer than the previous approach. Of course, you don't need to use a dollar sign. You could use your own scheme to make it less confusing, like bracketed percent symbols, etc.

```
    $str = 'this has a %fred% and %barney% in it';
    $str =~ s/%(\w+)%/$USER_VARS{$1}/g;   # no /e here at all
```

Another reason that folks sometimes think they want a variable to contain the name of a variable is because they don't know how to build proper data structures using hashes. For example, let's say they wanted two hashes in their program: %fred and %barney, and that they wanted to use another scalar variable to refer to those by name.

```
    $name = "fred";
    $$name{WIFE} = "wilma";     # set %fred

    $name = "barney";
    $$name{WIFE} = "betty";     # set %barney
```

This is still a symbolic reference, and is still saddled with the problems enumerated above. It would be far better to write:

```
    $folks{"fred"}{WIFE}   = "wilma";
    $folks{"barney"}{WIFE} = "betty";
```

And just use a multilevel hash to start with.

The only times that you absolutely *must* use symbolic references are when you really must refer to the symbol table. This may be because it's something that can't take a real reference to, such as a format name. Doing so may also be important for method calls, since these always go through the symbol table for resolution.

In those cases, you would turn off `strict 'refs'` temporarily so you can play around with the symbol table. For example:

```
    @colors = qw(red blue green yellow orange purple violet);
    for my $name (@colors) {
        no strict 'refs';  # renege for the block
        *$name = sub { "<FONT COLOR='$name'>@_</FONT>" };
    }
```

All those functions (red(), blue(), green(), etc.) appear to be separate, but the real code in the closure actually was compiled only once.

So, sometimes you might want to use symbolic references to directly manipulate the symbol table. This doesn't matter for formats, handles, and subroutines, because they are always global–you can't use my() on them. For scalars, arrays, and hashes, though–and usually for subroutines– you probably only want to use hard references.

23.1.29 What does "bad interpreter" mean?

The "bad interpreter" message comes from the shell, not perl. The actual message may vary depending on your platform, shell, and locale settings.

If you see "bad interpreter - no such file or directory", the first line in your perl script (the "shebang" line) does not contain the right path to perl (or any other program capable of running scripts). Sometimes this happens when you move the script from one machine to another and each machine has a different path to perl—/usr/bin/perl versus /usr/local/bin/perl for instance.

If you see "bad interpreter: Permission denied", you need to make your script executable.

In either case, you should still be able to run the scripts with perl explicitly:

```
        % perl script.pl
```

If you get a message like "perl: command not found", perl is not in your PATH, which might also mean that the location of perl is not where you expect it so you need to adjust your shebang line.

perlfaq8

System Interaction ($Revision: 1.17 $, $Date: 2003/01/26 17:44:04 $)

24.1 DESCRIPTION

This section of the Perl FAQ covers questions involving operating system interaction. Topics include interprocess communication (IPC), control over the user-interface (keyboard, screen and pointing devices), and most anything else not related to data manipulation.

Read the FAQs and documentation specific to the port of perl to your operating system (eg, *perlvms*, *perlplan9*, ...). These should contain more detailed information on the vagaries of your perl.

24.1.1 How do I find out which operating system I'm running under?

The $ˆO variable ($OSNAME if you use English) contains an indication of the name of the operating system (not its release number) that your perl binary was built for.

24.1.2 How come exec() doesn't return?

Because that's what it does: it replaces your currently running program with a different one. If you want to keep going (as is probably the case if you're asking this question) use system() instead.

24.1.3 How do I do fancy stuff with the keyboard/screen/mouse?

How you access/control keyboards, screens, and pointing devices ("mice") is system-dependent. Try the following modules:

Keyboard

```
        Term::Cap               Standard perl distribution
        Term::ReadKey           CPAN
        Term::ReadLine::Gnu     CPAN
        Term::ReadLine::Perl    CPAN
        Term::Screen            CPAN
```

Screen

```
        Term::Cap               Standard perl distribution
        Curses                  CPAN
        Term::ANSIColor         CPAN
```

Mouse

Tk CPAN

Some of these specific cases are shown below.

24.1.4 How do I print something out in color?

In general, you don't, because you don't know whether the recipient has a color-aware display device. If you know that they have an ANSI terminal that understands color, you can use the Term::ANSIColor module from CPAN:

```
use Term::ANSIColor;
print color("red"), "Stop!\n", color("reset");
print color("green"), "Go!\n", color("reset");
```

Or like this:

```
use Term::ANSIColor qw(:constants);
print RED, "Stop!\n", RESET;
print GREEN, "Go!\n", RESET;
```

24.1.5 How do I read just one key without waiting for a return key?

Controlling input buffering is a remarkably system-dependent matter. On many systems, you can just use the **stty** command as shown in getc in *perlfunc*, but as you see, that's already getting you into portability snags.

```
open(TTY, "+</dev/tty") or die "no tty: $!";
system "stty  cbreak </dev/tty >/dev/tty 2>&1";
$key = getc(TTY);           # perhaps this works
# OR ELSE
sysread(TTY, $key, 1);      # probably this does
system "stty -cbreak </dev/tty >/dev/tty 2>&1";
```

The Term::ReadKey module from CPAN offers an easy-to-use interface that should be more efficient than shelling out to **stty** for each key. It even includes limited support for Windows.

```
use Term::ReadKey;
ReadMode('cbreak');
$key = ReadKey(0);
ReadMode('normal');
```

However, using the code requires that you have a working C compiler and can use it to build and install a CPAN module. Here's a solution using the standard POSIX module, which is already on your systems (assuming your system supports POSIX).

```
use HotKey;
$key = readkey();
```

And here's the HotKey module, which hides the somewhat mystifying calls to manipulate the POSIX termios structures.

```
# HotKey.pm
package HotKey;
```

```
@ISA = qw(Exporter);
@EXPORT = qw(cbreak cooked readkey);

use strict;
use POSIX qw(:termios_h);
my ($term, $oterm, $echo, $noecho, $fd_stdin);

$fd_stdin = fileno(STDIN);
$term     = POSIX::Termios->new();
$term->getattr($fd_stdin);
$oterm     = $term->getlflag();

$echo     = ECHO | ECHOK | ICANON;
$noecho   = $oterm & ~$echo;

sub cbreak {
    $term->setlflag($noecho);  # ok, so i don't want echo either
    $term->setcc(VTIME, 1);
    $term->setattr($fd_stdin, TCSANOW);
}

sub cooked {
    $term->setlflag($oterm);
    $term->setcc(VTIME, 0);
    $term->setattr($fd_stdin, TCSANOW);
}

sub readkey {
    my $key = '';
    cbreak();
    sysread(STDIN, $key, 1);
    cooked();
    return $key;
}

END { cooked() }

1;
```

24.1.6 How do I check whether input is ready on the keyboard?

The easiest way to do this is to read a key in nonblocking mode with the Term::ReadKey module from CPAN, passing it an argument of -1 to indicate not to block:

```
use Term::ReadKey;

ReadMode('cbreak');

if (defined ($char = ReadKey(-1)) ) {
    # input was waiting and it was $char
} else {
    # no input was waiting
}

ReadMode('normal');                  # restore normal tty settings
```

24.1.7 How do I clear the screen?

If you only have do so infrequently, use `system`:

```
system("clear");
```

If you have to do this a lot, save the clear string so you can print it 100 times without calling a program 100 times:

```
$clear_string = ‘clear‘;
print $clear_string;
```

If you’re planning on doing other screen manipulations, like cursor positions, etc, you might wish to use Term::Cap module:

```
use Term::Cap;
$terminal = Term::Cap->Tgetent( {OSPEED => 9600} );
$clear_string = $terminal->Tputs(’cl’);
```

24.1.8 How do I get the screen size?

If you have Term::ReadKey module installed from CPAN, you can use it to fetch the width and height in characters and in pixels:

```
use Term::ReadKey;
($wchar, $hchar, $wpixels, $hpixels) = GetTerminalSize();
```

This is more portable than the raw `ioctl`, but not as illustrative:

```
require ’sys/ioctl.ph’;
die "no TIOCGWINSZ " unless defined &TIOCGWINSZ;
open(TTY, "+</dev/tty")                     or die "No tty: $!";
unless (ioctl(TTY, &TIOCGWINSZ, $winsize=’’)) {
    die sprintf "$0: ioctl TIOCGWINSZ (%08x: $!)\n", &TIOCGWINSZ;
}
($row, $col, $xpixel, $ypixel) = unpack(’S4’, $winsize);
print "(row,col) = ($row,$col)";
print "  (xpixel,ypixel) = ($xpixel,$ypixel)" if $xpixel || $ypixel;
print "\n";
```

24.1.9 How do I ask the user for a password?

(This question has nothing to do with the web. See a different FAQ for that.)

There’s an example of this in crypt in *perlfunc*). First, you put the terminal into "no echo" mode, then just read the password normally. You may do this with an old-style ioctl() function, POSIX terminal control (see *POSIX* or its documentation the Camel Book), or a call to the **stty** program, with varying degrees of portability.

You can also do this for most systems using the Term::ReadKey module from CPAN, which is easier to use and in theory more portable.

```
use Term::ReadKey;

ReadMode(’noecho’);
$password = ReadLine(0);
```

24.1.10 How do I read and write the serial port?

This depends on which operating system your program is running on. In the case of Unix, the serial ports will be accessible through files in /dev; on other systems, device names will doubtless differ. Several problem areas common to all device interaction are the following:

lockfiles

Your system may use lockfiles to control multiple access. Make sure you follow the correct protocol. Unpredictable behavior can result from multiple processes reading from one device.

open mode

If you expect to use both read and write operations on the device, you'll have to open it for update (see open in *perlfunc* for details). You may wish to open it without running the risk of blocking by using sysopen() and `O_RDWR|O_NDELAY|O_NOCTTY` from the Fcntl module (part of the standard perl distribution). See sysopen in *perlfunc* for more on this approach.

end of line

Some devices will be expecting a "\r" at the end of each line rather than a "\n". In some ports of perl, "\r" and "\n" are different from their usual (Unix) ASCII values of "\012" and "\015". You may have to give the numeric values you want directly, using octal ("\015"), hex ("0x0D"), or as a control-character specification ("\cM").

```
print DEV "atv1\012";       # wrong, for some devices
print DEV "atv1\015";       # right, for some devices
```

Even though with normal text files a "\n" will do the trick, there is still no unified scheme for terminating a line that is portable between Unix, DOS/Win, and Macintosh, except to terminate *ALL* line ends with "\015\012", and strip what you don't need from the output. This applies especially to socket I/O and autoflushing, discussed next.

flushing output

If you expect characters to get to your device when you print() them, you'll want to autoflush that filehandle. You can use select() and the $| variable to control autoflushing (see $| in *perlvar* and select in *perlfunc*, or *perlfaq5*, "How do I flush/unbuffer an output filehandle? Why must I do this?"):

```
$oldh = select(DEV);
$| = 1;
select($oldh);
```

You'll also see code that does this without a temporary variable, as in

```
select((select(DEV), $| = 1)[0]);
```

Or if you don't mind pulling in a few thousand lines of code just because you're afraid of a little $| variable:

```
use IO::Handle;
DEV->autoflush(1);
```

As mentioned in the previous item, this still doesn't work when using socket I/O between Unix and Macintosh. You'll need to hard code your line terminators, in that case.

non-blocking input

If you are doing a blocking read() or sysread(), you'll have to arrange for an alarm handler to provide a timeout (see alarm in *perlfunc*). If you have a non-blocking open, you'll likely have a non-blocking read, which means you may have to use a 4-arg select() to determine whether I/O is ready on that device (see select in *perlfunc*.

While trying to read from his caller-id box, the notorious Jamie Zawinski <jwz@netscape.com>, after much gnashing of teeth and fighting with sysread, sysopen, POSIX's tcgetattr business, and various other functions that go bump in the night, finally came up with this:

```
sub open_modem {
    use IPC::Open2;
    my $stty = `/bin/stty -g`;
    open2( \*MODEM_IN, \*MODEM_OUT, "cu -l$modem_device -s2400 2>&1");
    # starting cu hoses /dev/tty's stty settings, even when it has
    # been opened on a pipe...
    system("/bin/stty $stty");
    $_ = <MODEM_IN>;
    chomp;
    if ( !m/^Connected/ ) {
        print STDERR "$0: cu printed `$_' instead of `Connected'\n";
    }
}
```

24.1.11 How do I decode encrypted password files?

You spend lots and lots of money on dedicated hardware, but this is bound to get you talked about.

Seriously, you can't if they are Unix password files–the Unix password system employs one-way encryption. It's more like hashing than encryption. The best you can check is whether something else hashes to the same string. You can't turn a hash back into the original string. Programs like Crack can forcibly (and intelligently) try to guess passwords, but don't (can't) guarantee quick success.

If you're worried about users selecting bad passwords, you should proactively check when they try to change their password (by modifying passwd(1), for example).

24.1.12 How do I start a process in the background?

Several modules can start other processes that do not block your Perl program. You can use IPC::Open3, Parallel::Jobs, IPC::Run, and some of the POE modules. See CPAN for more details.

You could also use

```
system("cmd &")
```

or you could use fork as documented in fork in *perlfunc*, with further examples in *perlipc*. Some things to be aware of, if you're on a Unix-like system:

STDIN, STDOUT, and STDERR are shared

Both the main process and the backgrounded one (the "child" process) share the same STDIN, STDOUT and STDERR filehandles. If both try to access them at once, strange things can happen. You may want to close or reopen these for the child. You can get around this with opening a pipe (see open in *perlfunc*) but on some systems this means that the child process cannot outlive the parent.

Signals

You'll have to catch the SIGCHLD signal, and possibly SIGPIPE too. SIGCHLD is sent when the backgrounded process finishes. SIGPIPE is sent when you write to a filehandle whose child process has closed (an untrapped SIGPIPE can cause your program to silently die). This is not an issue with `system("cmd&")`.

Zombies

You have to be prepared to "reap" the child process when it finishes.

```
$SIG{CHLD} = sub { wait };
```

```
    $SIG{CHLD} = 'IGNORE';
```

You can also use a double fork. You immediately wait() for your first child, and the init daemon will wait() for your grandchild once it exits.

```
        unless ($pid = fork) {
                unless (fork) {
            exec "what you really wanna do";
            die "exec failed!";
                }
        exit 0;
        }
    waitpid($pid,0);
```

See Signals in *perlipc* for other examples of code to do this. Zombies are not an issue with `system("prog &")`.

24.1.13 How do I trap control characters/signals?

You don't actually "trap" a control character. Instead, that character generates a signal which is sent to your terminal's currently foregrounded process group, which you then trap in your process. Signals are documented in Signals in *perlipc* and the section on “Signals” in the Camel.

Be warned that very few C libraries are re-entrant. Therefore, if you attempt to print() in a handler that got invoked during another stdio operation your internal structures will likely be in an inconsistent state, and your program will dump core. You can sometimes avoid this by using syswrite() instead of print().

Unless you're exceedingly careful, the only safe things to do inside a signal handler are (1) set a variable and (2) exit. In the first case, you should only set a variable in such a way that malloc() is not called (eg, by setting a variable that already has a value).

For example:

```
    $Interrupted = 0;   # to ensure it has a value
    $SIG{INT} = sub {
        $Interrupted++;
        syswrite(STDERR, "ouch\n", 5);
    }
```

However, because syscalls restart by default, you'll find that if you're in a "slow" call, such as <FH>, read(), connect(), or wait(), that the only way to terminate them is by "longjumping" out; that is, by raising an exception. See the time-out handler for a blocking flock() in Signals in *perlipc* or the section on “Signals” in the Camel book.

24.1.14 How do I modify the shadow password file on a Unix system?

If perl was installed correctly and your shadow library was written properly, the getpw*() functions described in *perlfunc* should in theory provide (read-only) access to entries in the shadow password file. To change the file, make a new shadow password file (the format varies from system to system–see *passwd* for specifics) and use pwd_mkdb(8) to install it (see pwd_mkdb for more details).

24.1.15 How do I set the time and date?

Assuming you're running under sufficient permissions, you should be able to set the system-wide date and time by running the date(1) program. (There is no way to set the time and date on a per-process basis.) This mechanism will work for Unix, MS-DOS, Windows, and NT; the VMS equivalent is `set time`.

However, if all you want to do is change your time zone, you can probably get away with setting an environment variable:

```
    $ENV{TZ} = "MST7MDT";                  # unixish
    $ENV{'SYS$TIMEZONE_DIFFERENTIAL'}="-5" # vms
    system "trn comp.lang.perl.misc";
```

24.1.16 How can I sleep() or alarm() for under a second?

If you want finer granularity than the 1 second that the sleep() function provides, the easiest way is to use the select() function as documented in select in *perlfunc*. Try the Time::HiRes and the BSD::Itimer modules (available from CPAN, and starting from Perl 5.8 Time::HiRes is part of the standard distribution).

24.1.17 How can I measure time under a second?

In general, you may not be able to. The Time::HiRes module (available from CPAN, and starting from Perl 5.8 part of the standard distribution) provides this functionality for some systems.

If your system supports both the syscall() function in Perl as well as a system call like gettimeofday(2), then you may be able to do something like this:

```
require 'sys/syscall.ph';

$TIMEVAL_T = "LL";

$done = $start = pack($TIMEVAL_T, ());

syscall(&SYS_gettimeofday, $start, 0) != -1
           or die "gettimeofday: $!";

   ##########################
   # DO YOUR OPERATION HERE #
   ##########################

syscall( &SYS_gettimeofday, $done, 0) != -1
       or die "gettimeofday: $!";

@start = unpack($TIMEVAL_T, $start);
@done  = unpack($TIMEVAL_T, $done);

# fix microseconds
for ($done[1], $start[1]) { $_ /= 1_000_000 }

$delta_time = sprintf "%.4f", ($done[0]  + $done[1]  )
                                        -
                             ($start[0] + $start[1] );
```

24.1.18 How can I do an atexit() or setjmp()/longjmp()? (Exception handling)

Release 5 of Perl added the END block, which can be used to simulate atexit(). Each package's END block is called when the program or thread ends (see *perlmod* manpage for more details).

For example, you can use this to make sure your filter program managed to finish its output without filling up the disk:

```
END {
    close(STDOUT) || die "stdout close failed: $!";
}
```

The END block isn't called when untrapped signals kill the program, though, so if you use END blocks you should also use

```
    use sigtrap qw(die normal-signals);
```

Perl's exception-handling mechanism is its eval() operator. You can use eval() as setjmp and die() as longjmp. For details of this, see the section on signals, especially the time-out handler for a blocking flock() in Signals in *perlipc* or the section on "Signals" in the Camel Book.

If exception handling is all you're interested in, try the exceptions.pl library (part of the standard perl distribution).

If you want the atexit() syntax (and an rmexit() as well), try the AtExit module available from CPAN.

24.1.19 Why doesn't my sockets program work under System V (Solaris)? What does the error message "Protocol not supported" mean?

Some Sys-V based systems, notably Solaris 2.X, redefined some of the standard socket constants. Since these were constant across all architectures, they were often hardwired into perl code. The proper way to deal with this is to "use Socket" to get the correct values.

Note that even though SunOS and Solaris are binary compatible, these values are different. Go figure.

24.1.20 How can I call my system's unique C functions from Perl?

In most cases, you write an external module to do it–see the answer to "Where can I learn about linking C with Perl? [h2xs, xsubpp]". However, if the function is a system call, and your system supports syscall(), you can use the syscall function (documented in *perlfunc*).

Remember to check the modules that came with your distribution, and CPAN as well—someone may already have written a module to do it. On Windows, try Win32::API. On Macs, try Mac::Carbon. If no module has an interface to the C function, you can inline a bit of C in your Perl source with Inline::C.

24.1.21 Where do I get the include files to do ioctl() or syscall()?

Historically, these would be generated by the h2ph tool, part of the standard perl distribution. This program converts cpp(1) directives in C header files to files containing subroutine definitions, like &SYS_getitimer, which you can use as arguments to your functions. It doesn't work perfectly, but it usually gets most of the job done. Simple files like *errno.h*, *syscall.h*, and *socket.h* were fine, but the hard ones like *ioctl.h* nearly always need to hand-edited. Here's how to install the *.ph files:

```
    1.  become super-user
    2.  cd /usr/include
    3.  h2ph *.h */*.h
```

If your system supports dynamic loading, for reasons of portability and sanity you probably ought to use h2xs (also part of the standard perl distribution). This tool converts C header files to Perl extensions. See *perlxstut* for how to get started with h2xs.

If your system doesn't support dynamic loading, you still probably ought to use h2xs. See *perlxstut* and *ExtUtils::MakeMaker* for more information (in brief, just use **make perl** instead of a plain **make** to rebuild perl with a new static extension).

24.1.22 Why do setuid perl scripts complain about kernel problems?

Some operating systems have bugs in the kernel that make setuid scripts inherently insecure. Perl gives you a number of options (described in *perlsec*) to work around such systems.

24.1.23 How can I open a pipe both to and from a command?

The IPC::Open2 module (part of the standard perl distribution) is an easy-to-use approach that internally uses pipe(), fork(), and exec() to do the job. Make sure you read the deadlock warnings in its documentation, though (see *IPC::Open2*). See Bidirectional Communication with Another Process in *perlipc* and Bidirectional Communication with Yourself in *perlipc*

You may also use the IPC::Open3 module (part of the standard perl distribution), but be warned that it has a different order of arguments from IPC::Open2 (see *IPC::Open3*).

24.1.24 Why can't I get the output of a command with system()?

You're confusing the purpose of system() and backticks (“). system() runs a command and returns exit status information (as a 16 bit value: the low 7 bits are the signal the process died from, if any, and the high 8 bits are the actual exit value). Backticks (“) run a command and return what it sent to STDOUT.

```
$exit_status   = system("mail-users");
$output_string = ‘ls‘;
```

24.1.25 How can I capture STDERR from an external command?

There are three basic ways of running external commands:

```
system $cmd;                # using system()
$output = ‘$cmd‘;           # using backticks (‘‘)
open (PIPE, "cmd |");       # using open()
```

With system(), both STDOUT and STDERR will go the same place as the script's STDOUT and STDERR, unless the system() command redirects them. Backticks and open() read **only** the STDOUT of your command.

You can also use the open3() function from IPC::Open3. Benjamin Goldberg provides some sample code:

To capture a program's STDOUT, but discard its STDERR:

```
use IPC::Open3;
use File::Spec;
use Symbol qw(gensym);
open(NULL, ">", File::Spec->devnull);
my $pid = open3(gensym, \*PH, ">&NULL", "cmd");
while( <PH> ) { }
waitpid($pid, 0);
```

To capture a program's STDERR, but discard its STDOUT:

```
use IPC::Open3;
use File::Spec;
use Symbol qw(gensym);
open(NULL, ">", File::Spec->devnull);
my $pid = open3(gensym, ">&NULL", \*PH, "cmd");
while( <PH> ) { }
waitpid($pid, 0);
```

To capture a program's STDERR, and let its STDOUT go to our own STDERR:

```
use IPC::Open3;
use Symbol qw(gensym);
my $pid = open3(gensym, ">&STDERR", \*PH, "cmd");
while( <PH> ) { }
waitpid($pid, 0);
```

To read both a command's STDOUT and its STDERR separately, you can redirect them to temp files, let the command run, then read the temp files:

```
use IPC::Open3;
use Symbol qw(gensym);
use IO::File;
local *CATCHOUT = IO::File->new_tempfile;
local *CATCHERR = IO::File->new_tempfile;
my $pid = open3(gensym, ">&CATCHOUT", ">&CATCHERR", "cmd");
waitpid($pid, 0);
seek $_, 0, 0 for \*CATCHOUT, \*CATCHERR;
while( <CATCHOUT> ) {}
while( <CATCHERR> ) {}
```

But there's no real need for *both* to be tempfiles... the following should work just as well, without deadlocking:

```
use IPC::Open3;
use Symbol qw(gensym);
use IO::File;
local *CATCHERR = IO::File->new_tempfile;
my $pid = open3(gensym, \*CATCHOUT, ">&CATCHERR", "cmd");
while( <CATCHOUT> ) {}
waitpid($pid, 0);
seek CATCHERR, 0, 0;
while( <CATCHERR> ) {}
```

And it'll be faster, too, since we can begin processing the program's stdout immediately, rather than waiting for the program to finish.

With any of these, you can change file descriptors before the call:

```
open(STDOUT, ">logfile");
system("ls");
```

or you can use Bourne shell file-descriptor redirection:

```
$output = `$cmd 2>some_file`;
open (PIPE, "cmd 2>some_file |");
```

You can also use file-descriptor redirection to make STDERR a duplicate of STDOUT:

```
$output = `$cmd 2>&1`;
open (PIPE, "cmd 2>&1 |");
```

Note that you *cannot* simply open STDERR to be a dup of STDOUT in your Perl program and avoid calling the shell to do the redirection. This doesn't work:

```
open(STDERR, ">&STDOUT");
$alloutput = `cmd args`;  # stderr still escapes
```

This fails because the open() makes STDERR go to where STDOUT was going at the time of the open(). The backticks then make STDOUT go to a string, but don't change STDERR (which still goes to the old STDOUT).

Note that you *must* use Bourne shell (sh(1)) redirection syntax in backticks, not csh(1)! Details on why Perl's system() and backtick and pipe opens all use the Bourne shell are in the *versus/csh.whynot* article in the "Far More Than You Ever Wanted To Know" collection in http://www.cpan.org/misc/olddoc/FMTEYEWTK.tgz . To capture a command's STDERR and STDOUT together:

```
$output = `cmd 2>&1`;                       # either with backticks
$pid = open(PH, "cmd 2>&1 |");              # or with an open pipe
while (<PH>) { }                            #    plus a read
```

To capture a command's STDOUT but discard its STDERR:

```
    $output = `cmd 2>/dev/null`;            # either with backticks
    $pid = open(PH, "cmd 2>/dev/null |");   # or with an open pipe
    while (<PH>) { }                        #    plus a read
```

To capture a command's STDERR but discard its STDOUT:

```
    $output = `cmd 2>&1 1>/dev/null`;           # either with backticks
    $pid = open(PH, "cmd 2>&1 1>/dev/null |");  # or with an open pipe
    while (<PH>) { }                            #    plus a read
```

To exchange a command's STDOUT and STDERR in order to capture the STDERR but leave its STDOUT to come out our old STDERR:

```
    $output = `cmd 3>&1 1>&2 2>&3 3>&-`;        # either with backticks
    $pid = open(PH, "cmd 3>&1 1>&2 2>&3 3>&-|");# or with an open pipe
    while (<PH>) { }                            #    plus a read
```

To read both a command's STDOUT and its STDERR separately, it's easiest to redirect them separately to files, and then read from those files when the program is done:

```
    system("program args 1>program.stdout 2>program.stderr");
```

Ordering is important in all these examples. That's because the shell processes file descriptor redirections in strictly left to right order.

```
    system("prog args 1>tmpfile 2>&1");
    system("prog args 2>&1 1>tmpfile");
```

The first command sends both standard out and standard error to the temporary file. The second command sends only the old standard output there, and the old standard error shows up on the old standard out.

24.1.26 Why doesn't open() return an error when a pipe open fails?

If the second argument to a piped open() contains shell metacharacters, perl fork()s, then exec()s a shell to decode the metacharacters and eventually run the desired program. If the program couldn't be run, it's the shell that gets the message, not Perl. All your Perl program can find out is whether the shell itself could be successfully started. You can still capture the shell's STDERR and check it for error messages. See §24.1.25 elsewhere in this document, or use the IPC::Open3 module.

If there are no shell metacharacters in the argument of open(), Perl runs the command directly, without using the shell, and can correctly report whether the command started.

24.1.27 What's wrong with using backticks in a void context?

Strictly speaking, nothing. Stylistically speaking, it's not a good way to write maintainable code. Perl has several operators for running external commands. Backticks are one; they collect the output from the command for use in your program. The `system` function is another; it doesn't do this.

Writing backticks in your program sends a clear message to the readers of your code that you wanted to collect the output of the command. Why send a clear message that isn't true?

Consider this line:

```
    `cat /etc/termcap`;
```

You forgot to check `$?` to see whether the program even ran correctly. Even if you wrote

```
    print `cat /etc/termcap`;
```

this code could and probably should be written as

```
    system("cat /etc/termcap") == 0
        or die "cat program failed!";
```

which will get the output quickly (as it is generated, instead of only at the end) and also check the return value.
system() also provides direct control over whether shell wildcard processing may take place, whereas backticks do not.

24.1.28 How can I call backticks without shell processing?

This is a bit tricky. You can't simply write the command like this:

```
    @ok = `grep @opts '$search_string' @filenames`;
```

As of Perl 5.8.0, you can use open() with multiple arguments. Just like the list forms of system() and exec(), no shell escapes happen.

```
   open( GREP, "-|", 'grep', @opts, $search_string, @filenames );
   chomp(@ok = <GREP>);
   close GREP;
```

You can also:

```
    my @ok = ();
    if (open(GREP, "-|")) {
        while (<GREP>) {
            chomp;
            push(@ok, $_);
        }
        close GREP;
    } else {
        exec 'grep', @opts, $search_string, @filenames;
    }
```

Just as with system(), no shell escapes happen when you exec() a list. Further examples of this can be found in Safe Pipe Opens in *perlipc*.
Note that if you're use Microsoft, no solution to this vexing issue is even possible. Even if Perl were to emulate fork(), you'd still be stuck, because Microsoft does not have a argc/argv-style API.

24.1.29 Why can't my script read from STDIN after I gave it EOF (ˆD on Unix, ˆZ on MS-DOS)?

Some stdio's set error and eof flags that need clearing. The POSIX module defines clearerr() that you can use. That is the technically correct way to do it. Here are some less reliable workarounds:

1. Try keeping around the seekpointer and go there, like this:

```
    $where = tell(LOG);
    seek(LOG, $where, 0);
```

2. If that doesn't work, try seeking to a different part of the file and then back.
3. If that doesn't work, try seeking to a different part of the file, reading something, and then seeking back.
4. If that doesn't work, give up on your stdio package and use sysread.

24.1.30 How can I convert my shell script to perl?

Learn Perl and rewrite it. Seriously, there's no simple converter. Things that are awkward to do in the shell are easy to do in Perl, and this very awkwardness is what would make a shell->perl converter nigh-on impossible to write. By rewriting it, you'll think about what you're really trying to do, and hopefully will escape the shell's pipeline datastream paradigm, which while convenient for some matters, causes many inefficiencies.

24.1.31 Can I use perl to run a telnet or ftp session?

Try the Net::FTP, TCP::Client, and Net::Telnet modules (available from CPAN). http://www.cpan.org/scripts/netstuff/telnet.emul.shar will also help for emulating the telnet protocol, but Net::Telnet is quite probably easier to use..

If all you want to do is pretend to be telnet but don't need the initial telnet handshaking, then the standard dual-process approach will suffice:

```
use IO::Socket;             # new in 5.004
$handle = IO::Socket::INET->new('www.perl.com:80')
        || die "can't connect to port 80 on www.perl.com: $!";
$handle->autoflush(1);
if (fork()) {               # XXX: undef means failure
    select($handle);
    print while <STDIN>;    # everything from stdin to socket
} else {
    print while <$handle>;  # everything from socket to stdout
}
close $handle;
exit;
```

24.1.32 How can I write expect in Perl?

Once upon a time, there was a library called chat2.pl (part of the standard perl distribution), which never really got finished. If you find it somewhere, *don't use it*. These days, your best bet is to look at the Expect module available from CPAN, which also requires two other modules from CPAN, IO::Pty and IO::Stty.

24.1.33 Is there a way to hide perl's command line from programs such as "ps"?

First of all note that if you're doing this for security reasons (to avoid people seeing passwords, for example) then you should rewrite your program so that critical information is never given as an argument. Hiding the arguments won't make your program completely secure.

To actually alter the visible command line, you can assign to the variable $0 as documented in *perlvar*. This won't work on all operating systems, though. Daemon programs like sendmail place their state there, as in:

```
$0 = "orcus [accepting connections]";
```

24.1.34 I {changed directory, modified my environment} in a perl script. How come the change disappeared when I exited the script? How do I get my changes to be visible?

Unix

In the strictest sense, it can't be done–the script executes as a different process from the shell it was started from. Changes to a process are not reflected in its parent–only in any children created after the change. There is shell magic that may allow you to fake it by eval()ing the script's output in your shell; check out the comp.unix.questions FAQ for details.

24.1.35 How do I close a process's filehandle without waiting for it to complete?

Assuming your system supports such things, just send an appropriate signal to the process (see kill in *perlfunc*). It's common to first send a TERM signal, wait a little bit, and then send a KILL signal to finish it off.

24.1.36 How do I fork a daemon process?

If by daemon process you mean one that's detached (disassociated from its tty), then the following process is reported to work on most Unixish systems. Non-Unix users should check their Your_OS::Process module for other solutions.

- Open /dev/tty and use the TIOCNOTTY ioctl on it. See *tty* for details. Or better yet, you can just use the POSIX::setsid() function, so you don't have to worry about process groups.
- Change directory to /
- Reopen STDIN, STDOUT, and STDERR so they're not connected to the old tty.
- Background yourself like this:

```
    fork && exit;
```

The Proc::Daemon module, available from CPAN, provides a function to perform these actions for you.

24.1.37 How do I find out if I'm running interactively or not?

Good question. Sometimes `-t STDIN` and `-t STDOUT` can give clues, sometimes not.

```
if (-t STDIN && -t STDOUT) {
    print "Now what? ";
}
```

On POSIX systems, you can test whether your own process group matches the current process group of your controlling terminal as follows:

```
use POSIX qw/getpgrp tcgetpgrp/;
open(TTY, "/dev/tty") or die $!;
$tpgrp = tcgetpgrp(fileno(*TTY));
$pgrp = getpgrp();
if ($tpgrp == $pgrp) {
    print "foreground\n";
} else {
    print "background\n";
}
```

24.1.38 How do I timeout a slow event?

Use the alarm() function, probably in conjunction with a signal handler, as documented in Signals in *perlipc* and the section on "Signals" in the Camel. You may instead use the more flexible Sys::AlarmCall module available from CPAN.

The alarm() function is not implemented on all versions of Windows. Check the documentation for your specific version of Perl.

24.1.39 How do I set CPU limits?

Use the BSD::Resource module from CPAN.

24.1.40 How do I avoid zombies on a Unix system?

Use the reaper code from Signals in *perlipc* to call wait() when a SIGCHLD is received, or else use the double-fork technique described in How do I start a process in the background? in *perlfaq8*.

24.1.41 How do I use an SQL database?

The DBI module provides an abstract interface to most database servers and types, including Oracle, DB2, Sybase, mysql, Postgresql, ODBC, and flat files. The DBI module accesses each database type through a database driver, or DBD. You can see a complete list of available drivers on CPAN: http://www.cpan.org/modules/by-module/DBD/ . You can read more about DBI on http://dbi.perl.org .

Other modules provide more specific access: Win32::ODBC, Alzabo, iodbc, and others found on CPAN Search: http://search.cpan.org .

24.1.42 How do I make a system() exit on control-C?

You can't. You need to imitate the system() call (see *perlipc* for sample code) and then have a signal handler for the INT signal that passes the signal on to the subprocess. Or you can check for it:

```
$rc = system($cmd);
if ($rc & 127) { die "signal death" }
```

24.1.43 How do I open a file without blocking?

If you're lucky enough to be using a system that supports non-blocking reads (most Unixish systems do), you need only to use the O_NDELAY or O_NONBLOCK flag from the Fcntl module in conjunction with sysopen():

```
use Fcntl;
sysopen(FH, "/foo/somefile", O_WRONLY|O_NDELAY|O_CREAT, 0644)
    or die "can't open /foo/somefile: $!":
```

24.1.44 How do I install a module from CPAN?

The easiest way is to have a module also named CPAN do it for you. This module comes with perl version 5.004 and later.

```
$ perl -MCPAN -e shell

cpan shell -- CPAN exploration and modules installation (v1.59_54)
ReadLine support enabled

cpan> install Some::Module
```

To manually install the CPAN module, or any well-behaved CPAN module for that matter, follow these steps:

1. Unpack the source into a temporary area.
2. `perl Makefile.PL`
3. `make`
4. `make test`
5. `make install`

If your version of perl is compiled without dynamic loading, then you just need to replace step 3 (**make**) with **make perl** and you will get a new *perl* binary with your extension linked in.

See *ExtUtils::MakeMaker* for more details on building extensions. See also the next question, "What's the difference between require and use?".

24.1.45 What's the difference between require and use?

Perl offers several different ways to include code from one file into another. Here are the deltas between the various inclusion constructs:

```
1)  do $file is like eval `cat $file`, except the former
    1.1: searches @INC and updates %INC.
    1.2: bequeaths an *unrelated* lexical scope on the eval'ed code.

2)  require $file is like do $file, except the former
    2.1: checks for redundant loading, skipping already loaded files.
    2.2: raises an exception on failure to find, compile, or execute $file.

3)  require Module is like require "Module.pm", except the former
    3.1: translates each "::" into your system's directory separator.
    3.2: primes the parser to disambiguate class Module as an indirect object.

4)  use Module is like require Module, except the former
    4.1: loads the module at compile time, not run-time.
    4.2: imports symbols and semantics from that package to the current one.
```

In general, you usually want use and a proper Perl module.

24.1.46 How do I keep my own module/library directory?

When you build modules, use the PREFIX and LIB options when generating Makefiles:

```
perl Makefile.PL PREFIX=/mydir/perl LIB=/mydir/perl/lib
```

then either set the PERL5LIB environment variable before you run scripts that use the modules/libraries (see *perlrun*) or say

```
use lib '/mydir/perl/lib';
```

This is almost the same as

```
BEGIN {
    unshift(@INC, '/mydir/perl/lib');
}
```

except that the lib module checks for machine-dependent subdirectories. See Perl's *lib* for more information.

24.1.47 How do I add the directory my program lives in to the module/library search path?

```
use FindBin;
use lib "$FindBin::Bin";
use your_own_modules;
```

24.1.48 How do I add a directory to my include path (@INC) at runtime?

Here are the suggested ways of modifying your include path:

```
the PERLLIB environment variable
the PERL5LIB environment variable
the perl -Idir command line flag
the use lib pragma, as in
    use lib "$ENV{HOME}/myown_perllib";
```

The latter is particularly useful because it knows about machine dependent architectures. The lib.pm pragmatic module was first included with the 5.002 release of Perl.

24.1.49 What is socket.ph and where do I get it?

It's a perl4-style file defining values for system networking constants. Sometimes it is built using h2ph when Perl is installed, but other times it is not. Modern programs `use Socket;` instead.

Networking ($Revision: 1.15 $, $Date: 2003/01/31 17:36:57 $)

25.1 DESCRIPTION

This section deals with questions related to networking, the internet, and a few on the web.

25.1.1 What is the correct form of response from a CGI script?

(Alan Flavell <flavell+www@a5.ph.gla.ac.uk> answers...)

The Common Gateway Interface (CGI) specifies a software interface between a program ("CGI script") and a web server (HTTPD). It is not specific to Perl, and has its own FAQs and tutorials, and usenet group, comp.infosystems.www.authoring.cgi

The original CGI specification is at: http://hoohoo.ncsa.uiuc.edu/cgi/

Current best-practice RFC draft at: http://CGI-Spec.Golux.Com/

Other relevant documentation listed in: http://www.perl.org/CGI_MetaFAQ.html

These Perl FAQs very selectively cover some CGI issues. However, Perl programmers are strongly advised to use the CGI.pm module, to take care of the details for them.

The similarity between CGI response headers (defined in the CGI specification) and HTTP response headers (defined in the HTTP specification, RFC2616) is intentional, but can sometimes be confusing.

The CGI specification defines two kinds of script: the "Parsed Header" script, and the "Non Parsed Header" (NPH) script. Check your server documentation to see what it supports. "Parsed Header" scripts are simpler in various respects. The CGI specification allows any of the usual newline representations in the CGI response (it's the server's job to create an accurate HTTP response based on it). So "\n" written in text mode is technically correct, and recommended. NPH scripts are more tricky: they must put out a complete and accurate set of HTTP transaction response headers; the HTTP specification calls for records to be terminated with carriage-return and line-feed, i.e ASCII \015\012 written in binary mode.

Using CGI.pm gives excellent platform independence, including EBCDIC systems. CGI.pm selects an appropriate newline representation ($CGI::CRLF) and sets binmode as appropriate.

25.1.2 My CGI script runs from the command line but not the browser. (500 Server Error)

Several things could be wrong. You can go through the "Troubleshooting Perl CGI scripts" guide at

```
        http://www.perl.org/troubleshooting_CGI.html
```

If, after that, you can demonstrate that you've read the FAQs and that your problem isn't something simple that can be easily answered, you'll probably receive a courteous and useful reply to your question if you post it on comp.infosystems.www.authoring.cgi (if it's something to do with HTTP or the CGI protocols). Questions that appear to be Perl questions but are really CGI ones that are posted to comp.lang.perl.misc are not so well received.

The useful FAQs, related documents, and troubleshooting guides are listed in the CGI Meta FAQ:

```
        http://www.perl.org/CGI_MetaFAQ.html
```

25.1.3 How can I get better error messages from a CGI program?

Use the CGI::Carp module. It replaces `warn` and `die`, plus the normal Carp modules `carp`, `croak`, and `confess` functions with more verbose and safer versions. It still sends them to the normal server error log.

```
    use CGI::Carp;
    warn "This is a complaint";
    die "But this one is serious";
```

The following use of CGI::Carp also redirects errors to a file of your choice, placed in a BEGIN block to catch compile-time warnings as well:

```
    BEGIN {
        use CGI::Carp qw(carpout);
        open(LOG, ">>/var/local/cgi-logs/mycgi-log")
            or die "Unable to append to mycgi-log: $!\n";
        carpout(*LOG);
    }
```

You can even arrange for fatal errors to go back to the client browser, which is nice for your own debugging, but might confuse the end user.

```
    use CGI::Carp qw(fatalsToBrowser);
    die "Bad error here";
```

Even if the error happens before you get the HTTP header out, the module will try to take care of this to avoid the dreaded server 500 errors. Normal warnings still go out to the server error log (or wherever you've sent them with `carpout`) with the application name and date stamp prepended.

25.1.4 How do I remove HTML from a string?

The most correct way (albeit not the fastest) is to use HTML::Parser from CPAN. Another mostly correct way is to use HTML::FormatText which not only removes HTML but also attempts to do a little simple formatting of the resulting plain text.

Many folks attempt a simple-minded regular expression approach, like `s/<.*?>//g`, but that fails in many cases because the tags may continue over line breaks, they may contain quoted angle-brackets, or HTML comment may be present. Plus, folks forget to convert entities–like `&lt;` for example.

Here's one "simple-minded" approach, that works for most files:

```
    #!/usr/bin/perl -p0777
    s/<(?:[^>'"]*|(['"]).*?\1)*>//gs
```

If you want a more complete solution, see the 3-stage striphtml program in http://www.cpan.org/authors/Tom_Christiansen/scripts/striphtml.gz .

Here are some tricky cases that you should think about when picking a solution:

```
    <IMG SRC = "foo.gif" ALT = "A > B">

    <IMG SRC = "foo.gif"
         ALT = "A > B">

    <!-- <A comment> -->

    <script>if (a<b && a>c)</script>

    <# Just data #>

    <![INCLUDE CDATA [ >>>>>>>>>>>> ]]>
```

If HTML comments include other tags, those solutions would also break on text like this:

```
    <!-- This section commented out.
        <B>You can't see me!</B>
    -->
```

25.1.5 How do I extract URLs?

You can easily extract all sorts of URLs from HTML with `HTML::SimpleLinkExtor` which handles anchors, images, objects, frames, and many other tags that can contain a URL. If you need anything more complex, you can create your own subclass of `HTML::LinkExtor` or `HTML::Parser`. You might even use `HTML::SimpleLinkExtor` as an example for something specifically suited to your needs.

You can use URI::Find to extract URLs from an arbitrary text document.

Less complete solutions involving regular expressions can save you a lot of processing time if you know that the input is simple. One solution from Tom Christiansen runs 100 times faster than most module based approaches but only extracts URLs from anchors where the first attribute is HREF and there are no other attributes.

```
        #!/usr/bin/perl -n00
        # qxurl - tchrist@perl.com
        print "$2\n" while m{
            < \s*
              A \s+ HREF \s* = \s* (["']) (.*?) \1
            \s* >
        }gsix;
```

25.1.6 How do I download a file from the user's machine? How do I open a file on another machine?

In this case, download means to use the file upload feature of HTML forms. You allow the web surfer to specify a file to send to your web server. To you it looks like a download, and to the user it looks like an upload. No matter what you call it, you do it with what's known as **multipart/form-data** encoding. The CGI.pm module (which comes with Perl as part of the Standard Library) supports this in the start_multipart_form() method, which isn't the same as the startform() method.

See the section in the CGI.pm documentation on file uploads for code examples and details.

25.1.7 How do I make a pop-up menu in HTML?

Use the <**SELECT**> and <**OPTION**> tags. The CGI.pm module (available from CPAN) supports this widget, as well as many others, including some that it cleverly synthesizes on its own.

25.1.8 How do I fetch an HTML file?

One approach, if you have the lynx text-based HTML browser installed on your system, is this:

```
$html_code = ‘lynx -source $url‘;
$text_data = ‘lynx -dump $url‘;
```

The libwww-perl (LWP) modules from CPAN provide a more powerful way to do this. They don’t require lynx, but like lynx, can still work through proxies:

```
# simplest version
use LWP::Simple;
$content = get($URL);

# or print HTML from a URL
use LWP::Simple;
getprint "http://www.linpro.no/lwp/";

# or print ASCII from HTML from a URL
# also need HTML-Tree package from CPAN
use LWP::Simple;
use HTML::Parser;
use HTML::FormatText;
my ($html, $ascii);
$html = get("http://www.perl.com/");
defined $html
    or die "Can’t fetch HTML from http://www.perl.com/";
$ascii = HTML::FormatText->new->format(parse_html($html));
print $ascii;
```

25.1.9 How do I automate an HTML form submission?

If you’re submitting values using the GET method, create a URL and encode the form using the `query_form` method:

```
use LWP::Simple;
use URI::URL;

my $url = url(’http://www.perl.com/cgi-bin/cpan_mod’);
$url->query_form(module => ’DB_File’, readme => 1);
$content = get($url);
```

If you’re using the POST method, create your own user agent and encode the content appropriately.

```
use HTTP::Request::Common qw(POST);
use LWP::UserAgent;

$ua = LWP::UserAgent->new();
my $req = POST ’http://www.perl.com/cgi-bin/cpan_mod’,
               [ module => ’DB_File’, readme => 1 ];
$content = $ua->request($req)->as_string;
```

25.1.10 How do I decode or create those %-encodings on the web?

If you are writing a CGI script, you should be using the CGI.pm module that comes with perl, or some other equivalent module. The CGI module automatically decodes queries for you, and provides an escape() function to handle encoding.

The best source of detailed information on URI encoding is RFC 2396. Basically, the following substitutions do it:

```
s/([^\w()'*~!.-])/sprintf '%%%02x', ord $1/eg;   # encode

s/%([A-Fa-f\d]{2})/chr hex $1/eg;            # decode
```

However, you should only apply them to individual URI components, not the entire URI, otherwise you'll lose information and generally mess things up. If that didn't explain it, don't worry. Just go read section 2 of the RFC, it's probably the best explanation there is.

RFC 2396 also contains a lot of other useful information, including a regexp for breaking any arbitrary URI into components (Appendix B).

25.1.11 How do I redirect to another page?

Specify the complete URL of the destination (even if it is on the same server). This is one of the two different kinds of CGI "Location:" responses which are defined in the CGI specification for a Parsed Headers script. The other kind (an absolute URLpath) is resolved internally to the server without any HTTP redirection. The CGI specifications do not allow relative URLs in either case.

Use of CGI.pm is strongly recommended. This example shows redirection with a complete URL. This redirection is handled by the web browser.

```
use CGI qw/:standard/;

my $url = 'http://www.cpan.org/';
print redirect($url);
```

This example shows a redirection with an absolute URLpath. This redirection is handled by the local web server.

```
my $url = '/CPAN/index.html';
print redirect($url);
```

But if coded directly, it could be as follows (the final "\n" is shown separately, for clarity), using either a complete URL or an absolute URLpath.

```
print "Location: $url\n";   # CGI response header
print "\n";                 # end of headers
```

25.1.12 How do I put a password on my web pages?

To enable authentication for your web server, you need to configure your web server. The configuration is different for different sorts of web servers—apache does it differently from iPlanet which does it differently from IIS. Check your web server documentation for the details for your particular server.

25.1.13 How do I edit my .htpasswd and .htgroup files with Perl?

The HTTPD::UserAdmin and HTTPD::GroupAdmin modules provide a consistent OO interface to these files, regardless of how they're stored. Databases may be text, dbm, Berkeley DB or any database with a DBI compatible driver. HTTPD::UserAdmin supports files used by the 'Basic' and 'Digest' authentication schemes. Here's an example:

```
use HTTPD::UserAdmin ();
HTTPD::UserAdmin
      ->new(DB => "/foo/.htpasswd")
      ->add($username => $password);
```

25.1.14 How do I make sure users can't enter values into a form that cause my CGI script to do bad things?

See the security references listed in the CGI Meta FAQ

```
        http://www.perl.org/CGI_MetaFAQ.html
```

25.1.15 How do I parse a mail header?

For a quick-and-dirty solution, try this solution derived from split in *perlfunc*:

```
    $/ = '';
    $header = <MSG>;
    $header =~ s/\n\s+/ /g;      # merge continuation lines
    %head = ( UNIX_FROM_LINE, split /^([-\w]+):\s*/m, $header );
```

That solution doesn't do well if, for example, you're trying to maintain all the Received lines. A more complete approach is to use the Mail::Header module from CPAN (part of the MailTools package).

25.1.16 How do I decode a CGI form?

You use a standard module, probably CGI.pm. Under no circumstances should you attempt to do so by hand!

You'll see a lot of CGI programs that blindly read from STDIN the number of bytes equal to CONTENT_LENGTH for POSTs, or grab QUERY_STRING for decoding GETs. These programs are very poorly written. They only work sometimes. They typically forget to check the return value of the read() system call, which is a cardinal sin. They don't handle HEAD requests. They don't handle multipart forms used for file uploads. They don't deal with GET/POST combinations where query fields are in more than one place. They don't deal with keywords in the query string.

In short, they're bad hacks. Resist them at all costs. Please do not be tempted to reinvent the wheel. Instead, use the CGI.pm or CGI_Lite.pm (available from CPAN), or if you're trapped in the module-free land of perl1 .. perl4, you might look into cgi-lib.pl (available from http://cgi-lib.stanford.edu/cgi-lib/).

Make sure you know whether to use a GET or a POST in your form. GETs should only be used for something that doesn't update the server. Otherwise you can get mangled databases and repeated feedback mail messages. The fancy word for this is "idempotency". This simply means that there should be no difference between making a GET request for a particular URL once or multiple times. This is because the HTTP protocol definition says that a GET request may be cached by the browser, or server, or an intervening proxy. POST requests cannot be cached, because each request is independent and matters. Typically, POST requests change or depend on state on the server (query or update a database, send mail, or purchase a computer).

25.1.17 How do I check a valid mail address?

You can't, at least, not in real time. Bummer, eh?

Without sending mail to the address and seeing whether there's a human on the other hand to answer you, you cannot determine whether a mail address is valid. Even if you apply the mail header standard, you can have problems, because there are deliverable addresses that aren't RFC-822 (the mail header standard) compliant, and addresses that aren't deliverable which are compliant.

You can use the Email::Valid or RFC::RFC822::Address which check the format of the address, although they cannot actually tell you if it is a deliverable address (i.e. that mail to the address will not bounce). Modules like Mail::CheckUser and Mail::EXPN try to interact with the domain name system or particular mail servers to learn even more, but their methods do not work everywhere—especially for security conscious administrators.

Many are tempted to try to eliminate many frequently-invalid mail addresses with a simple regex, such as `/^[\w.-]+\@(?:[\w-]+\.)+\w+$/`. It's a very bad idea. However, this also throws out many valid ones, and says nothing about potential deliverability, so it is not suggested. Instead, see http://www.cpan.org/authors/Tom_Christiansen/scripts/ckaddr.gz , which actually checks against the full RFC spec (except for nested comments), looks for addresses you may not wish to accept mail to (say, Bill Clinton or your postmaster), and then makes sure that the hostname given can be looked up in the DNS MX records. It's not fast, but it works for what it tries to do.

Our best advice for verifying a person's mail address is to have them enter their address twice, just as you normally do to change a password. This usually weeds out typos. If both versions match, send mail to that address with a personal message that looks somewhat like:

```
    Dear someuser@host.com,

    Please confirm the mail address you gave us Wed May  6 09:38:41
    MDT 1998 by replying to this message.  Include the string
    "Rumpelstiltskin" in that reply, but spelled in reverse; that is,
    start with "Nik...".  Once this is done, your confirmed address will
    be entered into our records.
```

If you get the message back and they've followed your directions, you can be reasonably assured that it's real.

A related strategy that's less open to forgery is to give them a PIN (personal ID number). Record the address and PIN (best that it be a random one) for later processing. In the mail you send, ask them to include the PIN in their reply. But if it bounces, or the message is included via a "vacation" script, it'll be there anyway. So it's best to ask them to mail back a slight alteration of the PIN, such as with the characters reversed, one added or subtracted to each digit, etc.

25.1.18 How do I decode a MIME/BASE64 string?

The MIME-Base64 package (available from CPAN) handles this as well as the MIME/QP encoding. Decoding BASE64 becomes as simple as:

```
    use MIME::Base64;
    $decoded = decode_base64($encoded);
```

The MIME-Tools package (available from CPAN) supports extraction with decoding of BASE64 encoded attachments and content directly from email messages.

If the string to decode is short (less than 84 bytes long) a more direct approach is to use the unpack() function's "u" format after minor transliterations:

```
    tr#A-Za-z0-9+/##cd;                   # remove non-base64 chars
    tr#A-Za-z0-9+/# -_#;                  # convert to uuencoded format
    $len = pack("c", 32 + 0.75*length);   # compute length byte
    print unpack("u", $len . $_);         # uudecode and print
```

25.1.19 How do I return the user's mail address?

On systems that support getpwuid, the $< variable, and the Sys::Hostname module (which is part of the standard perl distribution), you can probably try using something like this:

```
    use Sys::Hostname;
    $address = sprintf('%s@%s', scalar getpwuid($<), hostname);
```

Company policies on mail address can mean that this generates addresses that the company's mail system will not accept, so you should ask for users' mail addresses when this matters. Furthermore, not all systems on which Perl runs are so forthcoming with this information as is Unix.

The Mail::Util module from CPAN (part of the MailTools package) provides a mailaddress() function that tries to guess the mail address of the user. It makes a more intelligent guess than the code above, using information given when the module was installed, but it could still be incorrect. Again, the best way is often just to ask the user.

25.1.20 How do I send mail?

Use the `sendmail` program directly:

```
    open(SENDMAIL, "|/usr/lib/sendmail -oi -t -odq")
                        or die "Can't fork for sendmail: $!\n";
    print SENDMAIL <<"EOF";
    From: User Originating Mail <me\@host>
    To: Final Destination <you\@otherhost>
    Subject: A relevant subject line

    Body of the message goes here after the blank line
    in as many lines as you like.
    EOF
    close(SENDMAIL)     or warn "sendmail didn't close nicely";
```

The **-oi** option prevents sendmail from interpreting a line consisting of a single dot as "end of message". The **-t** option says to use the headers to decide who to send the message to, and **-odq** says to put the message into the queue. This last option means your message won't be immediately delivered, so leave it out if you want immediate delivery.

Alternate, less convenient approaches include calling mail (sometimes called mailx) directly or simply opening up port 25 have having an intimate conversation between just you and the remote SMTP daemon, probably sendmail.

Or you might be able use the CPAN module Mail::Mailer:

```
    use Mail::Mailer;

    $mailer = Mail::Mailer->new();
    $mailer->open({ From    => $from_address,
                    To      => $to_address,
                    Subject => $subject,
                  })
        or die "Can't open: $!\n";
    print $mailer $body;
    $mailer->close();
```

The Mail::Internet module uses Net::SMTP which is less Unix-centric than Mail::Mailer, but less reliable. Avoid raw SMTP commands. There are many reasons to use a mail transport agent like sendmail. These include queuing, MX records, and security.

25.1.21 How do I use MIME to make an attachment to a mail message?

This answer is extracted directly from the MIME::Lite documentation. Create a multipart message (i.e., one with attachments).

```
    use MIME::Lite;

    ### Create a new multipart message:
    $msg = MIME::Lite->new(
                 From    =>'me@myhost.com',
                 To      =>'you@yourhost.com',
                 Cc      =>'some@other.com, some@more.com',
                 Subject =>'A message with 2 parts...',
                 Type    =>'multipart/mixed'
                 );
    ### Add parts (each "attach" has same arguments as "new"):
    $msg->attach(Type     =>'TEXT',
                 Data     =>"Here's the GIF file you wanted"
                 );
    $msg->attach(Type     =>'image/gif',
                 Path     =>'aaa000123.gif',
                 Filename =>'logo.gif'
                 );

    $text = $msg->as_string;
```

MIME::Lite also includes a method for sending these things.

```
    $msg->send;
```

This defaults to using *sendmail* but can be customized to use SMTP via *Net::SMTP*.

25.1.22 How do I read mail?

While you could use the Mail::Folder module from CPAN (part of the MailFolder package) or the Mail::Internet module from CPAN (part of the MailTools package), often a module is overkill. Here's a mail sorter.

```
    #!/usr/bin/perl

    my(@msgs, @sub);
    my $msgno = -1;
    $/ = '';                    # paragraph reads
    while (<>) {
        if (/^From /m) {
            /^Subject:\s*(?:Re:\s*)*(.*)/mi;
            $sub[++$msgno] = lc($1) || '';
        }
        $msgs[$msgno] .= $_;
    }
    for my $i (sort { $sub[$a] cmp $sub[$b] || $a <=> $b } (0 .. $#msgs)) {
        print $msgs[$i];
    }
```

Or more succinctly,

```
    #!/usr/bin/perl -n00
    # bysub2 - awkish sort-by-subject
    BEGIN { $msgno = -1 }
    $sub[++$msgno] = (/^Subject:\s*(?:Re:\s*)*(.*)/mi)[0] if /^From/m;
    $msg[$msgno] .= $_;
    END { print @msg[ sort { $sub[$a] cmp $sub[$b] || $a <=> $b } (0 .. $#msg) ] }
```

25.1.23 How do I find out my hostname/domainname/IP address?

The normal way to find your own hostname is to call the `` `hostname` `` program. While sometimes expedient, this has some problems, such as not knowing whether you've got the canonical name or not. It's one of those tradeoffs of convenience versus portability.

The Sys::Hostname module (part of the standard perl distribution) will give you the hostname after which you can find out the IP address (assuming you have working DNS) with a gethostbyname() call.

```
    use Socket;
    use Sys::Hostname;
    my $host = hostname();
    my $addr = inet_ntoa(scalar gethostbyname($host || 'localhost'));
```

Probably the simplest way to learn your DNS domain name is to grok it out of /etc/resolv.conf, at least under Unix. Of course, this assumes several things about your resolv.conf configuration, including that it exists.

(We still need a good DNS domain name-learning method for non-Unix systems.)

25.1.24 How do I fetch a news article or the active newsgroups?

Use the Net::NNTP or News::NNTPClient modules, both available from CPAN. This can make tasks like fetching the newsgroup list as simple as

```
    perl -MNews::NNTPClient
      -e 'print News::NNTPClient->new->list("newsgroups")'
```

25.1.25 How do I fetch/put an FTP file?

LWP::Simple (available from CPAN) can fetch but not put. Net::FTP (also available from CPAN) is more complex but can put as well as fetch.

25.1.26 How can I do RPC in Perl?

A DCE::RPC module is being developed (but is not yet available) and will be released as part of the DCE-Perl package (available from CPAN). The rpcgen suite, available from CPAN/authors/id/JAKE/, is an RPC stub generator and includes an RPC::ONC module.

Perl syntax

26.1 DESCRIPTION

A Perl program consists of a sequence of declarations and statements which run from the top to the bottom. Loops, subroutines and other control structures allow you to jump around within the code.

Perl is a **free-form** language, you can format and indent it however you like. Whitespace mostly serves to separate tokens, unlike languages like Python where it is an important part of the syntax.

Many of Perl's syntactic elements are **optional**. Rather than requiring you to put parentheses around every function call and declare every variable, you can often leave such explicit elements off and Perl will figure out what you meant. This is known as **Do What I Mean**, abbreviated **DWIM**. It allows programmers to be **lazy** and to code in a style with which they are comfortable.

Perl **borrows syntax** and concepts from many languages: awk, sed, C, Bourne Shell, Smalltalk, Lisp and even English. Other languages have borrowed syntax from Perl, particularly its regular expression extensions. So if you have programmed in another language you will see familiar pieces in Perl. They often work the same, but see *perltrap* for information about how they differ.

26.1.1 Declarations

The only things you need to declare in Perl are report formats and subroutines (and sometimes not even subroutines). A variable holds the undefined value (`undef`) until it has been assigned a defined value, which is anything other than `undef`. When used as a number, `undef` is treated as `0`; when used as a string, it is treated as the empty string, `""`; and when used as a reference that isn't being assigned to, it is treated as an error. If you enable warnings, you'll be notified of an uninitialized value whenever you treat `undef` as a string or a number. Well, usually. Boolean contexts, such as:

```
    my $a;
    if ($a) {}
```

are exempt from warnings (because they care about truth rather than definedness). Operators such as `++`, `-`, `+=`, `-=`, and `.=`, that operate on undefined left values such as:

```
    my $a;
    $a++;
```

are also always exempt from such warnings.

A declaration can be put anywhere a statement can, but has no effect on the execution of the primary sequence of statements–declarations all take effect at compile time. Typically all the declarations are put at the beginning or the end of the script. However, if you're using lexically-scoped private variables created with `my()`, you'll have to make sure your format or subroutine definition is within the same block scope as the my if you expect to be able to access those private variables.

Declaring a subroutine allows a subroutine name to be used as if it were a list operator from that point forward in the program. You can declare a subroutine without defining it by saying `sub name`, thus:

```
    sub myname;
    $me = myname $0             or die "can't get myname";
```

Note that myname() functions as a list operator, not as a unary operator; so be careful to use `or` instead of || in this case. However, if you were to declare the subroutine as `sub myname ($)`, then `myname` would function as a unary operator, so either `or` or || would work.

Subroutines declarations can also be loaded up with the `require` statement or both loaded and imported into your namespace with a `use` statement. See *perlmod* for details on this.

A statement sequence may contain declarations of lexically-scoped variables, but apart from declaring a variable name, the declaration acts like an ordinary statement, and is elaborated within the sequence of statements as if it were an ordinary statement. That means it actually has both compile-time and run-time effects.

26.1.2 Comments

Text from a `"#"` character until the end of the line is a comment, and is ignored. Exceptions include `"#"` inside a string or regular expression.

26.1.3 Simple Statements

The only kind of simple statement is an expression evaluated for its side effects. Every simple statement must be terminated with a semicolon, unless it is the final statement in a block, in which case the semicolon is optional. (A semicolon is still encouraged if the block takes up more than one line, because you may eventually add another line.) Note that there are some operators like `eval {}` and `do {}` that look like compound statements, but aren't (they're just TERMs in an expression), and thus need an explicit termination if used as the last item in a statement.

26.1.4 Truth and Falsehood

The number 0, the strings `'0'` and ", the empty list `()`, and `undef` are all false in a boolean context. All other values are true.

26.1.5 Statement Modifiers

Any simple statement may optionally be followed by a *SINGLE* modifier, just before the terminating semicolon (or block ending). The possible modifiers are:

```
    if EXPR
    unless EXPR
    while EXPR
    until EXPR
    foreach LIST
```

The `EXPR` following the modifier is referred to as the "condition". Its truth or falsehood determines how the modifier will behave.

`if` executes the statement once *if* and only if the condition is true. `unless` is the opposite, it executes the statement *unless* the condition is true (i.e., if the condition is false).

```
    print "Basset hounds got long ears" if length $ear >= 10;
    go_outside() and play() unless $is_raining;
```

The `foreach` modifier is an iterator: it executes the statement once for each item in the LIST (with `$_` aliased to each item in turn).

```
    print "Hello $_!\n" foreach qw(world Dolly nurse);
```

`while` repeats the statement *while* the condition is true. `until` does the opposite, it repeats the statement *until* the condition is true (or while the condition is false):

```
    # Both of these count from 0 to 10.
    print $i++ while $i <= 10;
    print $j++ until $j >  10;
```

The `while` and `until` modifiers have the usual "`while` loop" semantics (conditional evaluated first), except when applied to a `do`-BLOCK (or to the deprecated `do`-SUBROUTINE statement), in which case the block executes once before the conditional is evaluated. This is so that you can write loops like:

```
    do {
        $line = <STDIN>;
        ...
    } until $line  eq ".\n";
```

See `do` in *perlfunc*. Note also that the loop control statements described later will *NOT* work in this construct, because modifiers don't take loop labels. Sorry. You can always put another block inside of it (for `next`) or around it (for `last`) to do that sort of thing. For `next`, just double the braces:

```
    do {{
        next if $x == $y;
        # do something here
    }} until $x++ > $z;
```

For `last`, you have to be more elaborate:

```
    LOOP: {
            do {
                last if $x = $y**2;
                # do something here
            } while $x++ <= $z;
    }
```

NOTE: The behaviour of a `my` statement modified with a statement modifier conditional or loop construct (e.g. `my $x if ...`) is **undefined**. The value of the `my` variable may be `undef`, any previously assigned value, or possibly anything else. Don't rely on it. Future versions of perl might do something different from the version of perl you try it out on. Here be dragons.

26.1.6 Compound Statements

In Perl, a sequence of statements that defines a scope is called a block. Sometimes a block is delimited by the file containing it (in the case of a required file, or the program as a whole), and sometimes a block is delimited by the extent of a string (in the case of an eval).

But generally, a block is delimited by curly brackets, also known as braces. We will call this syntactic construct a BLOCK.

The following compound statements may be used to control flow:

```
if (EXPR) BLOCK
if (EXPR) BLOCK else BLOCK
if (EXPR) BLOCK elsif (EXPR) BLOCK ... else BLOCK
LABEL while (EXPR) BLOCK
LABEL while (EXPR) BLOCK continue BLOCK
LABEL for (EXPR; EXPR; EXPR) BLOCK
LABEL foreach VAR (LIST) BLOCK
LABEL foreach VAR (LIST) BLOCK continue BLOCK
LABEL BLOCK continue BLOCK
```

Note that, unlike C and Pascal, these are defined in terms of BLOCKs, not statements. This means that the curly brackets are *required*–no dangling statements allowed. If you want to write conditionals without curly brackets there are several other ways to do it. The following all do the same thing:

```
if (!open(FOO)) { die "Can't open $FOO: $!"; }
die "Can't open $FOO: $!" unless open(FOO);
open(FOO) or die "Can't open $FOO: $!";     # FOO or bust!
open(FOO) ? 'hi mom' : die "Can't open $FOO: $!";
                    # a bit exotic, that last one
```

The `if` statement is straightforward. Because BLOCKs are always bounded by curly brackets, there is never any ambiguity about which `if` an `else` goes with. If you use `unless` in place of `if`, the sense of the test is reversed.

The `while` statement executes the block as long as the expression is true (does not evaluate to the null string `""` or `0` or `"0"`). The LABEL is optional, and if present, consists of an identifier followed by a colon. The LABEL identifies the loop for the loop control statements `next`, `last`, and `redo`. If the LABEL is omitted, the loop control statement refers to the innermost enclosing loop. This may include dynamically looking back your call-stack at run time to find the LABEL. Such desperate behavior triggers a warning if you use the `use warnings` pragma or the **-w** flag.

If there is a `continue` BLOCK, it is always executed just before the conditional is about to be evaluated again. Thus it can be used to increment a loop variable, even when the loop has been continued via the `next` statement.

26.1.7 Loop Control

The `next` command starts the next iteration of the loop:

```
LINE: while (<STDIN>) {
    next LINE if /^#/;      # discard comments
    ...
}
```

The `last` command immediately exits the loop in question. The `continue` block, if any, is not executed:

```
LINE: while (<STDIN>) {
    last LINE if /^$/;      # exit when done with header
    ...
}
```

The `redo` command restarts the loop block without evaluating the conditional again. The `continue` block, if any, is *not* executed. This command is normally used by programs that want to lie to themselves about what was just input.

For example, when processing a file like */etc/termcap*. If your input lines might end in backslashes to indicate continuation, you want to skip ahead and get the next record.

```
    while (<>) {
        chomp;
        if (s/\\$//) {
            $_ .= <>;
            redo unless eof();
        }
        # now process $_
    }
```

which is Perl short-hand for the more explicitly written version:

```
    LINE: while (defined($line = <ARGV>)) {
        chomp($line);
        if ($line =~ s/\\$//) {
            $line .= <ARGV>;
            redo LINE unless eof(); # not eof(ARGV)!
        }
        # now process $line
    }
```

Note that if there were a `continue` block on the above code, it would get executed only on lines discarded by the regex (since redo skips the continue block). A continue block is often used to reset line counters or `?pat?` one-time matches:

```
    # inspired by :1,$g/fred/s//WILMA/
    while (<>) {
        ?(fred)?    && s//WILMA $1 WILMA/;
        ?(barney)?  && s//BETTY $1 BETTY/;
        ?(homer)?   && s//MARGE $1 MARGE/;
    } continue {
        print "$ARGV $.: $_";
        close ARGV  if eof();           # reset $.
        reset       if eof();           # reset ?pat?
    }
```

If the word `while` is replaced by the word `until`, the sense of the test is reversed, but the conditional is still tested before the first iteration.

The loop control statements don't work in an `if` or `unless`, since they aren't loops. You can double the braces to make them such, though.

```
    if (/pattern/) {{
        last if /fred/;
        next if /barney/; # same effect as "last", but doesn't document as well
        # do something here
    }}
```

This is caused by the fact that a block by itself acts as a loop that executes once, see §26.1.10.

The form `while/if BLOCK BLOCK`, available in Perl 4, is no longer available. Replace any occurrence of `if BLOCK` by `if (do BLOCK)`.

26.1.8 For Loops

Perl's C-style `for` loop works like the corresponding `while` loop; that means that this:

```
    for ($i = 1; $i < 10; $i++) {
        ...
    }
```

is the same as this:

```
$i = 1;
while ($i < 10) {
    ...
} continue {
    $i++;
}
```

There is one minor difference: if variables are declared with `my` in the initialization section of the `for`, the lexical scope of those variables is exactly the `for` loop (the body of the loop and the control sections).

Besides the normal array index looping, `for` can lend itself to many other interesting applications. Here's one that avoids the problem you get into if you explicitly test for end-of-file on an interactive file descriptor causing your program to appear to hang.

```
$on_a_tty = -t STDIN && -t STDOUT;
sub prompt { print "yes? " if $on_a_tty }
for ( prompt(); <STDIN>; prompt() ) {
    # do something
}
```

Using `readline` (or the operator form, `<EXPR>`) as the conditional of a `for` loop is shorthand for the following. This behaviour is the same as a `while` loop conditional.

```
for ( prompt(); defined( $_ = <STDIN> ); prompt() ) {
    # do something
}
```

26.1.9 Foreach Loops

The `foreach` loop iterates over a normal list value and sets the variable VAR to be each element of the list in turn. If the variable is preceded with the keyword `my`, then it is lexically scoped, and is therefore visible only within the loop. Otherwise, the variable is implicitly local to the loop and regains its former value upon exiting the loop. If the variable was previously declared with `my`, it uses that variable instead of the global one, but it's still localized to the loop. This implicit localisation occurs *only* in a `foreach` loop.

The `foreach` keyword is actually a synonym for the `for` keyword, so you can use `foreach` for readability or `for` for brevity. (Or because the Bourne shell is more familiar to you than *csh*, so writing `for` comes more naturally.) If VAR is omitted, `$_` is set to each value.

If any element of LIST is an lvalue, you can modify it by modifying VAR inside the loop. Conversely, if any element of LIST is NOT an lvalue, any attempt to modify that element will fail. In other words, the `foreach` loop index variable is an implicit alias for each item in the list that you're looping over.

If any part of LIST is an array, `foreach` will get very confused if you add or remove elements within the loop body, for example with `splice`. So don't do that.

`foreach` probably won't do what you expect if VAR is a tied or other special variable. Don't do that either.

Examples:

```
for (@ary) { s/foo/bar/ }

for my $elem (@elements) {
    $elem *= 2;
}
```

```
    for $count (10,9,8,7,6,5,4,3,2,1,'BOOM') {
        print $count, "\n"; sleep(1);
    }

    for (1..15) { print "Merry Christmas\n"; }

    foreach $item (split(/:[\\\n:]*/, $ENV{TERMCAP})) {
        print "Item: $item\n";
    }
```

Here's how a C programmer might code up a particular algorithm in Perl:

```
    for (my $i = 0; $i < @ary1; $i++) {
        for (my $j = 0; $j < @ary2; $j++) {
            if ($ary1[$i] > $ary2[$j]) {
                last; # can't go to outer :-(
            }
            $ary1[$i] += $ary2[$j];
        }
        # this is where that last takes me
    }
```

Whereas here's how a Perl programmer more comfortable with the idiom might do it:

```
    OUTER: for my $wid (@ary1) {
    INNER:   for my $jet (@ary2) {
                next OUTER if $wid > $jet;
                $wid += $jet;
             }
          }
```

See how much easier this is? It's cleaner, safer, and faster. It's cleaner because it's less noisy. It's safer because if code gets added between the inner and outer loops later on, the new code won't be accidentally executed. The `next` explicitly iterates the other loop rather than merely terminating the inner one. And it's faster because Perl executes a `foreach` statement more rapidly than it would the equivalent `for` loop.

26.1.10 Basic BLOCKs and Switch Statements

A BLOCK by itself (labeled or not) is semantically equivalent to a loop that executes once. Thus you can use any of the loop control statements in it to leave or restart the block. (Note that this is *NOT* true in `eval{}`, `sub{}`, or contrary to popular belief `do{}` blocks, which do *NOT* count as loops.) The `continue` block is optional.

The BLOCK construct is particularly nice for doing case structures.

```
    SWITCH: {
        if (/^abc/) { $abc = 1; last SWITCH; }
        if (/^def/) { $def = 1; last SWITCH; }
        if (/^xyz/) { $xyz = 1; last SWITCH; }
        $nothing = 1;
    }
```

There is no official `switch` statement in Perl, because there are already several ways to write the equivalent.

However, starting from Perl 5.8 to get switch and case one can use the Switch extension and say:

```
        use Switch;
```

after which one has switch and case. It is not as fast as it could be because it's not really part of the language (it's done using source filters) but it is available, and it's very flexible.

In addition to the above BLOCK construct, you could write

```
SWITCH: {
    $abc = 1, last SWITCH  if /^abc/;
    $def = 1, last SWITCH  if /^def/;
    $xyz = 1, last SWITCH  if /^xyz/;
    $nothing = 1;
}
```

(That's actually not as strange as it looks once you realize that you can use loop control "operators" within an expression. That's just the binary comma operator in scalar context. See Comma Operator in *perlop*.)

or

```
SWITCH: {
    /^abc/ && do { $abc = 1; last SWITCH; };
    /^def/ && do { $def = 1; last SWITCH; };
    /^xyz/ && do { $xyz = 1; last SWITCH; };
    $nothing = 1;
}
```

or formatted so it stands out more as a "proper" `switch` statement:

```
SWITCH: {
    /^abc/      && do {
                        $abc = 1;
                        last SWITCH;
                   };

    /^def/      && do {
                        $def = 1;
                        last SWITCH;
                   };

    /^xyz/      && do {
                        $xyz = 1;
                        last SWITCH;
                    };
    $nothing = 1;
}
```

or

```
SWITCH: {
    /^abc/ and $abc = 1, last SWITCH;
    /^def/ and $def = 1, last SWITCH;
    /^xyz/ and $xyz = 1, last SWITCH;
    $nothing = 1;
}
```

or even, horrors,

```
    if (/^abc/)
        { $abc = 1 }
    elsif (/^def/)
        { $def = 1 }
    elsif (/^xyz/)
        { $xyz = 1 }
    else
        { $nothing = 1 }
```

A common idiom for a `switch` statement is to use `foreach`'s aliasing to make a temporary assignment to `$_` for convenient matching:

```
    SWITCH: for ($where) {
                /In Card Names/     && do { push @flags, '-e'; last; };
                /Anywhere/          && do { push @flags, '-h'; last; };
                /In Rulings/        && do {                    last; };
                die "unknown value for form variable where: `$where'";
            }
```

Another interesting approach to a switch statement is arrange for a `do` block to return the proper value:

```
    $amode = do {
        if     ($flag & O_RDONLY) { "r" }       # XXX: isn't this 0?
        elsif  ($flag & O_WRONLY) { ($flag & O_APPEND) ? "a" : "w" }
        elsif  ($flag & O_RDWR)   {
            if ($flag & O_CREAT)  { "w+" }
            else                  { ($flag & O_APPEND) ? "a+" : "r+" }
        }
    };
```

Or

```
        print do {
            ($flags & O_WRONLY) ? "write-only"          :
            ($flags & O_RDWR)   ? "read-write"          :
                                  "read-only";
        };
```

Or if you are certain that all the `&&` clauses are true, you can use something like this, which "switches" on the value of the `HTTP_USER_AGENT` environment variable.

```
    #!/usr/bin/perl
    # pick out jargon file page based on browser
    $dir = 'http://www.wins.uva.nl/~mes/jargon';
    for ($ENV{HTTP_USER_AGENT}) {
        $page  =    /Mac/            && 'm/Macintrash.html'
                 || /Win(dows )?NT/  && 'e/evilandrude.html'
                 || /Win|MSIE|WebTV/ && 'm/MicroslothWindows.html'
                 || /Linux/          && 'l/Linux.html'
                 || /HP-UX/          && 'h/HP-SUX.html'
                 || /SunOS/          && 's/ScumOS.html'
                 ||                     'a/AppendixB.html';
    }
    print "Location: $dir/$page\015\012\015\012";
```

That kind of switch statement only works when you know the `&&` clauses will be true. If you don't, the previous `?:` example should be used.

You might also consider writing a hash of subroutine references instead of synthesizing a `switch` statement.

26.1.11 Goto

Although not for the faint of heart, Perl does support a `goto` statement. There are three forms: `goto`-LABEL, `goto`-EXPR, and `goto`-&NAME. A loop's LABEL is not actually a valid target for a `goto`; it's just the name of the loop.

The `goto`-LABEL form finds the statement labeled with LABEL and resumes execution there. It may not be used to go into any construct that requires initialization, such as a subroutine or a `foreach` loop. It also can't be used to go into a construct that is optimized away. It can be used to go almost anywhere else within the dynamic scope, including out of subroutines, but it's usually better to use some other construct such as `last` or `die`. The author of Perl has never felt the need to use this form of `goto` (in Perl, that is–C is another matter).

The `goto`-EXPR form expects a label name, whose scope will be resolved dynamically. This allows for computed `goto`s per FORTRAN, but isn't necessarily recommended if you're optimizing for maintainability:

```
    goto(("FOO", "BAR", "GLARCH")[$i]);
```

The `goto`-&NAME form is highly magical, and substitutes a call to the named subroutine for the currently running subroutine. This is used by `AUTOLOAD()` subroutines that wish to load another subroutine and then pretend that the other subroutine had been called in the first place (except that any modifications to `@_` in the current subroutine are propagated to the other subroutine.) After the `goto`, not even `caller()` will be able to tell that this routine was called first.

In almost all cases like this, it's usually a far, far better idea to use the structured control flow mechanisms of `next`, `last`, or `redo` instead of resorting to a `goto`. For certain applications, the catch and throw pair of `eval{}` and die() for exception processing can also be a prudent approach.

26.1.12 PODs: Embedded Documentation

Perl has a mechanism for intermixing documentation with source code. While it's expecting the beginning of a new statement, if the compiler encounters a line that begins with an equal sign and a word, like this

```
    =head1 Here There Be Pods!
```

Then that text and all remaining text up through and including a line beginning with `=cut` will be ignored. The format of the intervening text is described in *perlpod*.

This allows you to intermix your source code and your documentation text freely, as in

```
    =item snazzle($)

    The snazzle() function will behave in the most spectacular
    form that you can possibly imagine, not even excepting
    cybernetic pyrotechnics.

    =cut back to the compiler, nuff of this pod stuff!

    sub snazzle($) {
        my $thingie = shift;
        .........
    }
```

Note that pod translators should look at only paragraphs beginning with a pod directive (it makes parsing easier), whereas the compiler actually knows to look for pod escapes even in the middle of a paragraph. This means that the following secret stuff will be ignored by both the compiler and the translators.

```
    $a=3;
    =secret stuff
     warn "Neither POD nor CODE!?"
    =cut back
    print "got $a\n";
```

You probably shouldn't rely upon the `warn()` being podded out forever. Not all pod translators are well-behaved in this regard, and perhaps the compiler will become pickier.

One may also use pod directives to quickly comment out a section of code.

26.1.13 Plain Old Comments (Not!)

Perl can process line directives, much like the C preprocessor. Using this, one can control Perl's idea of filenames and line numbers in error or warning messages (especially for strings that are processed with `eval()`). The syntax for this mechanism is the same as for most C preprocessors: it matches the regular expression

```
# example: '# line 42 "new_filename.plx"'
/^\#   \s*
  line \s+ (\d+)   \s*
  (?:\s("?)([^"]+)\2)? \s*
 $/x
```

with `$1` being the line number for the next line, and `$3` being the optional filename (specified with or without quotes).

There is a fairly obvious gotcha included with the line directive: Debuggers and profilers will only show the last source line to appear at a particular line number in a given file. Care should be taken not to cause line number collisions in code you'd like to debug later.

Here are some examples that you should be able to type into your command shell:

```
% perl
# line 200 "bzzzt"
# the `#' on the previous line must be the first char on line
die 'foo';
__END__
foo at bzzzt line 201.

% perl
# line 200 "bzzzt"
eval qq[\n#line 2001 ""\ndie 'foo']; print $@;
__END__
foo at - line 2001.

% perl
eval qq[\n#line 200 "foo bar"\ndie 'foo']; print $@;
__END__
foo at foo bar line 200.

% perl
# line 345 "goop"
eval "\n#line " . __LINE__ . ' "' . __FILE__ ."\"\ndie 'foo'";
print $@;
__END__
foo at goop line 345.
```

Chapter 27

perldata

Perl data types

27.1 DESCRIPTION

27.1.1 Variable names

Perl has three built-in data types: scalars, arrays of scalars, and associative arrays of scalars, known as "hashes". A scalar is a single string (of any size, limited only by the available memory), number, or a reference to something (which will be discussed in *perlref*). Normal arrays are ordered lists of scalars indexed by number, starting with 0. Hashes are unordered collections of scalar values indexed by their associated string key.

Values are usually referred to by name, or through a named reference. The first character of the name tells you to what sort of data structure it refers. The rest of the name tells you the particular value to which it refers. Usually this name is a single *identifier*, that is, a string beginning with a letter or underscore, and containing letters, underscores, and digits. In some cases, it may be a chain of identifiers, separated by `::` (or by the slightly archaic `'`); all but the last are interpreted as names of packages, to locate the namespace in which to look up the final identifier (see Packages in *perlmod* for details). It's possible to substitute for a simple identifier, an expression that produces a reference to the value at runtime. This is described in more detail below and in *perlref*.

Perl also has its own built-in variables whose names don't follow these rules. They have strange names so they don't accidentally collide with one of your normal variables. Strings that match parenthesized parts of a regular expression are saved under names containing only digits after the `$` (see *perlop* and *perlre*). In addition, several special variables that provide windows into the inner working of Perl have names containing punctuation characters and control characters. These are documented in *perlvar*.

Scalar values are always named with '$', even when referring to a scalar that is part of an array or a hash. The '$' symbol works semantically like the English word "the" in that it indicates a single value is expected.

```
    $days               # the simple scalar value "days"
    $days[28]           # the 29th element of array @days
    $days{'Feb'}        # the 'Feb' value from hash %days
    $#days              # the last index of array @days
```

Entire arrays (and slices of arrays and hashes) are denoted by '@', which works much like the word "these" or "those" does in English, in that it indicates multiple values are expected.

```
    @days               # ($days[0], $days[1],... $days[n])
    @days[3,4,5]        # same as ($days[3],$days[4],$days[5])
    @days{'a','c'}      # same as ($days{'a'},$days{'c'})
```

Entire hashes are denoted by '%':

```
    %days               # (key1, val1, key2, val2 ...)
```

In addition, subroutines are named with an initial '&', though this is optional when unambiguous, just as the word "do" is often redundant in English. Symbol table entries can be named with an initial '*', but you don't really care about that yet (if ever :-).

Every variable type has its own namespace, as do several non-variable identifiers. This means that you can, without fear of conflict, use the same name for a scalar variable, an array, or a hash–or, for that matter, for a filehandle, a directory handle, a subroutine name, a format name, or a label. This means that $foo and @foo are two different variables. It also means that `$foo[1]` is a part of @foo, not a part of $foo. This may seem a bit weird, but that's okay, because it is weird.

Because variable references always start with '$', '@', or '%', the "reserved" words aren't in fact reserved with respect to variable names. They *are* reserved with respect to labels and filehandles, however, which don't have an initial special character. You can't have a filehandle named "log", for instance. Hint: you could say `open(LOG,'logfile')` rather than `open(log,'logfile')`. Using uppercase filehandles also improves readability and protects you from conflict with future reserved words. Case *is* significant–"FOO", "Foo", and "foo" are all different names. Names that start with a letter or underscore may also contain digits and underscores.

It is possible to replace such an alphanumeric name with an expression that returns a reference to the appropriate type. For a description of this, see *perlref*.

Names that start with a digit may contain only more digits. Names that do not start with a letter, underscore, digit or a caret (i.e. a control character) are limited to one character, e.g., `$%` or `$$`. (Most of these one character names have a predefined significance to Perl. For instance, `$$` is the current process id.)

27.1.2 Context

The interpretation of operations and values in Perl sometimes depends on the requirements of the context around the operation or value. There are two major contexts: list and scalar. Certain operations return list values in contexts wanting a list, and scalar values otherwise. If this is true of an operation it will be mentioned in the documentation for that operation. In other words, Perl overloads certain operations based on whether the expected return value is singular or plural. Some words in English work this way, like "fish" and "sheep".

In a reciprocal fashion, an operation provides either a scalar or a list context to each of its arguments. For example, if you say

```
    int( <STDIN> )
```

the integer operation provides scalar context for the <> operator, which responds by reading one line from STDIN and passing it back to the integer operation, which will then find the integer value of that line and return that. If, on the other hand, you say

```
    sort( <STDIN> )
```

then the sort operation provides list context for <>, which will proceed to read every line available up to the end of file, and pass that list of lines back to the sort routine, which will then sort those lines and return them as a list to whatever the context of the sort was.

Assignment is a little bit special in that it uses its left argument to determine the context for the right argument. Assignment to a scalar evaluates the right-hand side in scalar context, while assignment to an array or hash evaluates the righthand side in list context. Assignment to a list (or slice, which is just a list anyway) also evaluates the righthand side in list context.

When you use the `use warnings` pragma or Perl's **-w** command-line option, you may see warnings about useless uses of constants or functions in "void context". Void context just means the value has been discarded, such as a statement containing only `"fred";` or `getpwuid(0);`. It still counts as scalar context for functions that care whether or not they're being called in list context.

User-defined subroutines may choose to care whether they are being called in a void, scalar, or list context. Most subroutines do not need to bother, though. That's because both scalars and lists are automatically interpolated into lists. See wantarray in *perlfunc* for how you would dynamically discern your function's calling context.

27.1.3 Scalar values

All data in Perl is a scalar, an array of scalars, or a hash of scalars. A scalar may contain one single value in any of three different flavors: a number, a string, or a reference. In general, conversion from one form to another is transparent. Although a scalar may not directly hold multiple values, it may contain a reference to an array or hash which in turn contains multiple values.

Scalars aren't necessarily one thing or another. There's no place to declare a scalar variable to be of type "string", type "number", type "reference", or anything else. Because of the automatic conversion of scalars, operations that return scalars don't need to care (and in fact, cannot care) whether their caller is looking for a string, a number, or a reference. Perl is a contextually polymorphic language whose scalars can be strings, numbers, or references (which includes objects). Although strings and numbers are considered pretty much the same thing for nearly all purposes, references are strongly-typed, uncastable pointers with builtin reference-counting and destructor invocation.

A scalar value is interpreted as TRUE in the Boolean sense if it is not the null string or the number 0 (or its string equivalent, "0"). The Boolean context is just a special kind of scalar context where no conversion to a string or a number is ever performed.

There are actually two varieties of null strings (sometimes referred to as "empty" strings), a defined one and an undefined one. The defined version is just a string of length zero, such as `""`. The undefined version is the value that indicates that there is no real value for something, such as when there was an error, or at end of file, or when you refer to an uninitialized variable or element of an array or hash. Although in early versions of Perl, an undefined scalar could become defined when first used in a place expecting a defined value, this no longer happens except for rare cases of autovivification as explained in *perlref*. You can use the defined() operator to determine whether a scalar value is defined (this has no meaning on arrays or hashes), and the undef() operator to produce an undefined value.

To find out whether a given string is a valid non-zero number, it's sometimes enough to test it against both numeric 0 and also lexical "0" (although this will cause noises if warnings are on). That's because strings that aren't numbers count as 0, just as they do in **awk**:

```
    if ($str == 0 && $str ne "0")  {
        warn "That doesn't look like a number";
    }
```

That method may be best because otherwise you won't treat IEEE notations like `NaN` or `Infinity` properly. At other times, you might prefer to determine whether string data can be used numerically by calling the POSIX::strtod() function or by inspecting your string with a regular expression (as documented in *perlre*).

```
    warn "has nondigits"        if     /\D/;
    warn "not a natural number" unless /^\d+$/;             # rejects -3
    warn "not an integer"       unless /^-?\d+$/;           # rejects +3
    warn "not an integer"       unless /^[+-]?\d+$/;
    warn "not a decimal number" unless /^-?\d+\.?\d*$/;     # rejects .2
    warn "not a decimal number" unless /^-?(?:\d+(?:\.\d*)?|\.\d+)$/;
    warn "not a C float"
        unless /^([+-]?)(?=\d|\.\d)\d*(\.\d*)?([Ee]([+-]?\d+))?$/;
```

The length of an array is a scalar value. You may find the length of array @days by evaluating `$#days`, as in **csh**. However, this isn't the length of the array; it's the subscript of the last element, which is a different value since there is ordinarily a 0th element. Assigning to `$#days` actually changes the length of the array. Shortening an array this way destroys intervening values. Lengthening an array that was previously shortened does not recover values that were in those elements. (It used to do so in Perl 4, but we had to break this to make sure destructors were called when expected.)

You can also gain some minuscule measure of efficiency by pre-extending an array that is going to get big. You can also extend an array by assigning to an element that is off the end of the array. You can truncate an array down to nothing by assigning the null list () to it. The following are equivalent:

```
    @whatever = ();
    $#whatever = -1;
```

If you evaluate an array in scalar context, it returns the length of the array. (Note that this is not true of lists, which return the last value, like the C comma operator, nor of built-in functions, which return whatever they feel like returning.) The following is always true:

```
    scalar(@whatever) == $#whatever - $[ + 1;
```

Version 5 of Perl changed the semantics of `$[`: files that don't set the value of `$[` no longer need to worry about whether another file changed its value. (In other words, use of `$[` is deprecated.) So in general you can assume that

```
    scalar(@whatever) == $#whatever + 1;
```

Some programmers choose to use an explicit conversion so as to leave nothing to doubt:

```
    $element_count = scalar(@whatever);
```

If you evaluate a hash in scalar context, it returns false if the hash is empty. If there are any key/value pairs, it returns true; more precisely, the value returned is a string consisting of the number of used buckets and the number of allocated buckets, separated by a slash. This is pretty much useful only to find out whether Perl's internal hashing algorithm is performing poorly on your data set. For example, you stick 10,000 things in a hash, but evaluating %HASH in scalar context reveals `"1/16"`, which means only one out of sixteen buckets has been touched, and presumably contains all 10,000 of your items. This isn't supposed to happen.

You can preallocate space for a hash by assigning to the keys() function. This rounds up the allocated buckets to the next power of two:

```
    keys(%users) = 1000;                # allocate 1024 buckets
```

27.1.4 Scalar value constructors

Numeric literals are specified in any of the following floating point or integer formats:

```
    12345
    12345.67
    .23E-10             # a very small number
    3.14_15_92          # a very important number
    4_294_967_296       # underscore for legibility
    0xff                # hex
    0xdead_beef         # more hex
    0377                # octal
    0b011011            # binary
```

You are allowed to use underscores (underbars) in numeric literals between digits for legibility. You could, for example, group binary digits by threes (as for a Unix-style mode argument such as 0b110_100_100) or by fours (to represent nibbles, as in 0b1010_0110) or in other groups.

String literals are usually delimited by either single or double quotes. They work much like quotes in the standard Unix shells: double-quoted string literals are subject to backslash and variable substitution; single-quoted strings are not (except for `\'` and `\\`). The usual C-style backslash rules apply for making characters such as newline, tab, etc., as well as some more exotic forms. See Quote and Quote-like Operators in *perlop* for a list.

Hexadecimal, octal, or binary, representations in string literals (e.g. '0xff') are not automatically converted to their integer representation. The hex() and oct() functions make these conversions for you. See hex in *perlfunc* and oct in *perlfunc* for more details.

You can also embed newlines directly in your strings, i.e., they can end on a different line than they begin. This is nice, but if you forget your trailing quote, the error will not be reported until Perl finds another line containing the quote character, which may be much further on in the script. Variable substitution inside strings is limited to scalar variables, arrays, and array or hash slices. (In other words, names beginning with $ or @, followed by an optional bracketed expression as a subscript.) The following code segment prints out "The price is $100."

```
    $Price = '$100';    # not interpolated
    print "The price is $Price.\n";     # interpolated
```

There is no double interpolation in Perl, so the `$100` is left as is.

As in some shells, you can enclose the variable name in braces to disambiguate it from following alphanumerics (and underscores). You must also do this when interpolating a variable into a string to separate the variable name from a following double-colon or an apostrophe, since these would be otherwise treated as a package separator:

```
    $who = "Larry";
    print PASSWD "${who}::0:0:Superuser:/:/bin/perl\n";
    print "We use ${who}speak when ${who}'s here.\n";
```

Without the braces, Perl would have looked for a $whospeak, a `$who::0`, and a `$who's` variable. The last two would be the $0 and the $s variables in the (presumably) non-existent package `who`.

In fact, an identifier within such curlies is forced to be a string, as is any simple identifier within a hash subscript. Neither need quoting. Our earlier example, `$days{'Feb'}` can be written as `$days{Feb}` and the quotes will be assumed automatically. But anything more complicated in the subscript will be interpreted as an expression.

Version Strings

Note: Version Strings (v-strings) have been deprecated. They will not be available after Perl 5.8. The marginal benefits of v-strings were greatly outweighed by the potential for Surprise and Confusion.

A literal of the form `v1.20.300.4000` is parsed as a string composed of characters with the specified ordinals. This form, known as v-strings, provides an alternative, more readable way to construct strings, rather than use the somewhat less readable interpolation form `"\x{1}\x{14}\x{12c}\x{fa0}"`. This is useful for representing Unicode strings, and for comparing version "numbers" using the string comparison operators, `cmp`, `gt`, `lt` etc. If there are two or more dots in the literal, the leading `v` may be omitted.

```
    print v9786;              # prints UTF-8 encoded SMILEY, "\x{263a}"
    print v102.111.111;       # prints "foo"
    print 102.111.111;        # same
```

Such literals are accepted by both `require` and `use` for doing a version check. The `$^V` special variable also contains the running Perl interpreter's version in this form. See $^V in *perlvar*. Note that using the v-strings for IPv4 addresses is not portable unless you also use the inet_aton()/inet_ntoa() routines of the Socket package.

Note that since Perl 5.8.1 the single-number v-strings (like `v65`) are not v-strings before the => operator (which is usually used to separate a hash key from a hash value), instead they are interpreted as literal strings ('v65'). They were v-strings from Perl 5.6.0 to Perl 5.8.0, but that caused more confusion and breakage than good. Multi-number v-strings like `v65.66` and `65.66.67` continue to be v-strings always.

Special Literals

The special literals __FILE__, __LINE__, and __PACKAGE__ represent the current filename, line number, and package name at that point in your program. They may be used only as separate tokens; they will not be interpolated into strings. If there is no current package (due to an empty `package;` directive), __PACKAGE__ is the undefined value.

The two control characters ^D and ^Z, and the tokens __END__ and __DATA__ may be used to indicate the logical end of the script before the actual end of file. Any following text is ignored.

Text after __DATA__ but may be read via the filehandle `PACKNAME::DATA`, where `PACKNAME` is the package that was current when the __DATA__ token was encountered. The filehandle is left open pointing to the contents after __DATA__. It is the program's responsibility to `close DATA` when it is done reading from it. For compatibility with older scripts written before __DATA__ was introduced, __END__ behaves like __DATA__ in the toplevel script (but not in files loaded with `require` or `do`) and leaves the remaining contents of the file accessible via `main::DATA`.

See *SelfLoader* for more description of __DATA__, and an example of its use. Note that you cannot read from the DATA filehandle in a BEGIN block: the BEGIN block is executed as soon as it is seen (during compilation), at which point the corresponding __DATA__ (or __END__) token has not yet been seen.

Barewords

A word that has no other interpretation in the grammar will be treated as if it were a quoted string. These are known as "barewords". As with filehandles and labels, a bareword that consists entirely of lowercase letters risks conflict with future reserved words, and if you use the `use warnings` pragma or the **-w** switch, Perl will warn you about any such words. Some people may wish to outlaw barewords entirely. If you say

```
    use strict 'subs';
```

then any bareword that would NOT be interpreted as a subroutine call produces a compile-time error instead. The restriction lasts to the end of the enclosing block. An inner block may countermand this by saying `no strict 'subs'`.

Array Joining Delimiter

Arrays and slices are interpolated into double-quoted strings by joining the elements with the delimiter specified in the `$"` variable (`$LIST_SEPARATOR` if "use English;" is specified), space by default. The following are equivalent:

```
    $temp = join($", @ARGV);
    system "echo $temp";

    system "echo @ARGV";
```

Within search patterns (which also undergo double-quotish substitution) there is an unfortunate ambiguity: Is `/$foo[bar]/` to be interpreted as `/${foo}[bar]/` (where `[bar]` is a character class for the regular expression) or as `/${foo[bar]}/` (where `[bar]` is the subscript to array @foo)? If @foo doesn't otherwise exist, then it's obviously a character class. If @foo exists, Perl takes a good guess about `[bar]`, and is almost always right. If it does guess wrong, or if you're just plain paranoid, you can force the correct interpretation with curly braces as above.

If you're looking for the information on how to use here-documents, which used to be here, that's been moved to Quote and Quote-like Operators in *perlop*.

27.1.5 List value constructors

List values are denoted by separating individual values by commas (and enclosing the list in parentheses where precedence requires it):

```
    (LIST)
```

In a context not requiring a list value, the value of what appears to be a list literal is simply the value of the final element, as with the C comma operator. For example,

```
    @foo = ('cc', '-E', $bar);
```

assigns the entire list value to array @foo, but

```
    $foo = ('cc', '-E', $bar);
```

assigns the value of variable $bar to the scalar variable $foo. Note that the value of an actual array in scalar context is the length of the array; the following assigns the value 3 to $foo:

```
    @foo = ('cc', '-E', $bar);
    $foo = @foo;                # $foo gets 3
```

You may have an optional comma before the closing parenthesis of a list literal, so that you can say:

```
@foo = (
    1,
    2,
    3,
);
```

To use a here-document to assign an array, one line per element, you might use an approach like this:

```
@sauces = <<End_Lines =~ m/(\S.*\S)/g;
    normal tomato
    spicy tomato
    green chile
    pesto
    white wine
End_Lines
```

LISTs do automatic interpolation of sublists. That is, when a LIST is evaluated, each element of the list is evaluated in list context, and the resulting list value is interpolated into LIST just as if each individual element were a member of LIST. Thus arrays and hashes lose their identity in a LIST–the list

```
(@foo,@bar,&SomeSub,%glarch)
```

contains all the elements of @foo followed by all the elements of @bar, followed by all the elements returned by the subroutine named SomeSub called in list context, followed by the key/value pairs of %glarch. To make a list reference that does *NOT* interpolate, see *perlref*.

The null list is represented by (). Interpolating it in a list has no effect. Thus ((),(),()) is equivalent to (). Similarly, interpolating an array with no elements is the same as if no array had been interpolated at that point.

This interpolation combines with the facts that the opening and closing parentheses are optional (except when necessary for precedence) and lists may end with an optional comma to mean that multiple commas within lists are legal syntax. The list `1„3` is a concatenation of two lists, `1,` and `3`, the first of which ends with that optional comma. `1„3` is `(1,),(3)` is `1,3` (And similarly for `1„,3` is `(1,),(,),3` is `1,3` and so on.) Not that we'd advise you to use this obfuscation.

A list value may also be subscripted like a normal array. You must put the list in parentheses to avoid ambiguity. For example:

```
# Stat returns list value.
$time = (stat($file))[8];

# SYNTAX ERROR HERE.
$time = stat($file)[8];  # OOPS, FORGOT PARENTHESES

# Find a hex digit.
$hexdigit = ('a','b','c','d','e','f')[$digit-10];

# A "reverse comma operator".
return (pop(@foo),pop(@foo))[0];
```

Lists may be assigned to only when each element of the list is itself legal to assign to:

```
($a, $b, $c) = (1, 2, 3);

($map{'red'}, $map{'blue'}, $map{'green'}) = (0x00f, 0x0f0, 0xf00);
```

An exception to this is that you may assign to `undef` in a list. This is useful for throwing away some of the return values of a function:

```
    ($dev, $ino, undef, undef, $uid, $gid) = stat($file);
```

List assignment in scalar context returns the number of elements produced by the expression on the right side of the assignment:

```
    $x = (($foo,$bar) = (3,2,1));       # set $x to 3, not 2
    $x = (($foo,$bar) = f());           # set $x to f()'s return count
```

This is handy when you want to do a list assignment in a Boolean context, because most list functions return a null list when finished, which when assigned produces a 0, which is interpreted as FALSE.

It's also the source of a useful idiom for executing a function or performing an operation in list context and then counting the number of return values, by assigning to an empty list and then using that assignment in scalar context. For example, this code:

```
    $count = () = $string =~ /\d+/g;
```

will place into $count the number of digit groups found in $string. This happens because the pattern match is in list context (since it is being assigned to the empty list), and will therefore return a list of all matching parts of the string. The list assignment in scalar context will translate that into the number of elements (here, the number of times the pattern matched) and assign that to $count. Note that simply using

```
    $count = $string =~ /\d+/g;
```

would not have worked, since a pattern match in scalar context will only return true or false, rather than a count of matches.

The final element of a list assignment may be an array or a hash:

```
    ($a, $b, @rest) = split;
    my($a, $b, %rest) = @_;
```

You can actually put an array or hash anywhere in the list, but the first one in the list will soak up all the values, and anything after it will become undefined. This may be useful in a my() or local().

A hash can be initialized using a literal list holding pairs of items to be interpreted as a key and a value:

```
    # same as map assignment above
    %map = ('red',0x00f,'blue',0x0f0,'green',0xf00);
```

While literal lists and named arrays are often interchangeable, that's not the case for hashes. Just because you can subscript a list value like a normal array does not mean that you can subscript a list value as a hash. Likewise, hashes included as parts of other lists (including parameters lists and return lists from functions) always flatten out into key/value pairs. That's why it's good to use references sometimes.

It is often more readable to use the => operator between key/value pairs. The => operator is mostly just a more visually distinctive synonym for a comma, but it also arranges for its left-hand operand to be interpreted as a string – if it's a bareword that would be a legal simple identifier (=> doesn't quote compound identifiers, that contain double colons). This makes it nice for initializing hashes:

```
    %map = (
                 red   => 0x00f,
                 blue  => 0x0f0,
                 green => 0xf00,
   );
```

or for initializing hash references to be used as records:

```
    $rec = {
                witch => 'Mable the Merciless',
                cat   => 'Fluffy the Ferocious',
                date  => '10/31/1776',
    };
```

or for using call-by-named-parameter to complicated functions:

```
   $field = $query->radio_group(
               name      => 'group_name',
               values    => ['eenie','meenie','minie'],
               default   => 'meenie',
               linebreak => 'true',
               labels    => \%labels
   );
```

Note that just because a hash is initialized in that order doesn't mean that it comes out in that order. See sort in *perlfunc* for examples of how to arrange for an output ordering.

27.1.6 Subscripts

An array is subscripted by specifying a dollary sign ($), then the name of the array (without the leading @), then the subscript inside square brackets. For example:

```
    @myarray = (5, 50, 500, 5000);
    print "Element Number 2 is", $myarray[2], "\n";
```

The array indices start with 0. A negative subscript retrieves its value from the end. In our example, `$myarray[-1]` would have been 5000, and `$myarray[-2]` would have been 500.

Hash subscripts are similar, only instead of square brackets curly brackets are used. For example:

```
    %scientists =
    (
        "Newton" => "Isaac",
        "Einstein" => "Albert",
        "Darwin" => "Charles",
        "Feynman" => "Richard",
    );

    print "Darwin's First Name is ", $scientists{"Darwin"}, "\n";
```

27.1.7 Slices

A common way to access an array or a hash is one scalar element at a time. You can also subscript a list to get a single element from it.

```
    $whoami = $ENV{"USER"};             # one element from the hash
    $parent = $ISA[0];                  # one element from the array
    $dir    = (getpwnam("daemon"))[7];  # likewise, but with list
```

A slice accesses several elements of a list, an array, or a hash simultaneously using a list of subscripts. It's more convenient than writing out the individual elements as a list of separate scalar values.

```
    ($him, $her)   = @folks[0,-1];              # array slice
    @them          = @folks[0 .. 3];            # array slice
    ($who, $home)  = @ENV{"USER", "HOME"};      # hash slice
    ($uid, $dir)   = (getpwnam("daemon"))[2,7]; # list slice
```

Since you can assign to a list of variables, you can also assign to an array or hash slice.

```
    @days[3..5]    = qw/Wed Thu Fri/;
    @colors{'red','blue','green'}
                   = (0xff0000, 0x0000ff, 0x00ff00);
    @folks[0, -1]  = @folks[-1, 0];
```

The previous assignments are exactly equivalent to

```
    ($days[3], $days[4], $days[5]) = qw/Wed Thu Fri/;
    ($colors{'red'}, $colors{'blue'}, $colors{'green'})
                   = (0xff0000, 0x0000ff, 0x00ff00);
    ($folks[0], $folks[-1]) = ($folks[-1], $folks[0]);
```

Since changing a slice changes the original array or hash that it's slicing, a `foreach` construct will alter some–or even all–of the values of the array or hash.

```
    foreach (@array[ 4 .. 10 ]) { s/peter/paul/ }

    foreach (@hash{qw[key1 key2]}) {
        s/^\s+//;           # trim leading whitespace
        s/\s+$//;           # trim trailing whitespace
        s/(\w+)/\u\L$1/g;   # "titlecase" words
    }
```

A slice of an empty list is still an empty list. Thus:

```
    @a = ()[1,0];           # @a has no elements
    @b = (@a)[0,1];         # @b has no elements
    @c = (0,1)[2,3];        # @c has no elements
```

But:

```
    @a = (1)[1,0];          # @a has two elements
    @b = (1,undef)[1,0,2];  # @b has three elements
```

This makes it easy to write loops that terminate when a null list is returned:

```
    while ( ($home, $user) = (getpwent)[7,0]) {
        printf "%-8s %s\n", $user, $home;
    }
```

As noted earlier in this document, the scalar sense of list assignment is the number of elements on the right-hand side of the assignment. The null list contains no elements, so when the password file is exhausted, the result is 0, not 2.

If you're confused about why you use an '@' there on a hash slice instead of a '%', think of it like this. The type of bracket (square or curly) governs whether it's an array or a hash being looked at. On the other hand, the leading symbol ('$' or '@') on the array or hash indicates whether you are getting back a singular value (a scalar) or a plural one (a list).

27.1.8 Typeglobs and Filehandles

Perl uses an internal type called a *typeglob* to hold an entire symbol table entry. The type prefix of a typeglob is a *, because it represents all types. This used to be the preferred way to pass arrays and hashes by reference into a function, but now that we have real references, this is seldom needed.

The main use of typeglobs in modern Perl is create symbol table aliases. This assignment:

```
*this = *that;
```

makes $this an alias for $that, @this an alias for @that, %this an alias for %that, &this an alias for &that, etc. Much safer is to use a reference. This:

```
local *Here::blue = \$There::green;
```

temporarily makes $Here::blue an alias for $There::green, but doesn't make @Here::blue an alias for @There::green, or %Here::blue an alias for %There::green, etc. See Symbol Tables in *perlmod* for more examples of this. Strange though this may seem, this is the basis for the whole module import/export system.

Another use for typeglobs is to pass filehandles into a function or to create new filehandles. If you need to use a typeglob to save away a filehandle, do it this way:

```
$fh = *STDOUT;
```

or perhaps as a real reference, like this:

```
$fh = \*STDOUT;
```

See *perlsub* for examples of using these as indirect filehandles in functions.

Typeglobs are also a way to create a local filehandle using the local() operator. These last until their block is exited, but may be passed back. For example:

```
sub newopen {
    my $path = shift;
    local  *FH;  # not my!
    open   (FH, $path)          or  return undef;
    return *FH;
}
$fh = newopen('/etc/passwd');
```

Now that we have the `*foo{THING}` notation, typeglobs aren't used as much for filehandle manipulations, although they're still needed to pass brand new file and directory handles into or out of functions. That's because `*HANDLE{IO}` only works if HANDLE has already been used as a handle. In other words, `*FH` must be used to create new symbol table entries; `*foo{THING}` cannot. When in doubt, use `*FH`.

All functions that are capable of creating filehandles (open(), opendir(), pipe(), socketpair(), sysopen(), socket(), and accept()) automatically create an anonymous filehandle if the handle passed to them is an uninitialized scalar variable. This allows the constructs such as `open(my $fh, ...)` and `open(local $fh,...)` to be used to create filehandles that will conveniently be closed automatically when the scope ends, provided there are no other references to them. This largely eliminates the need for typeglobs when opening filehandles that must be passed around, as in the following example:

```
sub myopen {
    open my $fh, "@_"
         or die "Can't open '@_': $!";
    return $fh;
}
```

```
    {
        my $f = myopen("</etc/motd");
        print <$f>;
        # $f implicitly closed here
    }
```

Note that if an initialized scalar variable is used instead the result is different: `my $fh='zzz'; open($fh, ...)` is equivalent to `open( *{'zzz'}, ...)`. `use strict 'refs'` forbids such practice.

Another way to create anonymous filehandles is with the Symbol module or with the IO::Handle module and its ilk. These modules have the advantage of not hiding different types of the same name during the local(). See the bottom of open() in *perlfunc* for an example.

27.2 SEE ALSO

See *perlvar* for a description of Perl's built-in variables and a discussion of legal variable names. See *perlref*, *perlsub*, and Symbol Tables in *perlmod* for more discussion on typeglobs and the `*foo{THING}` syntax.

Chapter 28

perlop

Perl operators and precedence

28.1 DESCRIPTION

28.1.1 Operator Precedence and Associativity

Operator precedence and associativity work in Perl more or less like they do in mathematics.

Operator precedence means some operators are evaluated before others. For example, in `2 + 4 * 5`, the multiplication has higher precedence so `4 * 5` is evaluated first yielding `2 + 20 == 22` and not `6 * 5 == 30`.

Operator associativity defines what happens if a sequence of the same operators is used one after another: whether the evaluator will evaluate the left operations first or the right. For example, in `8 - 4 - 2`, subtraction is left associative so Perl evaluates the expression left to right. `8 - 4` is evaluated first making the expression `4 - 2 == 2` and not `8 - 2 == 6`.

Perl operators have the following associativity and precedence, listed from highest precedence to lowest. Operators borrowed from C keep the same precedence relationship with each other, even where C's precedence is slightly screwy. (This makes learning Perl easier for C folks.) With very few exceptions, these all operate on scalar values only, not array values.

```
    left        terms and list operators (leftward)
    left        ->
    nonassoc    ++ --
    right       **
    right       ! ~ \ and unary + and -
    left        =~ !~
    left        * / % x
    left        + - .
    left        << >>
    nonassoc    named unary operators
    nonassoc    < > <= >= lt gt le ge
    nonassoc    == != <=> eq ne cmp
    left        &
    left        | ^
    left        &&
    left        ||
    nonassoc    ..  ...
    right       ?:
    right       = += -= *= etc.
    left        , =>
    nonassoc    list operators (rightward)
    right       not
    left        and
    left        or xor
```

In the following sections, these operators are covered in precedence order.

Many operators can be overloaded for objects. See *overload*.

28.1.2 Terms and List Operators (Leftward)

A TERM has the highest precedence in Perl. They include variables, quote and quote-like operators, any expression in parentheses, and any function whose arguments are parenthesized. Actually, there aren't really functions in this sense, just list operators and unary operators behaving as functions because you put parentheses around the arguments. These are all documented in *perlfunc*.

If any list operator (print(), etc.) or any unary operator (chdir(), etc.) is followed by a left parenthesis as the next token, the operator and arguments within parentheses are taken to be of highest precedence, just like a normal function call.

In the absence of parentheses, the precedence of list operators such as `print`, `sort`, or `chmod` is either very high or very low depending on whether you are looking at the left side or the right side of the operator. For example, in

```
    @ary = (1, 3, sort 4, 2);
    print @ary;         # prints 1324
```

the commas on the right of the sort are evaluated before the sort, but the commas on the left are evaluated after. In other words, list operators tend to gobble up all arguments that follow, and then act like a simple TERM with regard to the preceding expression. Be careful with parentheses:

```
    # These evaluate exit before doing the print:
    print($foo, exit);  # Obviously not what you want.
    print $foo, exit;   # Nor is this.

    # These do the print before evaluating exit:
    (print $foo), exit; # This is what you want.
    print($foo), exit;  # Or this.
    print ($foo), exit; # Or even this.
```

Also note that

```
    print ($foo & 255) + 1, "\n";
```

probably doesn't do what you expect at first glance. The parentheses enclose the argument list for `print` which is evaluated (printing the result of `$foo & 255`). Then one is added to the return value of `print` (usually 1). The result is something like this:

```
    1 + 1, "\n";    # Obviously not what you meant.
```

To do what you meant properly, you must write:

```
    print(($foo & 255) + 1, "\n");
```

See Named Unary Operators for more discussion of this.

Also parsed as terms are the `do {}` and `eval {}` constructs, as well as subroutine and method calls, and the anonymous constructors `[]` and `{}`.

See also Quote and Quote-like Operators toward the end of this section, as well as §28.1.30.

28.1.3 The Arrow Operator

"->" is an infix dereference operator, just as it is in C and C++. If the right side is either a `[...]`, `{...}`, or a `(...)` subscript, then the left side must be either a hard or symbolic reference to an array, a hash, or a subroutine respectively. (Or technically speaking, a location capable of holding a hard reference, if it's an array or hash reference being used for assignment.) See *perlreftut* and *perlref*.

Otherwise, the right side is a method name or a simple scalar variable containing either the method name or a subroutine reference, and the left side must be either an object (a blessed reference) or a class name (that is, a package name). See *perlobj*.

28.1.4 Auto-increment and Auto-decrement

"++" and "–" work as in C. That is, if placed before a variable, they increment or decrement the variable by one before returning the value, and if placed after, increment or decrement after returning the value.

```
    $i = 0;  $j = 0;
    print $i++;  # prints 0
    print ++$j;  # prints 1
```

Note that just as in C, Perl doesn't define **when** the variable is incremented or decremented. You just know it will be done sometime before or after the value is returned. This also means that modifying a variable twice in the same statement will lead to undefined behaviour. Avoid statements like:

```
    $i = $i ++;
    print ++ $i + $i ++;
```

Perl will not guarantee what the result of the above statements is.

The auto-increment operator has a little extra builtin magic to it. If you increment a variable that is numeric, or that has ever been used in a numeric context, you get a normal increment. If, however, the variable has been used in only string contexts since it was set, and has a value that is not the empty string and matches the pattern `/^[a-zA-Z]*[0-9]*\z/`, the increment is done as a string, preserving each character within its range, with carry:

```
    print ++($foo = '99');      # prints '100'
    print ++($foo = 'a0');      # prints 'a1'
    print ++($foo = 'Az');      # prints 'Ba'
    print ++($foo = 'zz');      # prints 'aaa'
```

`undef` is always treated as numeric, and in particular is changed to `0` before incrementing (so that a post-increment of an undef value will return `0` rather than `undef`).

The auto-decrement operator is not magical.

28.1.5 Exponentiation

Binary "**" is the exponentiation operator. It binds even more tightly than unary minus, so -2**4 is -(2**4), not (-2)**4. (This is implemented using C's pow(3) function, which actually works on doubles internally.)

28.1.6 Symbolic Unary Operators

Unary "!" performs logical negation, i.e., "not". See also `not` for a lower precedence version of this.

Unary "-" performs arithmetic negation if the operand is numeric. If the operand is an identifier, a string consisting of a minus sign concatenated with the identifier is returned. Otherwise, if the string starts with a plus or minus, a string starting with the opposite sign is returned. One effect of these rules is that `-bareword` is equivalent to `"-bareword"`.

Unary "˜" performs bitwise negation, i.e., 1's complement. For example, `0666 & ˜027` is 0640. (See also Integer Arithmetic and Bitwise String Operators.) Note that the width of the result is platform-dependent: ˜0 is 32 bits wide on a 32-bit platform, but 64 bits wide on a 64-bit platform, so if you are expecting a certain bit width, remember to use the & operator to mask off the excess bits.

Unary "+" has no effect whatsoever, even on strings. It is useful syntactically for separating a function name from a parenthesized expression that would otherwise be interpreted as the complete list of function arguments. (See examples above under Terms and List Operators (Leftward).)

Unary "\" creates a reference to whatever follows it. See *perlreftut* and *perlref*. Do not confuse this behavior with the behavior of backslash within a string, although both forms do convey the notion of protecting the next thing from interpolation.

28.1.7 Binding Operators

Binary "=˜" binds a scalar expression to a pattern match. Certain operations search or modify the string $_ by default. This operator makes that kind of operation work on some other string. The right argument is a search pattern, substitution, or transliteration. The left argument is what is supposed to be searched, substituted, or transliterated instead of the default $_. When used in scalar context, the return value generally indicates the success of the operation. Behavior in list context depends on the particular operator. See §28.1.28 for details.

If the right argument is an expression rather than a search pattern, substitution, or transliteration, it is interpreted as a search pattern at run time.

Binary "!˜" is just like "=˜" except the return value is negated in the logical sense.

28.1.8 Multiplicative Operators

Binary "*" multiplies two numbers.

Binary "/" divides two numbers.

Binary "%" computes the modulus of two numbers. Given integer operands `$a` and `$b`: If `$b` is positive, then `$a % $b` is `$a` minus the largest multiple of `$b` that is not greater than `$a`. If `$b` is negative, then `$a % $b` is `$a` minus the smallest multiple of `$b` that is not less than `$a` (i.e. the result will be less than or equal to zero). Note that when `use integer` is in scope, "%" gives you direct access to the modulus operator as implemented by your C compiler. This operator is not as well defined for negative operands, but it will execute faster.

Binary "x" is the repetition operator. In scalar context or if the left operand is not enclosed in parentheses, it returns a string consisting of the left operand repeated the number of times specified by the right operand. In list context, if the left operand is enclosed in parentheses, it repeats the list. If the right operand is zero or negative, it returns an empty string or an empty list, depending on the context.

```
    print '-' x 80;             # print row of dashes

    print "\t" x ($tab/8), ' ' x ($tab%8);      # tab over

    @ones = (1) x 80;           # a list of 80 1's
    @ones = (5) x @ones;        # set all elements to 5
```

28.1.9 Additive Operators

Binary "+" returns the sum of two numbers.

Binary "-" returns the difference of two numbers.

Binary "." concatenates two strings.

28.1.10 Shift Operators

Binary "<<" returns the value of its left argument shifted left by the number of bits specified by the right argument. Arguments should be integers. (See also Integer Arithmetic.)

Binary ">>" returns the value of its left argument shifted right by the number of bits specified by the right argument. Arguments should be integers. (See also Integer Arithmetic.)

Note that both "<<" and ">>" in Perl are implemented directly using "<<" and ">>" in C. If `use integer` (see Integer Arithmetic) is in force then signed C integers are used, else unsigned C integers are used. Either way, the implementation isn't going to generate results larger than the size of the integer type Perl was built with (32 bits or 64 bits).

The result of overflowing the range of the integers is undefined because it is undefined also in C. In other words, using 32-bit integers, `1 << 32` is undefined. Shifting by a negative number of bits is also undefined.

28.1.11 Named Unary Operators

The various named unary operators are treated as functions with one argument, with optional parentheses.

If any list operator (print(), etc.) or any unary operator (chdir(), etc.) is followed by a left parenthesis as the next token, the operator and arguments within parentheses are taken to be of highest precedence, just like a normal function call. For example, because named unary operators are higher precedence than ||:

```
    chdir $foo    || die;       # (chdir $foo) || die
    chdir($foo)   || die;       # (chdir $foo) || die
    chdir ($foo)  || die;       # (chdir $foo) || die
    chdir +($foo) || die;       # (chdir $foo) || die
```

but, because * is higher precedence than named operators:

```
    chdir $foo * 20;    # chdir ($foo * 20)
    chdir($foo) * 20;   # (chdir $foo) * 20
    chdir ($foo) * 20;  # (chdir $foo) * 20
    chdir +($foo) * 20; # chdir ($foo * 20)

    rand 10 * 20;       # rand (10 * 20)
    rand(10) * 20;      # (rand 10) * 20
    rand (10) * 20;     # (rand 10) * 20
    rand +(10) * 20;    # rand (10 * 20)
```

Regarding precedence, the filetest operators, like `-f`, `-M`, etc. are treated like named unary operators, but they don't follow this functional parenthesis rule. That means, for example, that `-f($file).".bak"` is equivalent to `-f "$file.bak"`.

See also §28.1.2.

28.1.12 Relational Operators

Binary "<" returns true if the left argument is numerically less than the right argument.

Binary ">" returns true if the left argument is numerically greater than the right argument.

Binary "<=" returns true if the left argument is numerically less than or equal to the right argument.

Binary ">=" returns true if the left argument is numerically greater than or equal to the right argument.

Binary "lt" returns true if the left argument is stringwise less than the right argument.

Binary "gt" returns true if the left argument is stringwise greater than the right argument.

Binary "le" returns true if the left argument is stringwise less than or equal to the right argument.

Binary "ge" returns true if the left argument is stringwise greater than or equal to the right argument.

28.1.13 Equality Operators

Binary "==" returns true if the left argument is numerically equal to the right argument.

Binary "!=" returns true if the left argument is numerically not equal to the right argument.

Binary "<=>" returns -1, 0, or 1 depending on whether the left argument is numerically less than, equal to, or greater than the right argument. If your platform supports NaNs (not-a-numbers) as numeric values, using them with "<=>" returns undef. NaN is not "<", "==", ">", "<=" or ">=" anything (even NaN), so those 5 return false. NaN != NaN returns true, as does NaN != anything else. If your platform doesn't support NaNs then NaN is just a string with numeric value 0.

```
    perl -le '$a = NaN; print "No NaN support here" if $a == $a'
    perl -le '$a = NaN; print "NaN support here" if $a != $a'
```

Binary "eq" returns true if the left argument is stringwise equal to the right argument.

Binary "ne" returns true if the left argument is stringwise not equal to the right argument.

Binary "cmp" returns -1, 0, or 1 depending on whether the left argument is stringwise less than, equal to, or greater than the right argument.

"lt", "le", "ge", "gt" and "cmp" use the collation (sort) order specified by the current locale if `use locale` is in effect. See *perllocale*.

28.1.14 Bitwise And

Binary "&" returns its operands ANDed together bit by bit. (See also Integer Arithmetic and Bitwise String Operators.)

Note that "&" has lower priority than relational operators, so for example the brackets are essential in a test like

```
        print "Even\n" if ($x & 1) == 0;
```

28.1.15 Bitwise Or and Exclusive Or

Binary "|" returns its operands ORed together bit by bit. (See also Integer Arithmetic and Bitwise String Operators.)

Binary "^" returns its operands XORed together bit by bit. (See also Integer Arithmetic and Bitwise String Operators.)

Note that "|" and "^" have lower priority than relational operators, so for example the brackets are essential in a test like

```
        print "false\n" if (8 | 2) != 10;
```

28.1.16 C-style Logical And

Binary "&&" performs a short-circuit logical AND operation. That is, if the left operand is false, the right operand is not even evaluated. Scalar or list context propagates down to the right operand if it is evaluated.

28.1.17 C-style Logical Or

Binary "||" performs a short-circuit logical OR operation. That is, if the left operand is true, the right operand is not even evaluated. Scalar or list context propagates down to the right operand if it is evaluated.

The || and && operators return the last value evaluated (unlike C's || and &&, which return 0 or 1). Thus, a reasonably portable way to find out the home directory might be:

```
    $home = $ENV{'HOME'} || $ENV{'LOGDIR'} ||
        (getpwuid($<))[7] || die "You're homeless!\n";
```

In particular, this means that you shouldn't use this for selecting between two aggregates for assignment:

```
    @a = @b || @c;              # this is wrong
    @a = scalar(@b) || @c;      # really meant this
    @a = @b ? @b : @c;          # this works fine, though
```

As more readable alternatives to `&&` and `||` when used for control flow, Perl provides `and` and `or` operators (see below). The short-circuit behavior is identical. The precedence of "and" and "or" is much lower, however, so that you can safely use them after a list operator without the need for parentheses:

```
    unlink "alpha", "beta", "gamma"
            or gripe(), next LINE;
```

With the C-style operators that would have been written like this:

```
    unlink("alpha", "beta", "gamma")
            || (gripe(), next LINE);
```

Using "or" for assignment is unlikely to do what you want; see below.

28.1.18 Range Operators

Binary ".." is the range operator, which is really two different operators depending on the context. In list context, it returns a list of values counting (up by ones) from the left value to the right value. If the left value is greater than the right value then it returns the empty list. The range operator is useful for writing `foreach (1..10)` loops and for doing slice operations on arrays. In the current implementation, no temporary array is created when the range operator is used as the expression in `foreach` loops, but older versions of Perl might burn a lot of memory when you write something like this:

```
    for (1 .. 1_000_000) {
        # code
    }
```

The range operator also works on strings, using the magical auto-increment, see below.

In scalar context, ".." returns a boolean value. The operator is bistable, like a flip-flop, and emulates the line-range (comma) operator of **sed**, **awk**, and various editors. Each ".." operator maintains its own boolean state. It is false as long as its left operand is false. Once the left operand is true, the range operator stays true until the right operand is true, *AFTER* which the range operator becomes false again. It doesn't become false till the next time the range operator is evaluated. It can test the right operand and become false on the same evaluation it became true (as in **awk**), but it still returns true once. If you don't want it to test the right operand till the next evaluation, as in **sed**, just use three dots ("...") instead of two. In all other regards, "..." behaves just like ".." does.

The right operand is not evaluated while the operator is in the "false" state, and the left operand is not evaluated while the operator is in the "true" state. The precedence is a little lower than || and &&. The value returned is either the empty string for false, or a sequence number (beginning with 1) for true. The sequence number is reset for each range encountered. The final sequence number in a range has the string "E0" appended to it, which doesn't affect its numeric value, but gives you something to search for if you want to exclude the endpoint. You can exclude the beginning point by waiting for the sequence number to be greater than 1.

If either operand of scalar ".." is a constant expression, that operand is considered true if it is equal (==) to the current input line number (the `$.` variable).

To be pedantic, the comparison is actually `int(EXPR) == int(EXPR)`, but that is only an issue if you use a floating point expression; when implicitly using `$.` as described in the previous paragraph, the comparison is `int(EXPR) == int($.)` which is only an issue when `$.` is set to a floating point value and you are not reading from a file. Furthermore, `"span" .. "spat"` or `2.18 .. 3.14` will not do what you want in scalar context because each of the operands are evaluated using their integer representation.

Examples:

As a scalar operator:

```
    if (101 .. 200) { print; } # print 2nd hundred lines, short for
                               #   if ($. == 101 .. $. == 200) ...
    next line if (1 .. /^$/);  # skip header lines, short for
                               #   ... if ($. == 1 .. /^$/);
    s/^/> / if (/^$/ .. eof()); # quote body

    # parse mail messages
    while (<>) {
        $in_header =   1  .. /^$/;
        $in_body   = /^$/ .. eof;
        if ($in_header) {
            # ...
        } else { # in body
            # ...
        }
    } continue {
        close ARGV if eof;             # reset $. each file
    }
```

Here's a simple example to illustrate the difference between the two range operators:

```
    @lines = ("   - Foo",
              "01 - Bar",
              "1  - Baz",
              "   - Quux");

    foreach(@lines)
    {
        if (/0/ .. /1/)
        {
            print "$_\n";
        }
    }
```

This program will print only the line containing "Bar". If the range operator is changed to `...`, it will also print the "Baz" line.
And now some examples as a list operator:

```
    for (101 .. 200) { print; } # print $_ 100 times
    @foo = @foo[0 .. $#foo];    # an expensive no-op
    @foo = @foo[$#foo-4 .. $#foo];      # slice last 5 items
```

The range operator (in list context) makes use of the magical auto-increment algorithm if the operands are strings. You can say

```
    @alphabet = ('A' .. 'Z');
```

to get all normal letters of the English alphabet, or

```
    $hexdigit = (0 .. 9, 'a' .. 'f')[$num & 15];
```

to get a hexadecimal digit, or

```
    @z2 = ('01' .. '31');  print $z2[$mday];
```

to get dates with leading zeros. If the final value specified is not in the sequence that the magical increment would produce, the sequence goes until the next value would be longer than the final value specified.
Because each operand is evaluated in integer form, `2.18 ..  3.14` will return two elements in list context.

```
    @list = (2.18 .. 3.14); # same as @list = (2 .. 3);
```

28.1.19 Conditional Operator

Ternary "?:" is the conditional operator, just as in C. It works much like an if-then-else. If the argument before the ? is true, the argument before the : is returned, otherwise the argument after the : is returned. For example:

```
    printf "I have %d dog%s.\n", $n,
            ($n == 1) ? '' : "s";
```

Scalar or list context propagates downward into the 2nd or 3rd argument, whichever is selected.

```
    $a = $ok ? $b : $c;  # get a scalar
    @a = $ok ? @b : @c;  # get an array
    $a = $ok ? @b : @c;  # oops, that's just a count!
```

The operator may be assigned to if both the 2nd and 3rd arguments are legal lvalues (meaning that you can assign to them):

```
    ($a_or_b ? $a : $b) = $c;
```

Because this operator produces an assignable result, using assignments without parentheses will get you in trouble. For example, this:

```
    $a % 2 ? $a += 10 : $a += 2
```

Really means this:

```
    (($a % 2) ? ($a += 10) : $a) += 2
```

Rather than this:

```
    ($a % 2) ? ($a += 10) : ($a += 2)
```

That should probably be written more simply as:

```
    $a += ($a % 2) ? 10 : 2;
```

28.1.20 Assignment Operators

"=" is the ordinary assignment operator.

Assignment operators work as in C. That is,

```
    $a += 2;
```

is equivalent to

```
    $a = $a + 2;
```

although without duplicating any side effects that dereferencing the lvalue might trigger, such as from tie(). Other assignment operators work similarly. The following are recognized:

```
    **=    +=    *=    &=    <<=    &&=
           -=    /=    |=    >>=    ||=
           .=    %=    ^=
                 x=
```

Although these are grouped by family, they all have the precedence of assignment.

Unlike in C, the scalar assignment operator produces a valid lvalue. Modifying an assignment is equivalent to doing the assignment and then modifying the variable that was assigned to. This is useful for modifying a copy of something, like this:

```
    ($tmp = $global) =~ tr [A-Z] [a-z];
```

Likewise,

```
    ($a += 2) *= 3;
```

is equivalent to

```
    $a += 2;
    $a *= 3;
```

Similarly, a list assignment in list context produces the list of lvalues assigned to, and a list assignment in scalar context returns the number of elements produced by the expression on the right hand side of the assignment.

28.1.21 Comma Operator

Binary "," is the comma operator. In scalar context it evaluates its left argument, throws that value away, then evaluates its right argument and returns that value. This is just like C's comma operator.

In list context, it's just the list argument separator, and inserts both its arguments into the list.

The => operator is a synonym for the comma, but forces any word to its left to be interpreted as a string (as of 5.001). It is helpful in documenting the correspondence between keys and values in hashes, and other paired elements in lists.

28.1.22 List Operators (Rightward)

On the right side of a list operator, it has very low precedence, such that it controls all comma-separated expressions found there. The only operators with lower precedence are the logical operators "and", "or", and "not", which may be used to evaluate calls to list operators without the need for extra parentheses:

```
    open HANDLE, "filename"
        or die "Can't open: $!\n";
```

See also discussion of list operators in Terms and List Operators (Leftward).

28.1.23 Logical Not

Unary "not" returns the logical negation of the expression to its right. It's the equivalent of "!" except for the very low precedence.

28.1.24 Logical And

Binary "and" returns the logical conjunction of the two surrounding expressions. It's equivalent to && except for the very low precedence. This means that it short-circuits: i.e., the right expression is evaluated only if the left expression is true.

28.1.25 Logical or and Exclusive Or

Binary "or" returns the logical disjunction of the two surrounding expressions. It’s equivalent to || except for the very low precedence. This makes it useful for control flow

```
    print FH $data              or die "Can’t write to FH: $!";
```

This means that it short-circuits: i.e., the right expression is evaluated only if the left expression is false. Due to its precedence, you should probably avoid using this for assignment, only for control flow.

```
    $a = $b or $c;              # bug: this is wrong
    ($a = $b) or $c;            # really means this
    $a = $b || $c;              # better written this way
```

However, when it’s a list-context assignment and you’re trying to use "||" for control flow, you probably need "or" so that the assignment takes higher precedence.

```
    @info = stat($file) || die;     # oops, scalar sense of stat!
    @info = stat($file) or die;     # better, now @info gets its due
```

Then again, you could always use parentheses.

Binary "xor" returns the exclusive-OR of the two surrounding expressions. It cannot short circuit, of course.

28.1.26 C Operators Missing From Perl

Here is what C has that Perl doesn’t:

unary &

Address-of operator. (But see the "\" operator for taking a reference.)

unary *

Dereference-address operator. (Perl’s prefix dereferencing operators are typed: $, @, %, and &.)

(TYPE)

Type-casting operator.

28.1.27 Quote and Quote-like Operators

While we usually think of quotes as literal values, in Perl they function as operators, providing various kinds of interpolating and pattern matching capabilities. Perl provides customary quote characters for these behaviors, but also provides a way for you to choose your quote character for any of them. In the following table, a {} represents any pair of delimiters you choose.

Customary	Generic	Meaning	Interpolates
’’	q{}	Literal	no
""	qq{}	Literal	yes
‘‘	qx{}	Command	yes*
	qw{}	Word list	no
//	m{}	Pattern match	yes*
	qr{}	Pattern	yes*
	s{}{}	Substitution	yes*
	tr{}{}	Transliteration	no (but see below)
<<EOF		here-doc	yes*

```
        * unless the delimiter is ''.
```

Non-bracketing delimiters use the same character fore and aft, but the four sorts of brackets (round, angle, square, curly) will all nest, which means that

```
        q{foo{bar}baz}
```

is the same as

```
        'foo{bar}baz'
```

Note, however, that this does not always work for quoting Perl code:

```
        $s = q{ if($a eq "}") ... }; # WRONG
```

is a syntax error. The `Text::Balanced` module (from CPAN, and starting from Perl 5.8 part of the standard distribution) is able to do this properly.

There can be whitespace between the operator and the quoting characters, except when `#` is being used as the quoting character. `q#foo#` is parsed as the string `foo`, while `q #foo#` is the operator `q` followed by a comment. Its argument will be taken from the next line. This allows you to write:

```
    s {foo}  # Replace foo
      {bar}  # with bar.
```

The following escape sequences are available in constructs that interpolate and in transliterations.

```
    \t          tab             (HT, TAB)
    \n          newline         (NL)
    \r          return          (CR)
    \f          form feed       (FF)
    \b          backspace       (BS)
    \a          alarm (bell)    (BEL)
    \e          escape          (ESC)
    \033        octal char      (ESC)
    \x1b        hex char        (ESC)
    \x{263a}    wide hex char   (SMILEY)
    \c[         control char    (ESC)
    \N{name}    named Unicode character
```

NOTE: Unlike C and other languages, Perl has no \v escape sequence for the vertical tab (VT - ASCII 11).

The following escape sequences are available in constructs that interpolate but not in transliterations.

```
    \l          lowercase next char
    \u          uppercase next char
    \L          lowercase till \E
    \U          uppercase till \E
    \E          end case modification
    \Q          quote non-word characters till \E
```

If `use locale` is in effect, the case map used by `\l`, `\L`, `\u` and `\U` is taken from the current locale. See *perllocale*. If Unicode (for example, `\N{}` or wide hex characters of 0x100 or beyond) is being used, the case map used by `\l`, `\L`, `\u` and `\U` is as defined by Unicode. For documentation of `\N{name}`, see *charnames*.

All systems use the virtual "`\n`" to represent a line terminator, called a "newline". There is no such thing as an unvarying, physical newline character. It is only an illusion that the operating system, device drivers, C libraries, and Perl all conspire to preserve. Not all systems read `"\r"` as ASCII CR and `"\n"` as ASCII LF. For example, on a Mac, these are reversed, and on systems without line terminator, printing `"\n"` may emit no actual data. In general, use `"\n"` when you mean a "newline" for your system, but use the literal ASCII when you need an exact character. For example, most networking protocols expect and prefer a CR+LF (`"\015\012"` or `"\cM\cJ"`) for line terminators, and although they often accept just `"\012"`, they seldom tolerate just `"\015"`. If you get in the habit of using `"\n"` for networking, you may be burned some day.

For constructs that do interpolate, variables beginning with "`$`" or "`@`" are interpolated. Subscripted variables such as `$a[3]` or `$href->{key}[0]` are also interpolated, as are array and hash slices. But method calls such as `$obj->meth` are not.

Interpolating an array or slice interpolates the elements in order, separated by the value of `$"`, so is equivalent to interpolating `join $", @array`. "Punctuation" arrays such as `@+` are only interpolated if the name is enclosed in braces `@{+}`.

You cannot include a literal `$` or `@` within a `\Q` sequence. An unescaped `$` or `@` interpolates the corresponding variable, while escaping will cause the literal string `\$` to be inserted. You'll need to write something like `m/\Quser\E\@\Qhost/`.

Patterns are subject to an additional level of interpretation as a regular expression. This is done as a second pass, after variables are interpolated, so that regular expressions may be incorporated into the pattern from the variables. If this is not what you want, use `\Q` to interpolate a variable literally.

Apart from the behavior described above, Perl does not expand multiple levels of interpolation. In particular, contrary to the expectations of shell programmers, back-quotes do *NOT* interpolate within double quotes, nor do single quotes impede evaluation of variables when used within double quotes.

28.1.28 Regexp Quote-Like Operators

Here are the quote-like operators that apply to pattern matching and related activities.

?PATTERN?

This is just like the `/pattern/` search, except that it matches only once between calls to the reset() operator. This is a useful optimization when you want to see only the first occurrence of something in each file of a set of files, for instance. Only `??` patterns local to the current package are reset.

```
while (<>) {
    if (?^$?) {
                        # blank line between header and body
    }
} continue {
    reset if eof;       # clear ?? status for next file
}
```

This usage is vaguely deprecated, which means it just might possibly be removed in some distant future version of Perl, perhaps somewhere around the year 2168.

m/PATTERN/cgimosx

/PATTERN/cgimosx

Searches a string for a pattern match, and in scalar context returns true if it succeeds, false if it fails. If no string is specified via the `=~` or `!~` operator, the `$_` string is searched. (The string specified with `=~` need not be an lvalue–it may be the result of an expression evaluation, but remember the `=~` binds rather tightly.) See also *perlre*. See *perllocale* for discussion of additional considerations that apply when `use locale` is in effect.

Options are:

```
c   Do not reset search position on a failed match when /g is in effect.
g   Match globally, i.e., find all occurrences.
i   Do case-insensitive pattern matching.
```

```
    m   Treat string as multiple lines.
    o   Compile pattern only once.
    s   Treat string as single line.
    x   Use extended regular expressions.
```

If "/" is the delimiter then the initial `m` is optional. With the `m` you can use any pair of non-alphanumeric, non-whitespace characters as delimiters. This is particularly useful for matching path names that contain "/", to avoid LTS (leaning toothpick syndrome). If "?" is the delimiter, then the match-only-once rule of `?PATTERN?` applies. If "'" is the delimiter, no interpolation is performed on the PATTERN.

PATTERN may contain variables, which will be interpolated (and the pattern recompiled) every time the pattern search is evaluated, except for when the delimiter is a single quote. (Note that `$(`, `$)`, and `$|` are not interpolated because they look like end-of-string tests.) If you want such a pattern to be compiled only once, add a `/o` after the trailing delimiter. This avoids expensive run-time recompilations, and is useful when the value you are interpolating won't change over the life of the script. However, mentioning `/o` constitutes a promise that you won't change the variables in the pattern. If you change them, Perl won't even notice. See also §**??**.

If the PATTERN evaluates to the empty string, the last *successfully* matched regular expression is used instead. In this case, only the `g` and `c` flags on the empty pattern is honoured - the other flags are taken from the original pattern. If no match has previously succeeded, this will (silently) act instead as a genuine empty pattern (which will always match).

If the `/g` option is not used, `m//` in list context returns a list consisting of the subexpressions matched by the parentheses in the pattern, i.e., (`$1`, `$2`, `$3`...). (Note that here `$1` etc. are also set, and that this differs from Perl 4's behavior.) When there are no parentheses in the pattern, the return value is the list `(1)` for success. With or without parentheses, an empty list is returned upon failure.

Examples:

```
    open(TTY, '/dev/tty');
    <TTY> =~ /^y/i && foo();    # do foo if desired

    if (/Version: *([0-9.]*)/) { $version = $1; }

    next if m#^/usr/spool/uucp#;

    # poor man's grep
    $arg = shift;
    while (<>) {
        print if /$arg/o;       # compile only once
    }

    if (($F1, $F2, $Etc) = ($foo =~ /^(\S+)\s+(\S+)\s*(.*)/))
```

This last example splits $foo into the first two words and the remainder of the line, and assigns those three fields to $F1, $F2, and $Etc. The conditional is true if any variables were assigned, i.e., if the pattern matched.

The `/g` modifier specifies global pattern matching–that is, matching as many times as possible within the string. How it behaves depends on the context. In list context, it returns a list of the substrings matched by any capturing parentheses in the regular expression. If there are no parentheses, it returns a list of all the matched strings, as if there were parentheses around the whole pattern.

In scalar context, each execution of `m//g` finds the next match, returning true if it matches, and false if there is no further match. The position after the last match can be read or set using the pos() function; see pos in *perlfunc*. A failed match normally resets the search position to the beginning of the string, but you can avoid that by adding the `/c` modifier (e.g. `m//gc`). Modifying the target string also resets the search position.

You can intermix `m//g` matches with `m/\G.../g`, where `\G` is a zero-width assertion that matches the exact position where the previous `m//g`, if any, left off. Without the `/g` modifier, the `\G` assertion still anchors at pos(), but the match is of course only attempted once. Using `\G` without `/g` on a target string that has not previously had a `/g` match applied to it is the same as using the `\A` assertion to match the beginning of the string. Note also that, currently, `\G` is only properly supported when anchored at the very beginning of the pattern.

Examples:

```
    # list context
    ($one,$five,$fifteen) = (‘uptime‘ =~ /(\d+\.\d+)/g);

    # scalar context
    $/ = "";
    while (defined($paragraph = <>)) {
        while ($paragraph =~ /[a-z]['")]*[.!?]+['")]*\s/g) {
            $sentences++;
        }
    }
    print "$sentences\n";

    # using m//gc with \G
    $_ = "ppooqppqq";
    while ($i++ < 2) {
        print "1: '";
        print $1 while /(o)/gc; print "', pos=", pos, "\n";
        print "2: '";
        print $1 if /\G(q)/gc;  print "', pos=", pos, "\n";
        print "3: '";
        print $1 while /(p)/gc; print "', pos=", pos, "\n";
    }
    print "Final: '$1', pos=",pos,"\n" if /\G(.)/;
```

The last example should print:

```
    1: 'oo', pos=4
    2: 'q', pos=5
    3: 'pp', pos=7
    1: '', pos=7
    2: 'q', pos=8
    3: '', pos=8
    Final: 'q', pos=8
```

Notice that the final match matched `q` instead of `p`, which a match without the `\G` anchor would have done. Also note that the final match did not update `pos` – `pos` is only updated on a `/g` match. If the final match did indeed match `p`, it's a good bet that you're running an older (pre-5.6.0) Perl.

A useful idiom for `lex`-like scanners is `/\G.../gc`. You can combine several regexps like this to process a string part-by-part, doing different actions depending on which regexp matched. Each regexp tries to match where the previous one leaves off.

```
 $_ = <<'EOL';
      $url = new URI::URL "http://www/";   die if $url eq "xXx";
 EOL
 LOOP:
    {
      print(" digits"),         redo LOOP if /\G\d+\b[,.;]?\s*/gc;
      print(" lowercase"),      redo LOOP if /\G[a-z]+\b[,.;]?\s*/gc;
      print(" UPPERCASE"),      redo LOOP if /\G[A-Z]+\b[,.;]?\s*/gc;
      print(" Capitalized"),    redo LOOP if /\G[A-Z][a-z]+\b[,.;]?\s*/gc;
      print(" MiXeD"),          redo LOOP if /\G[A-Za-z]+\b[,.;]?\s*/gc;
      print(" alphanumeric"),   redo LOOP if /\G[A-Za-z0-9]+\b[,.;]?\s*/gc;
      print(" line-noise"),     redo LOOP if /\G[^A-Za-z0-9]+/gc;
      print ". That's all!\n";
    }
```

Here is the output (split into several lines):

```
line-noise lowercase line-noise lowercase UPPERCASE line-noise
UPPERCASE line-noise lowercase line-noise lowercase line-noise
lowercase lowercase line-noise lowercase lowercase line-noise
MiXeD line-noise. That’s all!
```

q/STRING/

`'STRING'`

A single-quoted, literal string. A backslash represents a backslash unless followed by the delimiter or another backslash, in which case the delimiter or backslash is interpolated.

```
    $foo = q!I said, "You said, ’She said it.’"!;
    $bar = q(’This is it.’);
    $baz = ’\n’;                # a two-character string
```

qq/STRING/

"STRING"

A double-quoted, interpolated string.

```
    $_ .= qq
     (*** The previous line contains the naughty word "$1".\n)
                if /\b(tcl|java|python)\b/i;      # :-)
    $baz = "\n";                # a one-character string
```

qr/STRING/imosx

This operator quotes (and possibly compiles) its *STRING* as a regular expression. *STRING* is interpolated the same way as *PATTERN* in `m/PATTERN/`. If "’" is used as the delimiter, no interpolation is done. Returns a Perl value which may be used instead of the corresponding `/STRING/imosx` expression.

For example,

```
    $rex = qr/my.STRING/is;
    s/$rex/foo/;
```

is equivalent to

```
    s/my.STRING/foo/is;
```

The result may be used as a subpattern in a match:

```
    $re = qr/$pattern/;
    $string =~ /foo${re}bar/;   # can be interpolated in other patterns
    $string =~ $re;             # or used standalone
    $string =~ /$re/;           # or this way
```

Since Perl may compile the pattern at the moment of execution of qr() operator, using qr() may have speed advantages in some situations, notably if the result of qr() is used standalone:

```
    sub match {
        my $patterns = shift;
        my @compiled = map qr/$_/i, @$patterns;
        grep {
            my $success = 0;
            foreach my $pat (@compiled) {
                $success = 1, last if /$pat/;
            }
            $success;
        } @_;
    }
```

Precompilation of the pattern into an internal representation at the moment of qr() avoids a need to recompile the pattern every time a match `/$pat/` is attempted. (Perl has many other internal optimizations, but none would be triggered in the above example if we did not use qr() operator.)

Options are:

```
    i   Do case-insensitive pattern matching.
    m   Treat string as multiple lines.
    o   Compile pattern only once.
    s   Treat string as single line.
    x   Use extended regular expressions.
```

See *perlre* for additional information on valid syntax for STRING, and for a detailed look at the semantics of regular expressions.

qx/STRING/

‘STRING‘

A string which is (possibly) interpolated and then executed as a system command with `/bin/sh` or its equivalent. Shell wildcards, pipes, and redirections will be honored. The collected standard output of the command is returned; standard error is unaffected. In scalar context, it comes back as a single (potentially multi-line) string, or undef if the command failed. In list context, returns a list of lines (however you've defined lines with $/ or $INPUT_RECORD_SEPARATOR), or an empty list if the command failed.

Because backticks do not affect standard error, use shell file descriptor syntax (assuming the shell supports this) if you care to address this. To capture a command's STDERR and STDOUT together:

```
    $output = `cmd 2>&1`;
```

To capture a command's STDOUT but discard its STDERR:

```
    $output = `cmd 2>/dev/null`;
```

To capture a command's STDERR but discard its STDOUT (ordering is important here):

```
    $output = `cmd 2>&1 1>/dev/null`;
```

To exchange a command's STDOUT and STDERR in order to capture the STDERR but leave its STDOUT to come out the old STDERR:

```
    $output = `cmd 3>&1 1>&2 2>&3 3>&-`;
```

To read both a command's STDOUT and its STDERR separately, it's easiest to redirect them separately to files, and then read from those files when the program is done:

```
    system("program args 1>program.stdout 2>program.stderr");
```

Using single-quote as a delimiter protects the command from Perl's double-quote interpolation, passing it on to the shell instead:

```
    $perl_info  = qx(ps $$);            # that's Perl's $$
    $shell_info = qx'ps $$';            # that's the new shell's $$
```

How that string gets evaluated is entirely subject to the command interpreter on your system. On most platforms, you will have to protect shell metacharacters if you want them treated literally. This is in practice difficult to do, as it's unclear how to escape which characters. See *perlsec* for a clean and safe example of a manual fork() and exec() to emulate backticks safely.

On some platforms (notably DOS-like ones), the shell may not be capable of dealing with multiline commands, so putting newlines in the string may not get you what you want. You may be able to evaluate multiple commands in a single line by separating them with the command separator character, if your shell supports that (e.g. `;` on many Unix shells; `&` on the Windows NT `cmd` shell).

Beginning with v5.6.0, Perl will attempt to flush all files opened for output before starting the child process, but this may not be supported on some platforms (see *perlport*). To be safe, you may need to set $| ($AUTOFLUSH in English) or call the `autoflush()` method of `IO::Handle` on any open handles.

Beware that some command shells may place restrictions on the length of the command line. You must ensure your strings don't exceed this limit after any necessary interpolations. See the platform-specific release notes for more details about your particular environment.

Using this operator can lead to programs that are difficult to port, because the shell commands called vary between systems, and may in fact not be present at all. As one example, the `type` command under the POSIX shell is very different from the `type` command under DOS. That doesn't mean you should go out of your way to avoid backticks when they're the right way to get something done. Perl was made to be a glue language, and one of the things it glues together is commands. Just understand what you're getting yourself into.

See §28.1.30 for more discussion.

qw/STRING/

Evaluates to a list of the words extracted out of STRING, using embedded whitespace as the word delimiters. It can be understood as being roughly equivalent to:

```
    split(' ', q/STRING/);
```

the differences being that it generates a real list at compile time, and in scalar context it returns the last element in the list. So this expression:

```
    qw(foo bar baz)
```

is semantically equivalent to the list:

```
    'foo', 'bar', 'baz'
```

Some frequently seen examples:

```
    use POSIX qw( setlocale localeconv )
    @EXPORT = qw( foo bar baz );
```

A common mistake is to try to separate the words with comma or to put comments into a multi-line `qw`-string. For this reason, the `use warnings` pragma and the **-w** switch (that is, the `$^W` variable) produces warnings if the STRING contains the "," or the "#" character.

s/PATTERN/REPLACEMENT/egimosx

Searches a string for a pattern, and if found, replaces that pattern with the replacement text and returns the number of substitutions made. Otherwise it returns false (specifically, the empty string).

If no string is specified via the =˜ or !˜ operator, the $_ variable is searched and modified. (The string specified with =˜ must be scalar variable, an array element, a hash element, or an assignment to one of those, i.e., an lvalue.)

If the delimiter chosen is a single quote, no interpolation is done on either the PATTERN or the REPLACEMENT. Otherwise, if the PATTERN contains a $ that looks like a variable rather than an end-of-string test, the variable will be interpolated into the pattern at run-time. If you want the pattern compiled only once the first time the variable is interpolated, use the /o option. If the pattern evaluates to the empty string, the last successfully executed regular expression is used instead. See *perlre* for further explanation on these. See *perllocale* for discussion of additional considerations that apply when use locale is in effect.

Options are:

```
e   Evaluate the right side as an expression.
g   Replace globally, i.e., all occurrences.
i   Do case-insensitive pattern matching.
m   Treat string as multiple lines.
o   Compile pattern only once.
s   Treat string as single line.
x   Use extended regular expressions.
```

Any non-alphanumeric, non-whitespace delimiter may replace the slashes. If single quotes are used, no interpretation is done on the replacement string (the /e modifier overrides this, however). Unlike Perl 4, Perl 5 treats backticks as normal delimiters; the replacement text is not evaluated as a command. If the PATTERN is delimited by bracketing quotes, the REPLACEMENT has its own pair of quotes, which may or may not be bracketing quotes, e.g., s(foo)(bar) or s<foo>/bar/. A /e will cause the replacement portion to be treated as a full-fledged Perl expression and evaluated right then and there. It is, however, syntax checked at compile-time. A second e modifier will cause the replacement portion to be evaled before being run as a Perl expression.

Examples:

```
s/\bgreen\b/mauve/g;                # don't change wintergreen

$path =~ s|/usr/bin|/usr/local/bin|;

s/Login: $foo/Login: $bar/; # run-time pattern

($foo = $bar) =~ s/this/that/;      # copy first, then change

$count = ($paragraph =~ s/Mister\b/Mr./g);  # get change-count

$_ = 'abc123xyz';
s/\d+/$&*2/e;               # yields 'abc246xyz'
s/\d+/sprintf("%5d",$&)/e;  # yields 'abc  246xyz'
s/\w/$& x 2/eg;             # yields 'aabbcc  224466xxyyzz'

s/%(.)/$percent{$1}/g;      # change percent escapes; no /e
s/%(.)/$percent{$1} || $&/ge;       # expr now, so /e
s/^=(\w+)/&pod($1)/ge;      # use function call

# expand variables in $_, but dynamics only, using
# symbolic dereferencing
s/\$(\w+)/${$1}/g;
```

```
    # Add one to the value of any numbers in the string
    s/(\d+)/1 + $1/eg;

    # This will expand any embedded scalar variable
    # (including lexicals) in $_ : First $1 is interpolated
    # to the variable name, and then evaluated
    s/(\$\w+)/$1/eeg;

    # Delete (most) C comments.
    $program =~ s {
        /\*     # Match the opening delimiter.
        .*?     # Match a minimal number of characters.
        \*/     # Match the closing delimiter.
    } []gsx;

    s/^\s*(.*?)\s*$/$1/;        # trim white space in $_, expensively

    for ($variable) {           # trim white space in $variable, cheap
        s/^\s+//;
        s/\s+$//;
    }

    s/([^ ]*) *([^ ]*)/$2 $1/;  # reverse 1st two fields
```

Note the use of $ instead of \ in the last example. Unlike **sed**, we use the \<*digit*> form in only the left hand side. Anywhere else it's $<*digit*>.

Occasionally, you can't use just a /g to get all the changes to occur that you might want. Here are two common cases:

```
    # put commas in the right places in an integer
    1 while s/(\d)(\d\d\d)(?!\d)/$1,$2/g;

    # expand tabs to 8-column spacing
    1 while s/\t+/' ' x (length($&)*8 - length($`)%8)/e;
```

tr/SEARCHLIST/REPLACEMENTLIST/cds

y/SEARCHLIST/REPLACEMENTLIST/cds

Transliterates all occurrences of the characters found in the search list with the corresponding character in the replacement list. It returns the number of characters replaced or deleted. If no string is specified via the =˜ or !˜ operator, the $_ string is transliterated. (The string specified with =˜ must be a scalar variable, an array element, a hash element, or an assignment to one of those, i.e., an lvalue.)

A character range may be specified with a hyphen, so `tr/A-J/0-9/` does the same replacement as `tr/ACEGIBDFHJ/0246813579/`. For **sed** devotees, `y` is provided as a synonym for `tr`. If the SEARCHLIST is delimited by bracketing quotes, the REPLACEMENTLIST has its own pair of quotes, which may or may not be bracketing quotes, e.g., `tr[A-Z][a-z]` or `tr(+\-*/)/ABCD/`.

Note that `tr` does **not** do regular expression character classes such as `\d` or `[:lower:]`. The <tr> operator is not equivalent to the tr(1) utility. If you want to map strings between lower/upper cases, see lc in *perlfunc* and uc in *perlfunc*, and in general consider using the `s` operator if you need regular expressions.

Note also that the whole range idea is rather unportable between character sets–and even within character sets they may cause results you probably didn't expect. A sound principle is to use only ranges that begin from and end at either alphabets of equal case (a-e, A-E), or digits (0-4). Anything else is unsafe. If in doubt, spell out the character sets in full.

Options:

```
    c   Complement the SEARCHLIST.
    d   Delete found but unreplaced characters.
    s   Squash duplicate replaced characters.
```

If the `/c` modifier is specified, the SEARCHLIST character set is complemented. If the `/d` modifier is specified, any characters specified by SEARCHLIST not found in REPLACEMENTLIST are deleted. (Note that this is slightly more flexible than the behavior of some **tr** programs, which delete anything they find in the SEARCHLIST, period.) If the `/s` modifier is specified, sequences of characters that were transliterated to the same character are squashed down to a single instance of the character.

If the `/d` modifier is used, the REPLACEMENTLIST is always interpreted exactly as specified. Otherwise, if the REPLACEMENTLIST is shorter than the SEARCHLIST, the final character is replicated till it is long enough. If the REPLACEMENTLIST is empty, the SEARCHLIST is replicated. This latter is useful for counting characters in a class or for squashing character sequences in a class.

Examples:

```
    $ARGV[1] =~ tr/A-Z/a-z/;    # canonicalize to lower case

    $cnt = tr/*/*/;             # count the stars in $_

    $cnt = $sky =~ tr/*/*/;     # count the stars in $sky

    $cnt = tr/0-9//;            # count the digits in $_

    tr/a-zA-Z//s;               # bookkeeper -> bokeper

    ($HOST = $host) =~ tr/a-z/A-Z/;

    tr/a-zA-Z/ /cs;             # change non-alphas to single space

    tr [\200-\377]
       [\000-\177];             # delete 8th bit
```

If multiple transliterations are given for a character, only the first one is used:

```
    tr/AAA/XYZ/
```

will transliterate any A to X.

Because the transliteration table is built at compile time, neither the SEARCHLIST nor the REPLACEMENTLIST are subjected to double quote interpolation. That means that if you want to use variables, you must use an eval():

```
    eval "tr/$oldlist/$newlist/";
    die $@ if $@;

    eval "tr/$oldlist/$newlist/, 1" or die $@;
```

<<**EOF**

A line-oriented form of quoting is based on the shell "here-document" syntax. Following a << you specify a string to terminate the quoted material, and all lines following the current line down to the terminating string are the value of the item. The terminating string may be either an identifier (a word), or some quoted text. If quoted, the type of quotes you use determines the treatment of the text, just as in regular quoting. An unquoted identifier works like double quotes. There must be no space between the << and the identifier, unless the identifier is quoted. (If you put a space it will be treated as a null identifier, which is valid, and matches the first empty line.) The terminating string must appear by itself (unquoted and with no surrounding whitespace) on the terminating line.

```
   print <<EOF;
The price is $Price.
EOF

   print << "EOF"; # same as above
The price is $Price.
EOF

   print << `EOC`; # execute commands
echo hi there
echo lo there
EOC

   print <<"foo", <<"bar"; # you can stack them
I said foo.
foo
I said bar.
bar

   myfunc(<< "THIS", 23, <<'THAT');
Here's a line
or two.
THIS
and here's another.
THAT
```

Just don't forget that you have to put a semicolon on the end to finish the statement, as Perl doesn't know you're not going to try to do this:

```
   print <<ABC
179231
ABC
   + 20;
```

If you want your here-docs to be indented with the rest of the code, you'll need to remove leading whitespace from each line manually:

```
($quote = <<'FINIS') =~ s/^\s+//gm;
   The Road goes ever on and on,
   down from the door where it began.
FINIS
```

If you use a here-doc within a delimited construct, such as in `s///eg`, the quoted material must come on the lines following the final delimiter. So instead of

```
s/this/<<E . 'that'
the other
E
 . 'more '/eg;
```

you have to write

```
s/this/<<E . 'that'
 . 'more '/eg;
the other
E
```

If the terminating identifier is on the last line of the program, you must be sure there is a newline after it; otherwise, Perl will give the warning **Can't find string terminator "END" anywhere before EOF...**.

Additionally, the quoting rules for the identifier are not related to Perl's quoting rules – `q()`, `qq()`, and the like are not supported in place of ” and `""`, and the only interpolation is for backslashing the quoting character:

```
print << "abc\"def";
testing...
abc"def
```

Finally, quoted strings cannot span multiple lines. The general rule is that the identifier must be a string literal. Stick with that, and you should be safe.

28.1.29 Gory details of parsing quoted constructs

When presented with something that might have several different interpretations, Perl uses the **DWIM** (that's "Do What I Mean") principle to pick the most probable interpretation. This strategy is so successful that Perl programmers often do not suspect the ambivalence of what they write. But from time to time, Perl's notions differ substantially from what the author honestly meant.

This section hopes to clarify how Perl handles quoted constructs. Although the most common reason to learn this is to unravel labyrinthine regular expressions, because the initial steps of parsing are the same for all quoting operators, they are all discussed together.

The most important Perl parsing rule is the first one discussed below: when processing a quoted construct, Perl first finds the end of that construct, then interprets its contents. If you understand this rule, you may skip the rest of this section on the first reading. The other rules are likely to contradict the user's expectations much less frequently than this first one.

Some passes discussed below are performed concurrently, but because their results are the same, we consider them individually. For different quoting constructs, Perl performs different numbers of passes, from one to five, but these passes are always performed in the same order.

Finding the end

The first pass is finding the end of the quoted construct, whether it be a multicharacter delimiter `"\nEOF\n"` in the `<<EOF` construct, a `/` that terminates a `qq//` construct, a `]` which terminates `qq[]` construct, or a `>` which terminates a fileglob started with `<`.

When searching for single-character non-pairing delimiters, such as `/`, combinations of `\\` and `\/` are skipped. However, when searching for single-character pairing delimiter like `[`, combinations of `\\`, `\]`, and `\[` are all skipped, and nested `[`, `]` are skipped as well. When searching for multicharacter delimiters, nothing is skipped.

For constructs with three-part delimiters (`s///`, `y///`, and `tr///`), the search is repeated once more.

During this search no attention is paid to the semantics of the construct. Thus:

```
"$hash{"$foo/$bar"}"
```

or:

```
m/
  bar       # NOT a comment, this slash / terminated m//!
 /x
```

do not form legal quoted expressions. The quoted part ends on the first `"` and `/`, and the rest happens to be a syntax error. Because the slash that terminated `m//` was followed by a `SPACE`, the example above is not `m//x`, but rather `m//` with no `/x` modifier. So the embedded `#` is interpreted as a literal `#`.

Removal of backslashes before delimiters

During the second pass, text between the starting and ending delimiters is copied to a safe location, and the \ is removed from combinations consisting of \ and delimiter–or delimiters, meaning both starting and ending delimiters will should these differ. This removal does not happen for multi-character delimiters. Note that the combination \\ is left intact, just as it was.

Starting from this step no information about the delimiters is used in parsing.

Interpolation

The next step is interpolation in the text obtained, which is now delimiter-independent. There are four different cases.

<<'EOF', m'', s''', tr///, y///

No interpolation is performed.

'', q//

The only interpolation is removal of \ from pairs \\.

"", ``, qq//, qx//, <file*glob>

`\Q`, `\U`, `\u`, `\L`, `\l` (possibly paired with `\E`) are converted to corresponding Perl constructs. Thus, `"$foo\Qbaz$bar"` is converted to `$foo . (quotemeta("baz" . $bar))` internally. The other combinations are replaced with appropriate expansions.

Let it be stressed that *whatever falls between* `\Q` *and* `\E` is interpolated in the usual way. Something like `"\Q\\E"` has no `\E` inside. instead, it has `\Q`, `\\`, and `E`, so the result is the same as for `"\\\\E"`. As a general rule, backslashes between `\Q` and `\E` may lead to counterintuitive results. So, `"\Q\t\E"` is converted to `quotemeta("\t")`, which is the same as `"\\\t"` (since TAB is not alphanumeric). Note also that:

```
$str = '\t';
return "\Q$str";
```

may be closer to the conjectural *intention* of the writer of `"\Q\t\E"`.

Interpolated scalars and arrays are converted internally to the `join` and `.` catenation operations. Thus, `"$foo XXX '@arr'"` becomes:

```
$foo . " XXX '" . (join $", @arr) . "'";
```

All operations above are performed simultaneously, left to right.

Because the result of `"\Q STRING \E"` has all metacharacters quoted, there is no way to insert a literal `$` or `@` inside a `\Q\E` pair. If protected by \, `$` will be quoted to became `"\\\$"`; if not, it is interpreted as the start of an interpolated scalar.

Note also that the interpolation code needs to make a decision on where the interpolated scalar ends. For instance, whether `"a $b -> {c}"` really means:

```
"a " . $b . " -> {c}";
```

or:

```
"a " . $b -> {c};
```

Most of the time, the longest possible text that does not include spaces between components and which contains matching braces or brackets. because the outcome may be determined by voting based on heuristic estimators, the result is not strictly predictable. Fortunately, it's usually correct for ambiguous cases.

?RE?, /RE/, m/RE/, s/RE/foo/,

Processing of `\Q`, `\U`, `\u`, `\L`, `\l`, and interpolation happens (almost) as with `qq//` constructs, but the substitution of \ followed by RE-special chars (including \) is not performed. Moreover, inside `(?{BLOCK})`, `(?# comment )`, and a `#`-comment in a `//x`-regular expression, no processing is performed whatsoever. This is the first step at which the presence of the `//x` modifier is relevant.

Interpolation has several quirks: `$|`, `$(`, and `$)` are not interpolated, and constructs `$var[SOMETHING]` are voted (by several different estimators) to be either an array element or `$var` followed by an RE alternative.

This is where the notation `${arr[$bar]}` comes handy: `/${arr[0-9]}/` is interpreted as array element `-9`, not as a regular expression from the variable `$arr` followed by a digit, which would be the interpretation of `/$arr[0-9]/`. Since voting among different estimators may occur, the result is not predictable.

It is at this step that `\1` is begrudgingly converted to `$1` in the replacement text of `s///` to correct the incorrigible *sed* hackers who haven't picked up the saner idiom yet. A warning is emitted if the `use warnings` pragma or the **-w** command-line flag (that is, the `$^W` variable) was set.

The lack of processing of `\\` creates specific restrictions on the post-processed text. If the delimiter is `/`, one cannot get the combination `\/` into the result of this step. `/` will finish the regular expression, `\/` will be stripped to `/` on the previous step, and `\\/` will be left as is. Because `/` is equivalent to `\/` inside a regular expression, this does not matter unless the delimiter happens to be character special to the RE engine, such as in `s*foo*bar*`, `m[foo]`, or `?foo?`; or an alphanumeric char, as in:

```
m m ^ a \s* b mmx;
```

In the RE above, which is intentionally obfuscated for illustration, the delimiter is `m`, the modifier is `mx`, and after backslash-removal the RE is the same as for `m/ ^ a \s* b /mx`. There's more than one reason you're encouraged to restrict your delimiters to non-alphanumeric, non-whitespace choices.

This step is the last one for all constructs except regular expressions, which are processed further.

Interpolation of regular expressions

Previous steps were performed during the compilation of Perl code, but this one happens at run time–although it may be optimized to be calculated at compile time if appropriate. After preprocessing described above, and possibly after evaluation if catenation, joining, casing translation, or metaquoting are involved, the resulting *string* is passed to the RE engine for compilation.

Whatever happens in the RE engine might be better discussed in *perlre*, but for the sake of continuity, we shall do so here.

This is another step where the presence of the `//x` modifier is relevant. The RE engine scans the string from left to right and converts it to a finite automaton.

Backslashed characters are either replaced with corresponding literal strings (as with `\{`), or else they generate special nodes in the finite automaton (as with `\b`). Characters special to the RE engine (such as `|`) generate corresponding nodes or groups of nodes. `(?#...)` comments are ignored. All the rest is either converted to literal strings to match, or else is ignored (as is whitespace and `#`-style comments if `//x` is present).

Parsing of the bracketed character class construct, `[...]`, is rather different than the rule used for the rest of the pattern. The terminator of this construct is found using the same rules as for finding the terminator of a `{}`-delimited construct, the only exception being that `]` immediately following `[` is treated as though preceded by a backslash. Similarly, the terminator of `(?{...})` is found using the same rules as for finding the terminator of a `{}`-delimited construct.

It is possible to inspect both the string given to RE engine and the resulting finite automaton. See the arguments `debug`/`debugcolor` in the `use re` pragma, as well as Perl's **-Dr** command-line switch documented in Command Switches in *perlrun*.

Optimization of regular expressions

This step is listed for completeness only. Since it does not change semantics, details of this step are not documented and are subject to change without notice. This step is performed over the finite automaton that was generated during the previous pass.

It is at this stage that `split()` silently optimizes `/^/` to mean `/^/m`.

28.1.30 I/O Operators

There are several I/O operators you should know about.

A string enclosed by backticks (grave accents) first undergoes double-quote interpolation. It is then interpreted as an external command, and the output of that command is the value of the backtick string, like in a shell. In scalar context, a single string consisting of all output is returned. In list context, a list of values is returned, one per line of output. (You can set `$/` to use a different line terminator.) The command is executed each time the pseudo-literal is evaluated. The status value of the command is returned in `$?` (see *perlvar* for the interpretation of `$?`). Unlike in **csh**, no translation is done on the return data–newlines remain newlines. Unlike in any of the shells, single quotes do not hide variable names in the command from interpretation. To pass a literal dollar-sign through to the shell you need to hide it with a backslash. The generalized form of backticks is `qx//`. (Because backticks always undergo shell expansion as well, see *perlsec* for security concerns.)

In scalar context, evaluating a filehandle in angle brackets yields the next line from that file (the newline, if any, included), or `undef` at end-of-file or on error. When `$/` is set to `undef` (sometimes known as file-slurp mode) and the file is empty, it returns ” the first time, followed by `undef` subsequently.

Ordinarily you must assign the returned value to a variable, but there is one situation where an automatic assignment happens. If and only if the input symbol is the only thing inside the conditional of a `while` statement (even if disguised as a `for(;;)` loop), the value is automatically assigned to the global variable $_, destroying whatever was there previously. (This may seem like an odd thing to you, but you'll use the construct in almost every Perl script you write.) The $_ variable is not implicitly localized. You'll have to put a `local $_;` before the loop if you want that to happen.

The following lines are equivalent:

```
while (defined($_ = <STDIN>)) { print; }
while ($_ = <STDIN>) { print; }
while (<STDIN>) { print; }
for (;<STDIN>;) { print; }
print while defined($_ = <STDIN>);
print while ($_ = <STDIN>);
print while <STDIN>;
```

This also behaves similarly, but avoids $_ :

```
while (my $line = <STDIN>) { print $line }
```

In these loop constructs, the assigned value (whether assignment is automatic or explicit) is then tested to see whether it is defined. The defined test avoids problems where line has a string value that would be treated as false by Perl, for example a "" or a "0" with no trailing newline. If you really mean for such values to terminate the loop, they should be tested for explicitly:

```
while (($_ = <STDIN>) ne '0') { ... }
while (<STDIN>) { last unless $_; ... }
```

In other boolean contexts, <*`filehandle`*> without an explicit `defined` test or comparison elicit a warning if the `use warnings` pragma or the **-w** command-line switch (the `$^W` variable) is in effect.

The filehandles STDIN, STDOUT, and STDERR are predefined. (The filehandles `stdin`, `stdout`, and `stderr` will also work except in packages, where they would be interpreted as local identifiers rather than global.) Additional filehandles may be created with the open() function, amongst others. See *perlopentut* and open in *perlfunc* for details on this.

If a <FILEHANDLE> is used in a context that is looking for a list, a list comprising all input lines is returned, one line per list element. It's easy to grow to a rather large data space this way, so use with care.

<FILEHANDLE> may also be spelled `readline(*FILEHANDLE)`. See readline in *perlfunc*.

The null filehandle <> is special: it can be used to emulate the behavior of **sed** and **awk**. Input from <> comes either from standard input, or from each file listed on the command line. Here's how it works: the first time <> is evaluated, the @ARGV array is checked, and if it is empty, `$ARGV[0]` is set to "-", which when opened gives you standard input. The @ARGV array is then processed as a list of filenames. The loop

```
while (<>) {
    ...                     # code for each line
}
```

is equivalent to the following Perl-like pseudo code:

```
unshift(@ARGV, '-') unless @ARGV;
while ($ARGV = shift) {
    open(ARGV, $ARGV);
    while (<ARGV>) {
        ...         # code for each line
    }
}
```

except that it isn't so cumbersome to say, and will actually work. It really does shift the @ARGV array and put the current filename into the $ARGV variable. It also uses filehandle *ARGV* internally–<> is just a synonym for <ARGV>, which is magical. (The pseudo code above doesn't work because it treats <ARGV> as non-magical.)

You can modify @ARGV before the first <> as long as the array ends up containing the list of filenames you really want. Line numbers (`$.`) continue as though the input were one big happy file. See the example in eof in *perlfunc* for how to reset line numbers on each file.

If you want to set @ARGV to your own list of files, go right ahead. This sets @ARGV to all plain text files if no @ARGV was given:

```
@ARGV = grep { -f && -T } glob('*') unless @ARGV;
```

You can even set them to pipe commands. For example, this automatically filters compressed arguments through **gzip**:

```
@ARGV = map { /\.(gz|Z)$/ ? "gzip -dc < $_ |" : $_ } @ARGV;
```

If you want to pass switches into your script, you can use one of the Getopts modules or put a loop on the front like this:

```
while ($_ = $ARGV[0], /^-/) {
    shift;
    last if /^--$/;
    if (/^-D(.*)/) { $debug = $1 }
    if (/^-v/)     { $verbose++  }
    # ...          # other switches
}

while (<>) {
    # ...          # code for each line
}
```

The <> symbol will return `undef` for end-of-file only once. If you call it again after this, it will assume you are processing another @ARGV list, and if you haven't set @ARGV, will read input from STDIN.

If what the angle brackets contain is a simple scalar variable (e.g., <$foo>), then that variable contains the name of the filehandle to input from, or its typeglob, or a reference to the same. For example:

```
$fh = \*STDIN;
$line = <$fh>;
```

If what's within the angle brackets is neither a filehandle nor a simple scalar variable containing a filehandle name, typeglob, or typeglob reference, it is interpreted as a filename pattern to be globbed, and either a list of filenames or the next filename in the list is returned, depending on context. This distinction is determined on syntactic grounds alone. That means `<$x>` is always a readline() from an indirect handle, but `<$hash{key}>` is always a glob(). That's because $x is a simple scalar variable, but `$hash{key}` is not–it's a hash element.

One level of double-quote interpretation is done first, but you can't say `<$foo>` because that's an indirect filehandle as explained in the previous paragraph. (In older versions of Perl, programmers would insert curly brackets to force interpretation as a filename glob: `<${foo}>`. These days, it's considered cleaner to call the internal function directly as `glob($foo)`, which is probably the right way to have done it in the first place.) For example:

```
    while (<*.c>) {
        chmod 0644, $_;
    }
```

is roughly equivalent to:

```
    open(FOO, "echo *.c | tr -s ' \t\r\f' '\\012\\012\\012\\012'|");
    while (<FOO>) {
        chomp;
        chmod 0644, $_;
    }
```

except that the globbing is actually done internally using the standard `File::Glob` extension. Of course, the shortest way to do the above is:

```
    chmod 0644, <*.c>;
```

A (file)glob evaluates its (embedded) argument only when it is starting a new list. All values must be read before it will start over. In list context, this isn't important because you automatically get them all anyway. However, in scalar context the operator returns the next value each time it's called, or `undef` when the list has run out. As with filehandle reads, an automatic `defined` is generated when the glob occurs in the test part of a `while`, because legal glob returns (e.g. a file called *0*) would otherwise terminate the loop. Again, `undef` is returned only once. So if you're expecting a single value from a glob, it is much better to say

```
    ($file) = <blurch*>;
```

than

```
    $file = <blurch*>;
```

because the latter will alternate between returning a filename and returning false.

If you're trying to do variable interpolation, it's definitely better to use the glob() function, because the older notation can cause people to become confused with the indirect filehandle notation.

```
    @files = glob("$dir/*.[ch]");
    @files = glob($files[$i]);
```

28.1.31 Constant Folding

Like C, Perl does a certain amount of expression evaluation at compile time whenever it determines that all arguments to an operator are static and have no side effects. In particular, string concatenation happens at compile time between literals that don't do variable substitution. Backslash interpolation also happens at compile time. You can say

```
    'Now is the time for all' . "\n" .
        'good men to come to.'
```

and this all reduces to one string internally. Likewise, if you say

```
    foreach $file (@filenames) {
        if (-s $file > 5 + 100 * 2**16) {  }
    }
```

the compiler will precompute the number which that expression represents so that the interpreter won't have to.

28.1.32 Bitwise String Operators

Bitstrings of any size may be manipulated by the bitwise operators (`~ | & ^`).

If the operands to a binary bitwise op are strings of different sizes, | and ^ ops act as though the shorter operand had additional zero bits on the right, while the **&** op acts as though the longer operand were truncated to the length of the shorter. The granularity for such extension or truncation is one or more bytes.

```
    # ASCII-based examples
    print "j p \n" ^ " a h";            # prints "JAPH\n"
    print "JA" | "  ph\n";              # prints "japh\n"
    print "japh\nJunk" & '_____';       # prints "JAPH\n";
    print 'p N$' ^ " E<H\n";            # prints "Perl\n";
```

If you are intending to manipulate bitstrings, be certain that you're supplying bitstrings: If an operand is a number, that will imply a **numeric** bitwise operation. You may explicitly show which type of operation you intend by using `""` or `0+`, as in the examples below.

```
    $foo =  150  |  105 ;       # yields 255  (0x96 | 0x69 is 0xFF)
    $foo = '150' |  105 ;       # yields 255
    $foo =  150  | '105';       # yields 255
    $foo = '150' | '105';       # yields string '155' (under ASCII)

    $baz = 0+$foo & 0+$bar;     # both ops explicitly numeric
    $biz = "$foo" ^ "$bar";     # both ops explicitly stringy
```

See vec in *perlfunc* for information on how to manipulate individual bits in a bit vector.

28.1.33 Integer Arithmetic

By default, Perl assumes that it must do most of its arithmetic in floating point. But by saying

```
    use integer;
```

you may tell the compiler that it's okay to use integer operations (if it feels like it) from here to the end of the enclosing BLOCK. An inner BLOCK may countermand this by saying

```
    no integer;
```

which lasts until the end of that BLOCK. Note that this doesn't mean everything is only an integer, merely that Perl may use integer operations if it is so inclined. For example, even under `use integer`, if you take the `sqrt(2)`, you'll still get `1.4142135623731` or so.

Used on numbers, the bitwise operators ("&", "|", "^", "~", "<<", and ">>") always produce integral results. (But see also Bitwise String Operators.) However, `use integer` still has meaning for them. By default, their results are interpreted as unsigned integers, but if `use integer` is in effect, their results are interpreted as signed integers. For example, `~0` usually evaluates to a large integral value. However, `use integer; ~0` is `-1` on twos-complement machines.

28.1.34 Floating-point Arithmetic

While `use integer` provides integer-only arithmetic, there is no analogous mechanism to provide automatic rounding or truncation to a certain number of decimal places. For rounding to a certain number of digits, sprintf() or printf() is usually the easiest route. See *perlfaq4*.

Floating-point numbers are only approximations to what a mathematician would call real numbers. There are infinitely more reals than floats, so some corners must be cut. For example:

```
    printf "%.20g\n", 123456789123456789;
    #        produces 123456789123456784
```

Testing for exact equality of floating-point equality or inequality is not a good idea. Here's a (relatively expensive) work-around to compare whether two floating-point numbers are equal to a particular number of decimal places. See Knuth, volume II, for a more robust treatment of this topic.

```
    sub fp_equal {
        my ($X, $Y, $POINTS) = @_;
        my ($tX, $tY);
        $tX = sprintf("%.${POINTS}g", $X);
        $tY = sprintf("%.${POINTS}g", $Y);
        return $tX eq $tY;
    }
```

The POSIX module (part of the standard perl distribution) implements ceil(), floor(), and other mathematical and trigonometric functions. The Math::Complex module (part of the standard perl distribution) defines mathematical functions that work on both the reals and the imaginary numbers. Math::Complex not as efficient as POSIX, but POSIX can't work with complex numbers.

Rounding in financial applications can have serious implications, and the rounding method used should be specified precisely. In these cases, it probably pays not to trust whichever system rounding is being used by Perl, but to instead implement the rounding function you need yourself.

28.1.35 Bigger Numbers

The standard Math::BigInt and Math::BigFloat modules provide variable-precision arithmetic and overloaded operators, although they're currently pretty slow. At the cost of some space and considerable speed, they avoid the normal pitfalls associated with limited-precision representations.

```
    use Math::BigInt;
    $x = Math::BigInt->new('123456789123456789');
    print $x * $x;

    # prints +15241578780673678515622620750190521
```

There are several modules that let you calculate with (bound only by memory and cpu-time) unlimited or fixed precision. There are also some non-standard modules that provide faster implementations via external C libraries.

Here is a short, but incomplete summary:

```
        Math::Fraction          big, unlimited fractions like 9973 / 12967
        Math::String            treat string sequences like numbers
        Math::FixedPrecision    calculate with a fixed precision
        Math::Currency          for currency calculations
        Bit::Vector             manipulate bit vectors fast (uses C)
        Math::BigIntFast        Bit::Vector wrapper for big numbers
        Math::Pari              provides access to the Pari C library
        Math::BigInteger        uses an external C library
        Math::Cephes            uses external Cephes C library (no big numbers)
        Math::Cephes::Fraction  fractions via the Cephes library
        Math::GMP               another one using an external C library
```

Choose wisely.

Chapter 29

perlsub

Perl subroutines

29.1 SYNOPSIS

To declare subroutines:

```
    sub NAME;                       # A "forward" declaration.
    sub NAME(PROTO);                #  ditto, but with prototypes
    sub NAME : ATTRS;               #  with attributes
    sub NAME(PROTO) : ATTRS;        #  with attributes and prototypes

    sub NAME BLOCK                  # A declaration and a definition.
    sub NAME(PROTO) BLOCK           #  ditto, but with prototypes
    sub NAME : ATTRS BLOCK          #  with attributes
    sub NAME(PROTO) : ATTRS BLOCK   #  with prototypes and attributes
```

To define an anonymous subroutine at runtime:

```
    $subref = sub BLOCK;                 # no proto
    $subref = sub (PROTO) BLOCK;         # with proto
    $subref = sub : ATTRS BLOCK;         # with attributes
    $subref = sub (PROTO) : ATTRS BLOCK; # with proto and attributes
```

To import subroutines:

```
    use MODULE qw(NAME1 NAME2 NAME3);
```

To call subroutines:

```
    NAME(LIST);    # & is optional with parentheses.
    NAME LIST;     # Parentheses optional if predeclared/imported.
    &NAME(LIST);   # Circumvent prototypes.
    &NAME;         # Makes current @_ visible to called subroutine.
```

29.2 DESCRIPTION

Like many languages, Perl provides for user-defined subroutines. These may be located anywhere in the main program, loaded in from other files via the `do`, `require`, or `use` keywords, or generated on the fly using `eval` or anonymous subroutines. You can even call a function indirectly using a variable containing its name or a CODE reference.

The Perl model for function call and return values is simple: all functions are passed as parameters one single flat list of scalars, and all functions likewise return to their caller one single flat list of scalars. Any arrays or hashes in these call and return lists will collapse, losing their identities–but you may always use pass-by-reference instead to avoid this. Both call and return lists may contain as many or as few scalar elements as you'd like. (Often a function without an explicit return statement is called a subroutine, but there's really no difference from Perl's perspective.)

Any arguments passed in show up in the array `@_`. Therefore, if you called a function with two arguments, those would be stored in `$_[0]` and `$_[1]`. The array `@_` is a local array, but its elements are aliases for the actual scalar parameters. In particular, if an element `$_[0]` is updated, the corresponding argument is updated (or an error occurs if it is not updatable). If an argument is an array or hash element which did not exist when the function was called, that element is created only when (and if) it is modified or a reference to it is taken. (Some earlier versions of Perl created the element whether or not the element was assigned to.) Assigning to the whole array `@_` removes that aliasing, and does not update any arguments.

The return value of a subroutine is the value of the last expression evaluated by that sub, or the empty list in the case of an empty sub. More explicitly, a `return` statement may be used to exit the subroutine, optionally specifying the returned value, which will be evaluated in the appropriate context (list, scalar, or void) depending on the context of the subroutine call. If you specify no return value, the subroutine returns an empty list in list context, the undefined value in scalar context, or nothing in void context. If you return one or more aggregates (arrays and hashes), these will be flattened together into one large indistinguishable list.

Perl does not have named formal parameters. In practice all you do is assign to a `my()` list of these. Variables that aren't declared to be private are global variables. For gory details on creating private variables, see §29.2.1 and §29.2.3. To create protected environments for a set of functions in a separate package (and probably a separate file), see Packages in *perlmod*.

Example:

```
sub max {
    my $max = shift(@_);
    foreach $foo (@_) {
        $max = $foo if $max < $foo;
    }
    return $max;
}
$bestday = max($mon,$tue,$wed,$thu,$fri);
```

Example:

```
# get a line, combining continuation lines
#  that start with whitespace

sub get_line {
    $thisline = $lookahead;  # global variables!
    LINE: while (defined($lookahead = <STDIN>)) {
        if ($lookahead =~ /^[ \t]/) {
            $thisline .= $lookahead;
        }
        else {
            last LINE;
        }
    }
    return $thisline;
}
```

```
    $lookahead = <STDIN>;       # get first line
    while (defined($line = get_line())) {
        ...
    }
```

Assigning to a list of private variables to name your arguments:

```
    sub maybeset {
        my($key, $value) = @_;
        $Foo{$key} = $value unless $Foo{$key};
    }
```

Because the assignment copies the values, this also has the effect of turning call-by-reference into call-by-value. Otherwise a function is free to do in-place modifications of `@_` and change its caller's values.

```
    upcase_in($v1, $v2);  # this changes $v1 and $v2
    sub upcase_in {
        for (@_) { tr/a-z/A-Z/ }
    }
```

You aren't allowed to modify constants in this way, of course. If an argument were actually literal and you tried to change it, you'd take a (presumably fatal) exception. For example, this won't work:

```
    upcase_in("frederick");
```

It would be much safer if the `upcase_in()` function were written to return a copy of its parameters instead of changing them in place:

```
    ($v3, $v4) = upcase($v1, $v2);  # this doesn't change $v1 and $v2
    sub upcase {
        return unless defined wantarray;  # void context, do nothing
        my @parms = @_;
        for (@parms) { tr/a-z/A-Z/ }
        return wantarray ? @parms : $parms[0];
    }
```

Notice how this (unprototyped) function doesn't care whether it was passed real scalars or arrays. Perl sees all arguments as one big, long, flat parameter list in `@_`. This is one area where Perl's simple argument-passing style shines. The `upcase()` function would work perfectly well without changing the `upcase()` definition even if we fed it things like this:

```
    @newlist   = upcase(@list1, @list2);
    @newlist   = upcase( split /:/, $var );
```

Do not, however, be tempted to do this:

```
    (@a, @b)   = upcase(@list1, @list2);
```

Like the flattened incoming parameter list, the return list is also flattened on return. So all you have managed to do here is stored everything in `@a` and made `@b` empty. See Pass by Reference for alternatives.

A subroutine may be called using an explicit `&` prefix. The `&` is optional in modern Perl, as are parentheses if the subroutine has been predeclared. The `&` is *not* optional when just naming the subroutine, such as when it's used as an argument to defined() or undef(). Nor is it optional when you want to do an indirect subroutine call with a subroutine name or reference using the `&$subref()` or `&{$subref}()` constructs, although the `$subref->()` notation solves that problem. See *perlref* for more about all that.

Subroutines may be called recursively. If a subroutine is called using the `&` form, the argument list is optional, and if omitted, no `@_` array is set up for the subroutine: the `@_` array at the time of the call is visible to subroutine instead. This is an efficiency mechanism that new users may wish to avoid.

```
    &foo(1,2,3);        # pass three arguments
    foo(1,2,3);         # the same

    foo();              # pass a null list
    &foo();             # the same

    &foo;               # foo() get current args, like foo(@_) !!
    foo;                # like foo() IFF sub foo predeclared, else "foo"
```

Not only does the `&` form make the argument list optional, it also disables any prototype checking on arguments you do provide. This is partly for historical reasons, and partly for having a convenient way to cheat if you know what you're doing. See *Prototypes* below.

Subroutines whose names are in all upper case are reserved to the Perl core, as are modules whose names are in all lower case. A subroutine in all capitals is a loosely-held convention meaning it will be called indirectly by the run-time system itself, usually due to a triggered event. Subroutines that do special, pre-defined things include `AUTOLOAD`, `CLONE`, `DESTROY` plus all functions mentioned in *perltie* and *PerlIO::via*.

The `BEGIN`, `CHECK`, `INIT` and `END` subroutines are not so much subroutines as named special code blocks, of which you can have more than one in a package, and which you can **not** call explicitely. See BEGIN, CHECK, INIT and END in *perlmod*

29.2.1 Private Variables via my()

Synopsis:

```
    my $foo;            # declare $foo lexically local
    my (@wid, %get);    # declare list of variables local
    my $foo = "flurp";  # declare $foo lexical, and init it
    my @oof = @bar;     # declare @oof lexical, and init it
    my $x : Foo = $y;   # similar, with an attribute applied
```

WARNING: The use of attribute lists on `my` declarations is still evolving. The current semantics and interface are subject to change. See *attributes* and *Attribute::Handlers*.

The `my` operator declares the listed variables to be lexically confined to the enclosing block, conditional (`if/unless/elsif/else`), loop (`for/foreach/while/until/continue`), subroutine, `eval`, or `do/require/use`'d file. If more than one value is listed, the list must be placed in parentheses. All listed elements must be legal lvalues. Only alphanumeric identifiers may be lexically scoped–magical built-ins like `$/` must currently be `local`ized with `local` instead.

Unlike dynamic variables created by the `local` operator, lexical variables declared with `my` are totally hidden from the outside world, including any called subroutines. This is true if it's the same subroutine called from itself or elsewhere–every call gets its own copy.

This doesn't mean that a `my` variable declared in a statically enclosing lexical scope would be invisible. Only dynamic scopes are cut off. For example, the `bumpx()` function below has access to the lexical $x variable because both the `my` and the `sub` occurred at the same scope, presumably file scope.

```
    my $x = 10;
    sub bumpx { $x++ }
```

An `eval()`, however, can see lexical variables of the scope it is being evaluated in, so long as the names aren't hidden by declarations within the `eval()` itself. See *perlref*.

The parameter list to my() may be assigned to if desired, which allows you to initialize your variables. (If no initializer is given for a particular variable, it is created with the undefined value.) Commonly this is used to name input parameters to a subroutine. Examples:

```
    $arg = "fred";        # "global" variable
    $n = cube_root(27);
    print "$arg thinks the root is $n\n";
 fred thinks the root is 3

    sub cube_root {
        my $arg = shift;  # name doesn't matter
        $arg **= 1/3;
        return $arg;
    }
```

The `my` is simply a modifier on something you might assign to. So when you do assign to variables in its argument list, `my` doesn't change whether those variables are viewed as a scalar or an array. So

```
    my ($foo) = <STDIN>;                # WRONG?
    my @FOO = <STDIN>;
```

both supply a list context to the right-hand side, while

```
    my $foo = <STDIN>;
```

supplies a scalar context. But the following declares only one variable:

```
    my $foo, $bar = 1;                  # WRONG
```

That has the same effect as

```
    my $foo;
    $bar = 1;
```

The declared variable is not introduced (is not visible) until after the current statement. Thus,

```
    my $x = $x;
```

can be used to initialize a new $x with the value of the old $x, and the expression

```
    my $x = 123 and $x == 123
```

is false unless the old $x happened to have the value `123`.

Lexical scopes of control structures are not bounded precisely by the braces that delimit their controlled blocks; control expressions are part of that scope, too. Thus in the loop

```
    while (my $line = <>) {
        $line = lc $line;
    } continue {
        print $line;
    }
```

the scope of $line extends from its declaration throughout the rest of the loop construct (including the `continue` clause), but not beyond it. Similarly, in the conditional

```
    if ((my $answer = <STDIN>) =~ /^yes$/i) {
        user_agrees();
    } elsif ($answer =~ /^no$/i) {
        user_disagrees();
    } else {
        chomp $answer;
        die "'$answer' is neither 'yes' nor 'no'";
    }
```

the scope of $answer extends from its declaration through the rest of that conditional, including any `elsif` and `else` clauses, but not beyond it. See Simple statements in *perlsyn* for information on the scope of variables in statements with modifiers.

The `foreach` loop defaults to scoping its index variable dynamically in the manner of `local`. However, if the index variable is prefixed with the keyword `my`, or if there is already a lexical by that name in scope, then a new lexical is created instead. Thus in the loop

```
    for my $i (1, 2, 3) {
        some_function();
    }
```

the scope of $i extends to the end of the loop, but not beyond it, rendering the value of $i inaccessible within `some_function()`.

Some users may wish to encourage the use of lexically scoped variables. As an aid to catching implicit uses to package variables, which are always global, if you say

```
    use strict 'vars';
```

then any variable mentioned from there to the end of the enclosing block must either refer to a lexical variable, be predeclared via `our` or `use vars`, or else must be fully qualified with the package name. A compilation error results otherwise. An inner block may countermand this with `no strict 'vars'`.

A `my` has both a compile-time and a run-time effect. At compile time, the compiler takes notice of it. The principal usefulness of this is to quiet `use strict 'vars'`, but it is also essential for generation of closures as detailed in *perlref*. Actual initialization is delayed until run time, though, so it gets executed at the appropriate time, such as each time through a loop, for example.

Variables declared with `my` are not part of any package and are therefore never fully qualified with the package name. In particular, you're not allowed to try to make a package variable (or other global) lexical:

```
    my $pack::var;      # ERROR!  Illegal syntax
    my $_;              # also illegal (currently)
```

In fact, a dynamic variable (also known as package or global variables) are still accessible using the fully qualified `::` notation even while a lexical of the same name is also visible:

```
    package main;
    local $x = 10;
    my    $x = 20;
    print "$x and $::x\n";
```

That will print out `20` and `10`.

You may declare `my` variables at the outermost scope of a file to hide any such identifiers from the world outside that file. This is similar in spirit to C's static variables when they are used at the file level. To do this with a subroutine requires the use of a closure (an anonymous function that accesses enclosing lexicals). If you want to create a private subroutine that cannot be called from outside that block, it can declare a lexical variable containing an anonymous sub reference:

```
my $secret_version = '1.001-beta';
my $secret_sub = sub { print $secret_version };
&$secret_sub();
```

As long as the reference is never returned by any function within the module, no outside module can see the subroutine, because its name is not in any package's symbol table. Remember that it's not *REALLY* called `$some_pack::secret_version` or anything; it's just $secret_version, unqualified and unqualifiable.

This does not work with object methods, however; all object methods have to be in the symbol table of some package to be found. See Function Templates in *perlref* for something of a work-around to this.

29.2.2 Persistent Private Variables

Just because a lexical variable is lexically (also called statically) scoped to its enclosing block, `eval`, or `do` FILE, this doesn't mean that within a function it works like a C static. It normally works more like a C auto, but with implicit garbage collection.

Unlike local variables in C or C++, Perl's lexical variables don't necessarily get recycled just because their scope has exited. If something more permanent is still aware of the lexical, it will stick around. So long as something else references a lexical, that lexical won't be freed–which is as it should be. You wouldn't want memory being free until you were done using it, or kept around once you were done. Automatic garbage collection takes care of this for you.

This means that you can pass back or save away references to lexical variables, whereas to return a pointer to a C auto is a grave error. It also gives us a way to simulate C's function statics. Here's a mechanism for giving a function private variables with both lexical scoping and a static lifetime. If you do want to create something like C's static variables, just enclose the whole function in an extra block, and put the static variable outside the function but in the block.

```
{
    my $secret_val = 0;
    sub gimme_another {
        return ++$secret_val;
    }
}
# $secret_val now becomes unreachable by the outside
# world, but retains its value between calls to gimme_another
```

If this function is being sourced in from a separate file via `require` or `use`, then this is probably just fine. If it's all in the main program, you'll need to arrange for the `my` to be executed early, either by putting the whole block above your main program, or more likely, placing merely a `BEGIN` code block around it to make sure it gets executed before your program starts to run:

```
BEGIN {
    my $secret_val = 0;
    sub gimme_another {
        return ++$secret_val;
    }
}
```

See BEGIN, CHECK, INIT and END in *perlmod* about the special triggered code blocks, `BEGIN`, `CHECK`, `INIT` and `END`.

If declared at the outermost scope (the file scope), then lexicals work somewhat like C's file statics. They are available to all functions in that same file declared below them, but are inaccessible from outside that file. This strategy is sometimes used in modules to create private variables that the whole module can see.

29.2.3 Temporary Values via local()

WARNING: In general, you should be using `my` instead of `local`, because it's faster and safer. Exceptions to this include the global punctuation variables, global filehandles and formats, and direct manipulation of the Perl symbol table itself. `local` is mostly used when the current value of a variable must be visible to called subroutines.

Synopsis:

```
    # localization of values

    local $foo;                # make $foo dynamically local
    local (@wid, %get);        # make list of variables local
    local $foo = "flurp";      # make $foo dynamic, and init it
    local @oof = @bar;         # make @oof dynamic, and init it

    local $hash{key} = "val";  # sets a local value for this hash entry
    local ($cond ? $v1 : $v2); # several types of lvalues support
                               # localization

    # localization of symbols

    local *FH;                 # localize $FH, @FH, %FH, &FH  ...
    local *merlyn = *randal;   # now $merlyn is really $randal, plus
                               #     @merlyn is really @randal, etc
    local *merlyn = 'randal';  # SAME THING: promote 'randal' to *randal
    local *merlyn = \$randal;  # just alias $merlyn, not @merlyn etc
```

A `local` modifies its listed variables to be "local" to the enclosing block, `eval`, or `do FILE`–and to *any subroutine called from within that block*. A `local` just gives temporary values to global (meaning package) variables. It does *not* create a local variable. This is known as dynamic scoping. Lexical scoping is done with `my`, which works more like C's auto declarations.

Some types of lvalues can be localized as well : hash and array elements and slices, conditionals (provided that their result is always localizable), and symbolic references. As for simple variables, this creates new, dynamically scoped values.

If more than one variable or expression is given to `local`, they must be placed in parentheses. This operator works by saving the current values of those variables in its argument list on a hidden stack and restoring them upon exiting the block, subroutine, or eval. This means that called subroutines can also reference the local variable, but not the global one. The argument list may be assigned to if desired, which allows you to initialize your local variables. (If no initializer is given for a particular variable, it is created with an undefined value.)

Because `local` is a run-time operator, it gets executed each time through a loop. Consequently, it's more efficient to localize your variables outside the loop.

Grammatical note on local()

A `local` is simply a modifier on an lvalue expression. When you assign to a `local`ized variable, the `local` doesn't change whether its list is viewed as a scalar or an array. So

```
    local($foo) = <STDIN>;
    local @FOO = <STDIN>;
```

both supply a list context to the right-hand side, while

```
    local $foo = <STDIN>;
```

supplies a scalar context.

Localization of special variables

If you localize a special variable, you'll be giving a new value to it, but its magic won't go away. That means that all side-effects related to this magic still work with the localized value.

This feature allows code like this to work :

```
    # Read the whole contents of FILE in $slurp
    { local $/ = undef; $slurp = <FILE>; }
```

Note, however, that this restricts localization of some values ; for example, the following statement dies, as of perl 5.9.0, with an error *Modification of a read-only value attempted*, because the $1 variable is magical and read-only :

```
    local $1 = 2;
```

Similarly, but in a way more difficult to spot, the following snippet will die in perl 5.9.0 :

```
    sub f { local $_ = "foo"; print }
    for ($1) {
        # now $_ is aliased to $1, thus is magic and readonly
        f();
    }
```

See next section for an alternative to this situation.

WARNING: Localization of tied arrays and hashes does not currently work as described. This will be fixed in a future release of Perl; in the meantime, avoid code that relies on any particular behaviour of localising tied arrays or hashes (localising individual elements is still okay). See Localising Tied Arrays and Hashes Is Broken in *perl58delta* for more details.

Localization of globs

The construct

```
    local *name;
```

creates a whole new symbol table entry for the glob `name` in the current package. That means that all variables in its glob slot ($name, @name, %name, &name, and the `name` filehandle) are dynamically reset.

This implies, among other things, that any magic eventually carried by those variables is locally lost. In other words, saying `local */` will not have any effect on the internal value of the input record separator.

Notably, if you want to work with a brand new value of the default scalar $_, and avoid the potential problem listed above about $_ previously carrying a magic value, you should use `local *_` instead of `local $_`.

Localization of elements of composite types

It's also worth taking a moment to explain what happens when you `local`ize a member of a composite type (i.e. an array or hash element). In this case, the element is `local`ized *by name*. This means that when the scope of the `local()` ends, the saved value will be restored to the hash element whose key was named in the `local()`, or the array element whose index was named in the `local()`. If that element was deleted while the `local()` was in effect (e.g. by a `delete()` from a hash or a `shift()` of an array), it will spring back into existence, possibly extending an array and filling in the skipped elements with `undef`. For instance, if you say

```
    %hash = ( 'This' => 'is', 'a' => 'test' );
    @ary  = ( 0..5 );
    {
         local($ary[5]) = 6;
         local($hash{'a'}) = 'drill';
         while (my $e = pop(@ary)) {
             print "$e . . .\n";
             last unless $e > 3;
         }
         if (@ary) {
             $hash{'only a'} = 'test';
             delete $hash{'a'};
         }
    }
    print join(' ', map { "$_ $hash{$_}" } sort keys %hash),".\n";
    print "The array has ",scalar(@ary)," elements: ",
          join(', ', map { defined $_ ? $_ : 'undef' } @ary),"\n";
```

Perl will print

```
    6 . . .
    4 . . .
    3 . . .
    This is a test only a test.
    The array has 6 elements: 0, 1, 2, undef, undef, 5
```

The behavior of local() on non-existent members of composite types is subject to change in future.

29.2.4 Lvalue subroutines

WARNING: Lvalue subroutines are still experimental and the implementation may change in future versions of Perl.

It is possible to return a modifiable value from a subroutine. To do this, you have to declare the subroutine to return an lvalue.

```
    my $val;
    sub canmod : lvalue {
        # return $val; this doesn't work, don't say "return"
        $val;
    }
    sub nomod {
        $val;
    }

    canmod() = 5;   # assigns to $val
    nomod()  = 5;   # ERROR
```

The scalar/list context for the subroutine and for the right-hand side of assignment is determined as if the subroutine call is replaced by a scalar. For example, consider:

```
    data(2,3) = get_data(3,4);
```

Both subroutines here are called in a scalar context, while in:

```
    (data(2,3)) = get_data(3,4);
```

and in:

```
    (data(2),data(3)) = get_data(3,4);
```

all the subroutines are called in a list context.

Lvalue subroutines are EXPERIMENTAL

They appear to be convenient, but there are several reasons to be circumspect.

You can't use the return keyword, you must pass out the value before falling out of subroutine scope. (see comment in example above). This is usually not a problem, but it disallows an explicit return out of a deeply nested loop, which is sometimes a nice way out.

They violate encapsulation. A normal mutator can check the supplied argument before setting the attribute it is protecting, an lvalue subroutine never gets that chance. Consider;

```
    my $some_array_ref = [];    # protected by mutators ??

    sub set_arr {               # normal mutator
        my $val = shift;
        die("expected array, you supplied ", ref $val)
           unless ref $val eq 'ARRAY';
        $some_array_ref = $val;
    }
    sub set_arr_lv : lvalue {   # lvalue mutator
        $some_array_ref;
    }

    # set_arr_lv cannot stop this !
    set_arr_lv() = { a => 1 };
```

29.2.5 Passing Symbol Table Entries (typeglobs)

WARNING: The mechanism described in this section was originally the only way to simulate pass-by-reference in older versions of Perl. While it still works fine in modern versions, the new reference mechanism is generally easier to work with. See below.

Sometimes you don't want to pass the value of an array to a subroutine but rather the name of it, so that the subroutine can modify the global copy of it rather than working with a local copy. In perl you can refer to all objects of a particular name by prefixing the name with a star: `*foo`. This is often known as a "typeglob", because the star on the front can be thought of as a wildcard match for all the funny prefix characters on variables and subroutines and such.

When evaluated, the typeglob produces a scalar value that represents all the objects of that name, including any filehandle, format, or subroutine. When assigned to, it causes the name mentioned to refer to whatever * value was assigned to it. Example:

```
    sub doubleary {
        local(*someary) = @_;
        foreach $elem (@someary) {
            $elem *= 2;
        }
    }
    doubleary(*foo);
    doubleary(*bar);
```

Scalars are already passed by reference, so you can modify scalar arguments without using this mechanism by referring explicitly to `$_[0]` etc. You can modify all the elements of an array by passing all the elements as scalars, but you have to use the * mechanism (or the equivalent reference mechanism) to `push`, `pop`, or change the size of an array. It will certainly be faster to pass the typeglob (or reference).

Even if you don't want to modify an array, this mechanism is useful for passing multiple arrays in a single LIST, because normally the LIST mechanism will merge all the array values so that you can't extract out the individual arrays. For more on typeglobs, see Typeglobs and Filehandles in *perldata*.

29.2.6 When to Still Use local()

Despite the existence of `my`, there are still three places where the `local` operator still shines. In fact, in these three places, you *must* use `local` instead of `my`.

1. You need to give a global variable a temporary value, especially $_.

   The global variables, like `@ARGV` or the punctuation variables, must be `local`ized with `local()`. This block reads in */etc/motd*, and splits it up into chunks separated by lines of equal signs, which are placed in `@Fields`.

   ```
   {
       local @ARGV = ("/etc/motd");
       local $/ = undef;
       local $_ = <>;
       @Fields = split /^\s*=+\s*$/;
   }
   ```

   It particular, it's important to `local`ize $_ in any routine that assigns to it. Look out for implicit assignments in `while` conditionals.

2. You need to create a local file or directory handle or a local function.

   A function that needs a filehandle of its own must use `local()` on a complete typeglob. This can be used to create new symbol table entries:

   ```
   sub ioqueue {
       local  (*READER, *WRITER);    # not my!
       pipe    (READER,  WRITER)     or die "pipe: $!";
       return (*READER, *WRITER);
   }
   ($head, $tail) = ioqueue();
   ```

   See the Symbol module for a way to create anonymous symbol table entries.

   Because assignment of a reference to a typeglob creates an alias, this can be used to create what is effectively a local function, or at least, a local alias.

   ```
   {
       local *grow = \&shrink; # only until this block exists
       grow();                 # really calls shrink()
       move();                 # if move() grow()s, it shrink()s too
   }
   grow();                     # get the real grow() again
   ```

   See Function Templates in *perlref* for more about manipulating functions by name in this way.

3. You want to temporarily change just one element of an array or hash.

   You can `local`ize just one element of an aggregate. Usually this is done on dynamics:

   ```
   {
       local $SIG{INT} = 'IGNORE';
       funct();                            # uninterruptible
   }
   # interruptibility automatically restored here
   ```

   But it also works on lexically declared aggregates. Prior to 5.005, this operation could on occasion misbehave.

29.2.7 Pass by Reference

If you want to pass more than one array or hash into a function–or return them from it–and have them maintain their integrity, then you're going to have to use an explicit pass-by-reference. Before you do that, you need to understand references as detailed in *perlref*. This section may not make much sense to you otherwise.

Here are a few simple examples. First, let's pass in several arrays to a function and have it pop all of then, returning a new list of all their former last elements:

```
    @tailings = popmany ( \@a, \@b, \@c, \@d );

    sub popmany {
        my $aref;
        my @retlist = ();
        foreach $aref ( @_ ) {
            push @retlist, pop @$aref;
        }
        return @retlist;
    }
```

Here's how you might write a function that returns a list of keys occurring in all the hashes passed to it:

```
    @common = inter( \%foo, \%bar, \%joe );
    sub inter {
        my ($k, $href, %seen); # locals
        foreach $href (@_) {
            while ( $k = each %$href ) {
                $seen{$k}++;
            }
        }
        return grep { $seen{$_} == @_ } keys %seen;
    }
```

So far, we're using just the normal list return mechanism. What happens if you want to pass or return a hash? Well, if you're using only one of them, or you don't mind them concatenating, then the normal calling convention is ok, although a little expensive.

Where people get into trouble is here:

```
    (@a, @b) = func(@c, @d);
or
    (%a, %b) = func(%c, %d);
```

That syntax simply won't work. It sets just @a or %a and clears the @b or %b. Plus the function didn't get passed into two separate arrays or hashes: it got one long list in @_, as always.

If you can arrange for everyone to deal with this through references, it's cleaner code, although not so nice to look at. Here's a function that takes two array references as arguments, returning the two array elements in order of how many elements they have in them:

```
    ($aref, $bref) = func(\@c, \@d);
    print "@$aref has more than @$bref\n";
    sub func {
        my ($cref, $dref) = @_;
        if (@$cref > @$dref) {
            return ($cref, $dref);
        } else {
            return ($dref, $cref);
        }
    }
```

It turns out that you can actually do this also:

```
    (*a, *b) = func(\@c, \@d);
    print "@a has more than @b\n";
    sub func {
        local (*c, *d) = @_;
        if (@c > @d) {
            return (\@c, \@d);
        } else {
            return (\@d, \@c);
        }
    }
```

Here we're using the typeglobs to do symbol table aliasing. It's a tad subtle, though, and also won't work if you're using `my` variables, because only globals (even in disguise as `locals`) are in the symbol table.

If you're passing around filehandles, you could usually just use the bare typeglob, like `*STDOUT`, but typeglobs references work, too. For example:

```
    splutter(\*STDOUT);
    sub splutter {
        my $fh = shift;
        print $fh "her um well a hmmm\n";
    }

    $rec = get_rec(\*STDIN);
    sub get_rec {
        my $fh = shift;
        return scalar <$fh>;
    }
```

If you're planning on generating new filehandles, you could do this. Notice to pass back just the bare *FH, not its reference.

```
    sub openit {
        my $path = shift;
        local *FH;
        return open (FH, $path) ? *FH : undef;
    }
```

29.2.8 Prototypes

Perl supports a very limited kind of compile-time argument checking using function prototyping. If you declare

```
    sub mypush (\@@)
```

then `mypush()` takes arguments exactly like `push()` does. The function declaration must be visible at compile time. The prototype affects only interpretation of new-style calls to the function, where new-style is defined as not using the `&` character. In other words, if you call it like a built-in function, then it behaves like a built-in function. If you call it like an old-fashioned subroutine, then it behaves like an old-fashioned subroutine. It naturally falls out from this rule that prototypes have no influence on subroutine references like `\&foo` or on indirect subroutine calls like `&{$subref}` or `$subref->()`.

Method calls are not influenced by prototypes either, because the function to be called is indeterminate at compile time, since the exact code called depends on inheritance.

Because the intent of this feature is primarily to let you define subroutines that work like built-in functions, here are prototypes for some other functions that parse almost exactly like the corresponding built-in.

```
    Declared as                 Called as

    sub mylink ($$)          mylink $old, $new
    sub myvec ($$$)          myvec $var, $offset, 1
    sub myindex ($$;$)       myindex &getstring, "substr"
    sub mysyswrite ($$$;$)   mysyswrite $buf, 0, length($buf) - $off, $off
    sub myreverse (@)        myreverse $a, $b, $c
    sub myjoin ($@)          myjoin ":", $a, $b, $c
    sub mypop (\@)           mypop @array
    sub mysplice (\@$$@)     mysplice @array, @array, 0, @pushme
    sub mykeys (\%)          mykeys %{$hashref}
    sub myopen (*;$)         myopen HANDLE, $name
    sub mypipe (**)          mypipe READHANDLE, WRITEHANDLE
    sub mygrep (&@)          mygrep { /foo/ } $a, $b, $c
    sub myrand ($)           myrand 42
    sub mytime ()            mytime
```

Any backslashed prototype character represents an actual argument that absolutely must start with that character. The value passed as part of `@_` will be a reference to the actual argument given in the subroutine call, obtained by applying \ to that argument.

You can also backslash several argument types simultaneously by using the `\[]` notation:

```
    sub myref (\[$@%&*])
```

will allow calling myref() as

```
    myref $var
    myref @array
    myref %hash
    myref &sub
    myref *glob
```

and the first argument of myref() will be a reference to a scalar, an array, a hash, a code, or a glob.

Unbackslashed prototype characters have special meanings. Any unbackslashed `@` or `%` eats all remaining arguments, and forces list context. An argument represented by `$` forces scalar context. An `&` requires an anonymous subroutine, which, if passed as the first argument, does not require the `sub` keyword or a subsequent comma.

A * allows the subroutine to accept a bareword, constant, scalar expression, typeglob, or a reference to a typeglob in that slot. The value will be available to the subroutine either as a simple scalar, or (in the latter two cases) as a reference to the typeglob. If you wish to always convert such arguments to a typeglob reference, use Symbol::qualify_to_ref() as follows:

```
    use Symbol 'qualify_to_ref';

    sub foo (*) {
        my $fh = qualify_to_ref(shift, caller);
        ...
    }
```

A semicolon separates mandatory arguments from optional arguments. It is redundant before `@` or `%`, which gobble up everything else.

Note how the last three examples in the table above are treated specially by the parser. `mygrep()` is parsed as a true list operator, `myrand()` is parsed as a true unary operator with unary precedence the same as `rand()`, and `mytime()` is truly without arguments, just like `time()`. That is, if you say

```
    mytime +2;
```

you'll get `mytime() + 2`, not `mytime(2)`, which is how it would be parsed without a prototype.

The interesting thing about `&` is that you can generate new syntax with it, provided it's in the initial position:

```
sub try (&@) {
    my($try,$catch) = @_;
    eval { &$try };
    if ($@) {
        local $_ = $@;
        &$catch;
    }
}
sub catch (&) { $_[0] }

try {
    die "phooey";
} catch {
    /phooey/ and print "unphooey\n";
};
```

That prints `"unphooey"`. (Yes, there are still unresolved issues having to do with visibility of `@_`. I'm ignoring that question for the moment. (But note that if we make `@_` lexically scoped, those anonymous subroutines can act like closures... (Gee, is this sounding a little Lispish? (Never mind.))))

And here's a reimplementation of the Perl `grep` operator:

```
sub mygrep (&@) {
    my $code = shift;
    my @result;
    foreach $_ (@_) {
        push(@result, $_) if &$code;
    }
    @result;
}
```

Some folks would prefer full alphanumeric prototypes. Alphanumerics have been intentionally left out of prototypes for the express purpose of someday in the future adding named, formal parameters. The current mechanism's main goal is to let module writers provide better diagnostics for module users. Larry feels the notation quite understandable to Perl programmers, and that it will not intrude greatly upon the meat of the module, nor make it harder to read. The line noise is visually encapsulated into a small pill that's easy to swallow.

If you try to use an alphanumeric sequence in a prototype you will generate an optional warning - "Illegal character in prototype...". Unfortunately earlier versions of Perl allowed the prototype to be used as long as its prefix was a valid prototype. The warning may be upgraded to a fatal error in a future version of Perl once the majority of offending code is fixed.

It's probably best to prototype new functions, not retrofit prototyping into older ones. That's because you must be especially careful about silent impositions of differing list versus scalar contexts. For example, if you decide that a function should take just one parameter, like this:

```
sub func ($) {
    my $n = shift;
    print "you gave me $n\n";
}
```

and someone has been calling it with an array or expression returning a list:

```
func(@foo);
func( split /:/ );
```

Then you've just supplied an automatic `scalar` in front of their argument, which can be more than a bit surprising. The old `@foo` which used to hold one thing doesn't get passed in. Instead, `func()` now gets passed in a `1`; that is, the number of elements in `@foo`. And the `split` gets called in scalar context so it starts scribbling on your `@_` parameter list. Ouch!

This is all very powerful, of course, and should be used only in moderation to make the world a better place.

29.2.9 Constant Functions

Functions with a prototype of `()` are potential candidates for inlining. If the result after optimization and constant folding is either a constant or a lexically-scoped scalar which has no other references, then it will be used in place of function calls made without `&`. Calls made using `&` are never inlined. (See *constant.pm* for an easy way to declare most constants.)

The following functions would all be inlined:

```
    sub pi ()           { 3.14159 }             # Not exact, but close.
    sub PI ()           { 4 * atan2 1, 1 }      # As good as it gets,
                                                # and it's inlined, too!
    sub ST_DEV ()       { 0 }
    sub ST_INO ()       { 1 }

    sub FLAG_FOO ()     { 1 << 8 }
    sub FLAG_BAR ()     { 1 << 9 }
    sub FLAG_MASK ()    { FLAG_FOO | FLAG_BAR }

    sub OPT_BAZ ()      { not (0x1B58 & FLAG_MASK) }

    sub N () { int(OPT_BAZ) / 3 }

    sub FOO_SET () { 1 if FLAG_MASK & FLAG_FOO }
```

Be aware that these will not be inlined; as they contain inner scopes, the constant folding doesn't reduce them to a single constant:

```
    sub foo_set () { if (FLAG_MASK & FLAG_FOO) { 1 } }

    sub baz_val () {
        if (OPT_BAZ) {
            return 23;
        }
        else {
            return 42;
        }
    }
```

If you redefine a subroutine that was eligible for inlining, you'll get a mandatory warning. (You can use this warning to tell whether or not a particular subroutine is considered constant.) The warning is considered severe enough not to be optional because previously compiled invocations of the function will still be using the old value of the function. If you need to be able to redefine the subroutine, you need to ensure that it isn't inlined, either by dropping the `()` prototype (which changes calling semantics, so beware) or by thwarting the inlining mechanism in some other way, such as

```
    sub not_inlined () {
        23 if $];
    }
```

29.2.10 Overriding Built-in Functions

Many built-in functions may be overridden, though this should be tried only occasionally and for good reason. Typically this might be done by a package attempting to emulate missing built-in functionality on a non-Unix system.

Overriding may be done only by importing the name from a module at compile time–ordinary predeclaration isn't good enough. However, the `use subs` pragma lets you, in effect, predeclare subs via the import syntax, and these names may then override built-in ones:

```
    use subs 'chdir', 'chroot', 'chmod', 'chown';
    chdir $somewhere;
    sub chdir { ... }
```

To unambiguously refer to the built-in form, precede the built-in name with the special package qualifier `CORE::`. For example, saying `CORE::open()` always refers to the built-in `open()`, even if the current package has imported some other subroutine called `&open()` from elsewhere. Even though it looks like a regular function call, it isn't: you can't take a reference to it, such as the incorrect `\&CORE::open` might appear to produce.

Library modules should not in general export built-in names like `open` or `chdir` as part of their default `@EXPORT` list, because these may sneak into someone else's namespace and change the semantics unexpectedly. Instead, if the module adds that name to `@EXPORT_OK`, then it's possible for a user to import the name explicitly, but not implicitly. That is, they could say

```
    use Module 'open';
```

and it would import the `open` override. But if they said

```
    use Module;
```

they would get the default imports without overrides.

The foregoing mechanism for overriding built-in is restricted, quite deliberately, to the package that requests the import. There is a second method that is sometimes applicable when you wish to override a built-in everywhere, without regard to namespace boundaries. This is achieved by importing a sub into the special namespace `CORE::GLOBAL::`. Here is an example that quite brazenly replaces the `glob` operator with something that understands regular expressions.

```
    package REGlob;
    require Exporter;
    @ISA = 'Exporter';
    @EXPORT_OK = 'glob';

    sub import {
        my $pkg = shift;
        return unless @_;
        my $sym = shift;
        my $where = ($sym =~ s/^GLOBAL_// ? 'CORE::GLOBAL' : caller(0));
        $pkg->export($where, $sym, @_);
    }

    sub glob {
        my $pat = shift;
        my @got;
        local *D;
        if (opendir D, '.') {
            @got = grep /$pat/, readdir D;
            closedir D;
        }
        return @got;
    }
    1;
```

And here's how it could be (ab)used:

```
    #use REGlob 'GLOBAL_glob';      # override glob() in ALL namespaces
    package Foo;
    use REGlob 'glob';              # override glob() in Foo:: only
    print for <^[a-z_]+\.pm\$>;     # show all pragmatic modules
```

The initial comment shows a contrived, even dangerous example. By overriding glob globally, you would be forcing the new (and subversive) behavior for the glob operator for *every* namespace, without the complete cognizance or cooperation of the modules that own those namespaces. Naturally, this should be done with extreme caution–if it must be done at all.

The REGlob example above does not implement all the support needed to cleanly override perl's glob operator. The built-in glob has different behaviors depending on whether it appears in a scalar or list context, but our REGlob doesn't. Indeed, many perl built-in have such context sensitive behaviors, and these must be adequately supported by a properly written override. For a fully functional example of overriding glob, study the implementation of File::DosGlob in the standard library.

When you override a built-in, your replacement should be consistent (if possible) with the built-in native syntax. You can achieve this by using a suitable prototype. To get the prototype of an overridable built-in, use the prototype function with an argument of "CORE::builtin_name" (see prototype in *perlfunc*).

Note however that some built-ins can't have their syntax expressed by a prototype (such as system or chomp). If you override them you won't be able to fully mimic their original syntax.

The built-ins do, require and glob can also be overridden, but due to special magic, their original syntax is preserved, and you don't have to define a prototype for their replacements. (You can't override the do BLOCK syntax, though).

require has special additional dark magic: if you invoke your require replacement as require Foo::Bar, it will actually receive the argument "Foo/Bar.pm" in @_. See require in *perlfunc*.

And, as you'll have noticed from the previous example, if you override glob, the <*> glob operator is overridden as well.

In a similar fashion, overriding the readline function also overrides the equivalent I/O operator <FILEHANDLE>.

Finally, some built-ins (e.g. exists or grep) can't be overridden.

29.2.11 Autoloading

If you call a subroutine that is undefined, you would ordinarily get an immediate, fatal error complaining that the subroutine doesn't exist. (Likewise for subroutines being used as methods, when the method doesn't exist in any base class of the class's package.) However, if an AUTOLOAD subroutine is defined in the package or packages used to locate the original subroutine, then that AUTOLOAD subroutine is called with the arguments that would have been passed to the original subroutine. The fully qualified name of the original subroutine magically appears in the global $AUTOLOAD variable of the same package as the AUTOLOAD routine. The name is not passed as an ordinary argument because, er, well, just because, that's why...

Many AUTOLOAD routines load in a definition for the requested subroutine using eval(), then execute that subroutine using a special form of goto() that erases the stack frame of the AUTOLOAD routine without a trace. (See the source to the standard module documented in *AutoLoader*, for example.) But an AUTOLOAD routine can also just emulate the routine and never define it. For example, let's pretend that a function that wasn't defined should just invoke system with those arguments. All you'd do is:

```
sub AUTOLOAD {
    my $program = $AUTOLOAD;
    $program =~ s/.*:://;
    system($program, @_);
}
date();
who('am', 'i');
ls('-l');
```

In fact, if you predeclare functions you want to call that way, you don't even need parentheses:

```
use subs qw(date who ls);
date;
who "am", "i";
ls -l;
```

A more complete example of this is the standard Shell module, which can treat undefined subroutine calls as calls to external programs.

Mechanisms are available to help modules writers split their modules into autoloadable files. See the standard AutoLoader module described in *AutoLoader* and in *AutoSplit*, the standard SelfLoader modules in *SelfLoader*, and the document on adding C functions to Perl code in *perlxs*.

29.2.12 Subroutine Attributes

A subroutine declaration or definition may have a list of attributes associated with it. If such an attribute list is present, it is broken up at space or colon boundaries and treated as though a `use attributes` had been seen. See *attributes* for details about what attributes are currently supported. Unlike the limitation with the obsolescent `use attrs`, the `sub : ATTRLIST` syntax works to associate the attributes with a pre-declaration, and not just with a subroutine definition.

The attributes must be valid as simple identifier names (without any punctuation other than the '_' character). They may have a parameter list appended, which is only checked for whether its parentheses ('(',')') nest properly.

Examples of valid syntax (even though the attributes are unknown):

```
    sub fnord (&\%) : switch(10,foo(7,3))  :  expensive ;
    sub plugh () : Ugly('\(") :Bad ;
    sub xyzzy : _5x5 { ... }
```

Examples of invalid syntax:

```
    sub fnord : switch(10,foo() ; # ()-string not balanced
    sub snoid : Ugly('(') ;       # ()-string not balanced
    sub xyzzy : 5x5 ;             # "5x5" not a valid identifier
    sub plugh : Y2::north ;       # "Y2::north" not a simple identifier
    sub snurt : foo + bar ;       # "+" not a colon or space
```

The attribute list is passed as a list of constant strings to the code which associates them with the subroutine. In particular, the second example of valid syntax above currently looks like this in terms of how it's parsed and invoked:

```
    use attributes __PACKAGE__, \&plugh, q[Ugly('\(")], 'Bad';
```

For further details on attribute lists and their manipulation, see *attributes* and *Attribute::Handlers*.

Chapter 30

perlfunc

Perl builtin functions

30.1 DESCRIPTION

The functions in this section can serve as terms in an expression. They fall into two major categories: list operators and named unary operators. These differ in their precedence relationship with a following comma. (See the precedence table in *perlop*.) List operators take more than one argument, while unary operators can never take more than one argument. Thus, a comma terminates the argument of a unary operator, but merely separates the arguments of a list operator. A unary operator generally provides a scalar context to its argument, while a list operator may provide either scalar or list contexts for its arguments. If it does both, the scalar arguments will be first, and the list argument will follow. (Note that there can ever be only one such list argument.) For instance, splice() has three scalar arguments followed by a list, whereas gethostbyname() has four scalar arguments.

In the syntax descriptions that follow, list operators that expect a list (and provide list context for the elements of the list) are shown with LIST as an argument. Such a list may consist of any combination of scalar arguments or list values; the list values will be included in the list as if each individual element were interpolated at that point in the list, forming a longer single-dimensional list value. Elements of the LIST should be separated by commas.

Any function in the list below may be used either with or without parentheses around its arguments. (The syntax descriptions omit the parentheses.) If you use the parentheses, the simple (but occasionally surprising) rule is this: It *looks* like a function, therefore it *is* a function, and precedence doesn't matter. Otherwise it's a list operator or unary operator, and precedence does matter. And whitespace between the function and left parenthesis doesn't count–so you need to be careful sometimes:

```
    print 1+2+4;        # Prints 7.
    print(1+2) + 4;     # Prints 3.
    print (1+2)+4;      # Also prints 3!
    print +(1+2)+4;     # Prints 7.
    print ((1+2)+4);    # Prints 7.
```

If you run Perl with the **-w** switch it can warn you about this. For example, the third line above produces:

```
    print (...) interpreted as function at - line 1.
    Useless use of integer addition in void context at - line 1.
```

A few functions take no arguments at all, and therefore work as neither unary nor list operators. These include such functions as `time` and `endpwent`. For example, `time+86_400` always means `time() + 86_400`.

For functions that can be used in either a scalar or list context, nonabortive failure is generally indicated in a scalar context by returning the undefined value, and in a list context by returning the null list.

Remember the following important rule: There is **no rule** that relates the behavior of an expression in list context to its behavior in scalar context, or vice versa. It might do two totally different things. Each operator and function decides which sort of value it would be most appropriate to return in scalar context. Some operators return the length of the list that would have been returned in list context. Some operators return the first value in the list. Some operators return the last value in the list. Some operators return a count of successful operations. In general, they do what you want, unless you want consistency.

A named array in scalar context is quite different from what would at first glance appear to be a list in scalar context. You can't get a list like `(1,2,3)` into being in scalar context, because the compiler knows the context at compile time. It would generate the scalar comma operator there, not the list construction version of the comma. That means it was never a list to start with.

In general, functions in Perl that serve as wrappers for system calls of the same name (like chown(2), fork(2), closedir(2), etc.) all return true when they succeed and `undef` otherwise, as is usually mentioned in the descriptions below. This is different from the C interfaces, which return `-1` on failure. Exceptions to this rule are `wait`, `waitpid`, and `syscall`. System calls also set the special `$!` variable on failure. Other functions do not, except accidentally.

30.1.1 Perl Functions by Category

Here are Perl's functions (including things that look like functions, like some keywords and named operators) arranged by category. Some functions appear in more than one place.

Functions for SCALARs or strings

`chomp`, `chop`, `chr`, `crypt`, `hex`, `index`, `lc`, `lcfirst`, `length`, `oct`, `ord`, `pack`, `q/STRING/`, `qq/STRING/`, `reverse`, `rindex`, `sprintf`, `substr`, `tr///`, `uc`, `ucfirst`, `y///`

Regular expressions and pattern matching

`m//`, `pos`, `quotemeta`, `s///`, `split`, `study`, `qr//`

Numeric functions

`abs`, `atan2`, `cos`, `exp`, `hex`, `int`, `log`, `oct`, `rand`, `sin`, `sqrt`, `srand`

Functions for real @ARRAYs

`pop`, `push`, `shift`, `splice`, `unshift`

Functions for list data

`grep`, `join`, `map`, `qw/STRING/`, `reverse`, `sort`, `unpack`

Functions for real %HASHes

`delete`, `each`, `exists`, `keys`, `values`

Input and output functions

`binmode`, `close`, `closedir`, `dbmclose`, `dbmopen`, `die`, `eof`, `fileno`, `flock`, `format`, `getc`, `print`, `printf`, `read`, `readdir`, `rewinddir`, `seek`, `seekdir`, `select`, `syscall`, `sysread`, `sysseek`, `syswrite`, `tell`, `telldir`, `truncate`, `warn`, `write`

Functions for fixed length data or records

`pack`, `read`, `syscall`, `sysread`, `syswrite`, `unpack`, `vec`

Functions for filehandles, files, or directories

`-X`, `chdir`, `chmod`, `chown`, `chroot`, `fcntl`, `glob`, `ioctl`, `link`, `lstat`, `mkdir`, `open`, `opendir`, `readlink`, `rename`, `rmdir`, `stat`, `symlink`, `sysopen`, `umask`, `unlink`, `utime`

Keywords related to the control flow of your perl program

`caller`, `continue`, `die`, `do`, `dump`, `eval`, `exit`, `goto`, `last`, `next`, `redo`, `return`, `sub`, `wantarray`

Keywords related to scoping

caller, import, local, my, our, package, use

Miscellaneous functions

defined, dump, eval, formline, local, my, our, reset, scalar, undef, wantarray

Functions for processes and process groups

alarm, exec, fork, getpgrp, getppid, getpriority, kill, pipe, qx/STRING/, setpgrp, setpriority, sleep, system, times, wait, waitpid

Keywords related to perl modules

do, import, no, package, require, use

Keywords related to classes and object-orientedness

bless, dbmclose, dbmopen, package, ref, tie, tied, untie, use

Low-level socket functions

accept, bind, connect, getpeername, getsockname, getsockopt, listen, recv, send, setsockopt, shutdown, socket, socketpair

System V interprocess communication functions

msgctl, msgget, msgrcv, msgsnd, semctl, semget, semop, shmctl, shmget, shmread, shmwrite

Fetching user and group info

endgrent, endhostent, endnetent, endpwent, getgrent, getgrgid, getgrnam, getlogin, getpwent, getpwnam, getpwuid, setgrent, setpwent

Fetching network info

endprotoent, endservent, gethostbyaddr, gethostbyname, gethostent, getnetbyaddr, getnetbyname, getnetent, getprotobyname, getprotobynumber, getprotoent, getservbyname, getservbyport, getservent, sethostent, setnetent, setprotoent, setservent

Time-related functions

gmtime, localtime, time, times

Functions new in perl5

abs, bless, chomp, chr, exists, formline, glob, import, lc, lcfirst, map, my, no, our, prototype, qx, qw, readline, readpipe, ref, sub*, sysopen, tie, tied, uc, ucfirst, untie, use

* - sub was a keyword in perl4, but in perl5 it is an operator, which can be used in expressions.

Functions obsoleted in perl5

dbmclose, dbmopen

30.1.2 Portability

Perl was born in Unix and can therefore access all common Unix system calls. In non-Unix environments, the functionality of some Unix system calls may not be available, or details of the available functionality may differ slightly. The Perl functions affected by this are:

-X, binmode, chmod, chown, chroot, crypt, dbmclose, dbmopen, dump, endgrent, endhostent, endnetent, endprotoent, endpwent, endservent, exec, fcntl, flock, fork, getgrent, getgrgid, gethostbyname, gethostent, getlogin, getnetbyaddr, getnetbyname, getnetent, getppid, getprgp, getpriority, getprotobynumber, getprotoent, getpwent, getpwnam, getpwuid, getservbyport, getservent, getsockopt, glob, ioctl, kill, link, lstat, msgctl, msgget, msgrcv, msgsnd, open, pipe, readlink, rename, select, semctl, semget, semop, setgrent, sethostent, setnetent, setpgrp, setpriority, setprotoent, setpwent, setservent, setsockopt, shmctl, shmget, shmread, shmwrite, socket, socketpair, stat, symlink, syscall, sysopen, system, times, truncate, umask, unlink, utime, wait, waitpid

For more information about the portability of these functions, see *perlport* and other available platform-specific documentation.

-X EXPR

-X

A file test, where X is one of the letters listed below. This unary operator takes one argument, either a filename or a filehandle, and tests the associated file to see if something is true about it. If the argument is omitted, tests `$_`, except for `-t`, which tests STDIN. Unless otherwise documented, it returns 1 for true and '' for false, or the undefined value if the file doesn't exist. Despite the funny names, precedence is the same as any other named unary operator, and the argument may be parenthesized like any other unary operator. The operator may be any of:

```
    -r  File is readable by effective uid/gid.
    -w  File is writable by effective uid/gid.
    -x  File is executable by effective uid/gid.
    -o  File is owned by effective uid.

    -R  File is readable by real uid/gid.
    -W  File is writable by real uid/gid.
    -X  File is executable by real uid/gid.
    -O  File is owned by real uid.

    -e  File exists.
    -z  File has zero size (is empty).
    -s  File has nonzero size (returns size in bytes).

    -f  File is a plain file.
    -d  File is a directory.
    -l  File is a symbolic link.
    -p  File is a named pipe (FIFO), or Filehandle is a pipe.
    -S  File is a socket.
    -b  File is a block special file.
    -c  File is a character special file.
    -t  Filehandle is opened to a tty.

    -u  File has setuid bit set.
    -g  File has setgid bit set.
    -k  File has sticky bit set.

    -T  File is an ASCII text file (heuristic guess).
    -B  File is a "binary" file (opposite of -T).

    -M  Script start time minus file modification time, in days.
    -A  Same for access time.
    -C  Same for inode change time (Unix, may differ for other platforms)
```

Example:

```
    while (<>) {
        chomp;
        next unless -f $_;      # ignore specials
        #...
    }
```

The interpretation of the file permission operators `-r`, `-R`, `-w`, `-W`, `-x`, and `-X` is by default based solely on the mode of the file and the uids and gids of the user. There may be other reasons you can't actually read, write, or execute the file. Such reasons may be for example network filesystem access controls, ACLs (access control lists), read-only filesystems, and unrecognized executable formats.

Also note that, for the superuser on the local filesystems, the `-r`, `-R`, `-w`, and `-W` tests always return 1, and `-x` and `-X` return 1 if any execute bit is set in the mode. Scripts run by the superuser may thus need to do a stat() to determine the actual mode of the file, or temporarily set their effective uid to something else.

If you are using ACLs, there is a pragma called `filetest` that may produce more accurate results than the bare stat() mode bits. When under the `use filetest 'access'` the above-mentioned filetests will test whether the permission can (not) be granted using the access() family of system calls. Also note that the `-x` and `-X` may under this pragma return true even if there are no execute permission bits set (nor any extra execute permission ACLs). This strangeness is due to the underlying system calls' definitions. Read the documentation for the `filetest` pragma for more information.

Note that `-s/a/b/` does not do a negated substitution. Saying `-exp($foo)` still works as expected, however–only single letters following a minus are interpreted as file tests.

The `-T` and `-B` switches work as follows. The first block or so of the file is examined for odd characters such as strange control codes or characters with the high bit set. If too many strange characters (>30%) are found, it's a `-B` file, otherwise it's a `-T` file. Also, any file containing null in the first block is considered a binary file. If `-T` or `-B` is used on a filehandle, the current IO buffer is examined rather than the first block. Both `-T` and `-B` return true on a null file, or a file at EOF when testing a filehandle. Because you have to read a file to do the `-T` test, on most occasions you want to use a `-f` against the file first, as in `next unless -f $file && -T $file`.

If any of the file tests (or either the `stat` or `lstat` operators) are given the special filehandle consisting of a solitary underline, then the stat structure of the previous file test (or stat operator) is used, saving a system call. (This doesn't work with `-t`, and you need to remember that lstat() and `-l` will leave values in the stat structure for the symbolic link, not the real file.) (Also, if the stat buffer was filled by a `lstat` call, `-T` and `-B` will reset it with the results of `stat _`). Example:

```
print "Can do.\n" if -r $a || -w _ || -x _;

stat($filename);
print "Readable\n" if -r _;
print "Writable\n" if -w _;
print "Executable\n" if -x _;
print "Setuid\n" if -u _;
print "Setgid\n" if -g _;
print "Sticky\n" if -k _;
print "Text\n" if -T _;
print "Binary\n" if -B _;
```

abs VALUE

abs

Returns the absolute value of its argument. If VALUE is omitted, uses `$_`.

accept NEWSOCKET,GENERICSOCKET

Accepts an incoming socket connect, just as the accept(2) system call does. Returns the packed address if it succeeded, false otherwise. See the example in Sockets: Client/Server Communication in *perlipc*.

On systems that support a close-on-exec flag on files, the flag will be set for the newly opened file descriptor, as determined by the value of $^F. See $^F in *perlvar*.

alarm SECONDS

alarm

Arranges to have a SIGALRM delivered to this process after the specified number of wallclock seconds have elapsed. If SECONDS is not specified, the value stored in `$_` is used. (On some machines, unfortunately, the elapsed time may be up to one second less or more than you specified because of how seconds are counted, and process scheduling may delay the delivery of the signal even further.)

Only one timer may be counting at once. Each call disables the previous timer, and an argument of `0` may be supplied to cancel the previous timer without starting a new one. The returned value is the amount of time remaining on the previous timer.

For delays of finer granularity than one second, you may use Perl's four-argument version of select() leaving the first three arguments undefined, or you might be able to use the `syscall` interface to access setitimer(2) if your system supports it. The Time::HiRes module (from CPAN, and starting from Perl 5.8 part of the standard distribution) may also prove useful.

It is usually a mistake to intermix `alarm` and `sleep` calls. (`sleep` may be internally implemented in your system with `alarm`)

If you want to use `alarm` to time out a system call you need to use an `eval`/`die` pair. You can't rely on the alarm causing the system call to fail with `$!` set to `EINTR` because Perl sets up signal handlers to restart system calls on some systems. Using `eval`/`die` always works, modulo the caveats given in Signals in *perlipc*.

```
eval {
    local $SIG{ALRM} = sub { die "alarm\n" }; # NB: \n required
    alarm $timeout;
    $nread = sysread SOCKET, $buffer, $size;
    alarm 0;
};
if ($@) {
    die unless $@ eq "alarm\n";   # propagate unexpected errors
    # timed out
}
else {
    # didn't
}
```

For more information see *perlipc*.

atan2 Y,X

Returns the arctangent of Y/X in the range -PI to PI.

For the tangent operation, you may use the `Math::Trig::tan` function, or use the familiar relation:

```
sub tan { sin($_[0]) / cos($_[0])  }
```

bind SOCKET,NAME

Binds a network address to a socket, just as the bind system call does. Returns true if it succeeded, false otherwise. NAME should be a packed address of the appropriate type for the socket. See the examples in Sockets: Client/Server Communication in *perlipc*.

binmode FILEHANDLE, LAYER

binmode FILEHANDLE

Arranges for FILEHANDLE to be read or written in "binary" or "text" mode on systems where the run-time libraries distinguish between binary and text files. If FILEHANDLE is an expression, the value is taken as the name of the filehandle. Returns true on success, otherwise it returns `undef` and sets `$!` (errno).

On some systems (in general, DOS and Windows-based systems) binmode() is necessary when you're not working with a text file. For the sake of portability it is a good idea to always use it when appropriate, and to never use it when it isn't appropriate. Also, people can set their I/O to be by default UTF-8 encoded Unicode, not bytes.

In other words: regardless of platform, use binmode() on binary data, like for example images.

If LAYER is present it is a single string, but may contain multiple directives. The directives alter the behaviour of the file handle. When LAYER is present using binmode on text file makes sense.

If LAYER is omitted or specified as `:raw` the filehandle is made suitable for passing binary data. This includes turning off possible CRLF translation and marking it as bytes (as opposed to Unicode characters). Note that, despite what may be implied in *"Programming Perl"* (the Camel) or elsewhere, `:raw` is *not* the simply inverse of `:crlf` – other layers which would affect binary nature of the stream are *also* disabled. See *PerlIO*, *perlrun* and the discussion about the PERLIO environment variable.

The `:bytes`, `:crlf`, and `:utf8`, and any other directives of the form `:...`, are called I/O *layers*. The `open` pragma can be used to establish default I/O layers. See *open*.

The LAYER parameter of the binmode() function is described as "DISCIPLINE" in "Programming Perl, 3rd Edition". However, since the publishing of this book, by many known as "Camel III", the consensus of the naming of this functionality has moved from "discipline" to "layer". All documentation of this version of Perl therefore refers to "layers" rather than to "disciplines". Now back to the regularly scheduled documentation...

To mark FILEHANDLE as UTF-8, use `:utf8`.

In general, binmode() should be called after open() but before any I/O is done on the filehandle. Calling binmode() will normally flush any pending buffered output data (and perhaps pending input data) on the handle. An exception to this is the `:encoding` layer that changes the default character encoding of the handle, see *open*. The `:encoding` layer sometimes needs to be called in mid-stream, and it doesn't flush the stream. The `:encoding` also implicitly pushes on top of itself the `:utf8` layer because internally Perl will operate on UTF-8 encoded Unicode characters.

The operating system, device drivers, C libraries, and Perl run-time system all work together to let the programmer treat a single character (`\n`) as the line terminator, irrespective of the external representation. On many operating systems, the native text file representation matches the internal representation, but on some platforms the external representation of `\n` is made up of more than one character.

Mac OS, all variants of Unix, and Stream_LF files on VMS use a single character to end each line in the external representation of text (even though that single character is CARRIAGE RETURN on Mac OS and LINE FEED on Unix and most VMS files). In other systems like OS/2, DOS and the various flavors of MS-Windows your program sees a `\n` as a simple `\cJ`, but what's stored in text files are the two characters `\cM\cJ`. That means that, if you don't use binmode() on these systems, `\cM\cJ` sequences on disk will be converted to `\n` on input, and any `\n` in your program will be converted back to `\cM\cJ` on output. This is what you want for text files, but it can be disastrous for binary files.

Another consequence of using binmode() (on some systems) is that special end-of-file markers will be seen as part of the data stream. For systems from the Microsoft family this means that if your binary data contains `\cZ`, the I/O subsystem will regard it as the end of the file, unless you use binmode().

binmode() is not only important for readline() and print() operations, but also when using read(), seek(), sysread(), syswrite() and tell() (see *perlport* for more details). See the `$/` and `$\` variables in *perlvar* for how to manually set your input and output line-termination sequences.

bless REF,CLASSNAME

bless REF

This function tells the thingy referenced by REF that it is now an object in the CLASSNAME package. If CLASSNAME is omitted, the current package is used. Because a `bless` is often the last thing in a constructor, it returns the reference for convenience. Always use the two-argument version if the function doing the blessing might be inherited by a derived class. See *perltoot* and *perlobj* for more about the blessing (and blessings) of objects.

Consider always blessing objects in CLASSNAMEs that are mixed case. Namespaces with all lowercase names are considered reserved for Perl pragmata. Builtin types have all uppercase names, so to prevent confusion, you may wish to avoid such package names as well. Make sure that CLASSNAME is a true value.

See Perl Modules in *perlmod*.

caller EXPR

caller

Returns the context of the current subroutine call. In scalar context, returns the caller's package name if there is a caller, that is, if we're in a subroutine or `eval` or `require`, and the undefined value otherwise. In list context, returns

```
($package, $filename, $line) = caller;
```

With EXPR, it returns some extra information that the debugger uses to print a stack trace. The value of EXPR indicates how many call frames to go back before the current one.

```
($package, $filename, $line, $subroutine, $hasargs,
$wantarray, $evaltext, $is_require, $hints, $bitmask) = caller($i);
```

Here $subroutine may be `(eval)` if the frame is not a subroutine call, but an `eval`. In such a case additional elements $evaltext and `$is_require` are set: `$is_require` is true if the frame is created by a `require` or `use` statement, $evaltext contains the text of the `eval EXPR` statement. In particular, for an `eval BLOCK` statement, $filename is `(eval)`, but $evaltext is undefined. (Note also that each `use` statement creates a `require` frame inside an `eval EXPR` frame.) $subroutine may also be `(unknown)` if this particular subroutine happens to have been deleted from the symbol table. `$hasargs` is true if a new instance of `@_` was set up for the frame. `$hints` and `$bitmask` contain pragmatic hints that the caller was compiled with. The `$hints` and `$bitmask` values are subject to change between versions of Perl, and are not meant for external use.

Furthermore, when called from within the DB package, caller returns more detailed information: it sets the list variable `@DB::args` to be the arguments with which the subroutine was invoked.

Be aware that the optimizer might have optimized call frames away before `caller` had a chance to get the information. That means that `caller(N)` might not return information about the call frame you expect it do, for `N > 1`. In particular, `@DB::args` might have information from the previous time `caller` was called.

chdir EXPR

Changes the working directory to EXPR, if possible. If EXPR is omitted, changes to the directory specified by `$ENV{HOME}`, if set; if not, changes to the directory specified by `$ENV{LOGDIR}`. (Under VMS, the variable `$ENV{SYS$LOGIN}` is also checked, and used if it is set.) If neither is set, `chdir` does nothing. It returns true upon success, false otherwise. See the example under `die`.

chmod LIST

Changes the permissions of a list of files. The first element of the list must be the numerical mode, which should probably be an octal number, and which definitely should *not* a string of octal digits: `0644` is okay, `'0644'` is not. Returns the number of files successfully changed. See also oct, if all you have is a string.

```
$cnt = chmod 0755, 'foo', 'bar';
chmod 0755, @executables;
$mode = '0644'; chmod $mode, 'foo';      # !!! sets mode to
                                         # --w----r-T
$mode = '0644'; chmod oct($mode), 'foo'; # this is better
$mode = 0644;   chmod $mode, 'foo';      # this is best
```

You can also import the symbolic `S_I*` constants from the Fcntl module:

```
use Fcntl ':mode';

chmod S_IRWXU|S_IRGRP|S_IXGRP|S_IROTH|S_IXOTH, @executables;
# This is identical to the chmod 0755 of the above example.
```

chomp VARIABLE

chomp(LIST)

chomp

This safer version of chop removes any trailing string that corresponds to the current value of `$/` (also known as $INPUT_RECORD_SEPARATOR in the `English` module). It returns the total number of characters removed from all its arguments. It's often used to remove the newline from the end of an input record when you're worried that the final record may be missing its newline. When in paragraph mode (`$/ = ""`), it removes all trailing newlines from the string. When in slurp mode (`$/ = undef`) or fixed-length record mode (`$/` is a reference to an integer or the like, see *perlvar*) chomp() won't remove anything. If VARIABLE is omitted, it chomps `$_`. Example:

```
while (<>) {
    chomp;  # avoid \n on last field
    @array = split(/:/);
    # ...
}
```

If VARIABLE is a hash, it chomps the hash's values, but not its keys.

You can actually chomp anything that's an lvalue, including an assignment:

```
chomp($cwd = `pwd`);
chomp($answer = <STDIN>);
```

If you chomp a list, each element is chomped, and the total number of characters removed is returned.

If the `encoding` pragma is in scope then the lengths returned are calculated from the length of `$/` in Unicode characters, which is not always the same as the length of `$/` in the native encoding.

Note that parentheses are necessary when you're chomping anything that is not a simple variable. This is because `chomp $cwd = `pwd`;` is interpreted as `(chomp $cwd) = `pwd`;`, rather than as `chomp( $cwd = `pwd` )` which you might expect. Similarly, `chomp $a, $b` is interpreted as `chomp($a), $b` rather than as `chomp($a, $b)`.

chop VARIABLE

chop(LIST)

chop

Chops off the last character of a string and returns the character chopped. It is much more efficient than `s/.$//s` because it neither scans nor copies the string. If VARIABLE is omitted, chops `$_`. If VARIABLE is a hash, it chops the hash's values, but not its keys.

You can actually chop anything that's an lvalue, including an assignment.

If you chop a list, each element is chopped. Only the value of the last `chop` is returned.

Note that `chop` returns the last character. To return all but the last character, use `substr($string, 0, -1)`.

See also chomp.

chown LIST

Changes the owner (and group) of a list of files. The first two elements of the list must be the *numeric* uid and gid, in that order. A value of -1 in either position is interpreted by most systems to leave that value unchanged. Returns the number of files successfully changed.

```
$cnt = chown $uid, $gid, 'foo', 'bar';
chown $uid, $gid, @filenames;
```

Here's an example that looks up nonnumeric uids in the passwd file:

```
print "User: ";
chomp($user = <STDIN>);
print "Files: ";
chomp($pattern = <STDIN>);

($login,$pass,$uid,$gid) = getpwnam($user)
    or die "$user not in passwd file";
@ary = glob($pattern);      # expand filenames
chown $uid, $gid, @ary;
```

On most systems, you are not allowed to change the ownership of the file unless you're the superuser, although you should be able to change the group to any of your secondary groups. On insecure systems, these restrictions may be relaxed, but this is not a portable assumption. On POSIX systems, you can detect this condition this way:

```
    use POSIX qw(sysconf _PC_CHOWN_RESTRICTED);
    $can_chown_giveaway = not sysconf(_PC_CHOWN_RESTRICTED);
```

chr NUMBER

chr

Returns the character represented by that NUMBER in the character set. For example, `chr(65)` is `"A"` in either ASCII or Unicode, and chr(0x263a) is a Unicode smiley face. Note that characters from 128 to 255 (inclusive) are by default not encoded in UTF-8 Unicode for backward compatibility reasons (but see *encoding*).

If NUMBER is omitted, uses `$_`.

For the reverse, use ord.

Note that under the `bytes` pragma the NUMBER is masked to the low eight bits.

See *perlunicode* and *encoding* for more about Unicode.

chroot FILENAME

chroot

This function works like the system call by the same name: it makes the named directory the new root directory for all further pathnames that begin with a `/` by your process and all its children. (It doesn't change your current working directory, which is unaffected.) For security reasons, this call is restricted to the superuser. If FILENAME is omitted, does a `chroot` to `$_`.

close FILEHANDLE

close

Closes the file or pipe associated with the file handle, returning true only if IO buffers are successfully flushed and closes the system file descriptor. Closes the currently selected filehandle if the argument is omitted.

You don't have to close FILEHANDLE if you are immediately going to do another `open` on it, because `open` will close it for you. (See `open`.) However, an explicit `close` on an input file resets the line counter (`$.`), while the implicit close done by `open` does not.

If the file handle came from a piped open, `close` will additionally return false if one of the other system calls involved fails, or if the program exits with non-zero status. (If the only problem was that the program exited non-zero, `$!` will be set to `0`.) Closing a pipe also waits for the process executing on the pipe to complete, in case you want to look at the output of the pipe afterwards, and implicitly puts the exit status value of that command into `$?`.

Prematurely closing the read end of a pipe (i.e. before the process writing to it at the other end has closed it) will result in a SIGPIPE being delivered to the writer. If the other end can't handle that, be sure to read all the data before closing the pipe.

Example:

```
    open(OUTPUT, '|sort >foo')  # pipe to sort
        or die "Can't start sort: $!";
    #...                        # print stuff to output
    close OUTPUT                # wait for sort to finish
        or warn $! ? "Error closing sort pipe: $!"
                   : "Exit status $? from sort";
    open(INPUT, 'foo')          # get sort's results
        or die "Can't open 'foo' for input: $!";
```

FILEHANDLE may be an expression whose value can be used as an indirect filehandle, usually the real filehandle name.

closedir DIRHANDLE

Closes a directory opened by `opendir` and returns the success of that system call.

connect SOCKET,NAME

Attempts to connect to a remote socket, just as the connect system call does. Returns true if it succeeded, false otherwise. NAME should be a packed address of the appropriate type for the socket. See the examples in Sockets: Client/Server Communication in *perlipc*.

continue BLOCK

Actually a flow control statement rather than a function. If there is a `continue` BLOCK attached to a BLOCK (typically in a `while` or `foreach`), it is always executed just before the conditional is about to be evaluated again, just like the third part of a `for` loop in C. Thus it can be used to increment a loop variable, even when the loop has been continued via the `next` statement (which is similar to the C `continue` statement).

`last`, `next`, or `redo` may appear within a `continue` block. `last` and `redo` will behave as if they had been executed within the main block. So will `next`, but since it will execute a `continue` block, it may be more entertaining.

```
    while (EXPR) {
        ### redo always comes here
        do_something;
    } continue {
        ### next always comes here
        do_something_else;
        # then back the top to re-check EXPR
    }
    ### last always comes here
```

Omitting the `continue` section is semantically equivalent to using an empty one, logically enough. In that case, `next` goes directly back to check the condition at the top of the loop.

cos EXPR

cos

Returns the cosine of EXPR (expressed in radians). If EXPR is omitted, takes cosine of `$_`.

For the inverse cosine operation, you may use the `Math::Trig::acos()` function, or use this relation:

```
    sub acos { atan2( sqrt(1 - $_[0] * $_[0]), $_[0] ) }
```

crypt PLAINTEXT,SALT

Encrypts a string exactly like the crypt(3) function in the C library (assuming that you actually have a version there that has not been extirpated as a potential munition). This can prove useful for checking the password file for lousy passwords, amongst other things. Only the guys wearing white hats should do this.

Note that crypt is intended to be a one-way function, much like breaking eggs to make an omelette. There is no (known) corresponding decrypt function (in other words, the crypt() is a one-way hash function). As a result, this function isn't all that useful for cryptography. (For that, see your nearby CPAN mirror.)

When verifying an existing encrypted string you should use the encrypted text as the salt (like `crypt($plain, $crypted) eq $crypted`). This allows your code to work with the standard crypt and with more exotic implementations. In other words, do not assume anything about the returned string itself, or how many bytes in the encrypted string matter.

Traditionally the result is a string of 13 bytes: two first bytes of the salt, followed by 11 bytes from the set `[./0-9A-Za-z]`, and only the first eight bytes of the encrypted string mattered, but alternative hashing schemes (like MD5), higher level security schemes (like C2), and implementations on non-UNIX platforms may produce different strings.

When choosing a new salt create a random two character string whose characters come from the set `[./0-9A-Za-z]` (like `join '', ('.', '/', 0..9, 'A'..'Z', 'a'..'z')[rand 64, rand 64]`). This set of characters is just a recommendation; the characters allowed in the salt depend solely on your system's crypt library, and Perl can't restrict what salts `crypt()` accepts.

Here's an example that makes sure that whoever runs this program knows their own password:

```
    $pwd = (getpwuid($<))[1];

    system "stty -echo";
    print "Password: ";
    chomp($word = <STDIN>);
    print "\n";
    system "stty echo";

    if (crypt($word, $pwd) ne $pwd) {
        die "Sorry...\n";
    } else {
        print "ok\n";
    }
```

Of course, typing in your own password to whoever asks you for it is unwise.

The crypt function is unsuitable for encrypting large quantities of data, not least of all because you can't get the information back. Look at the *by-module/Crypt* and *by-module/PGP* directories on your favorite CPAN mirror for a slew of potentially useful modules.

If using crypt() on a Unicode string (which *potentially* has characters with codepoints above 255), Perl tries to make sense of the situation by trying to downgrade (a copy of the string) the string back to an eight-bit byte string before calling crypt() (on that copy). If that works, good. If not, crypt() dies with `Wide character in crypt`.

dbmclose HASH

[This function has been largely superseded by the `untie` function.]

Breaks the binding between a DBM file and a hash.

dbmopen HASH,DBNAME,MASK

[This function has been largely superseded by the `tie` function.]

This binds a dbm(3), ndbm(3), sdbm(3), gdbm(3), or Berkeley DB file to a hash. HASH is the name of the hash. (Unlike normal `open`, the first argument is *not* a filehandle, even though it looks like one). DBNAME is the name of the database (without the *.dir* or *.pag* extension if any). If the database does not exist, it is created with protection specified by MASK (as modified by the `umask`). If your system supports only the older DBM functions, you may perform only one `dbmopen` in your program. In older versions of Perl, if your system had neither DBM nor ndbm, calling `dbmopen` produced a fatal error; it now falls back to sdbm(3).

If you don't have write access to the DBM file, you can only read hash variables, not set them. If you want to test whether you can write, either use file tests or try setting a dummy hash entry inside an `eval`, which will trap the error.

Note that functions such as `keys` and `values` may return huge lists when used on large DBM files. You may prefer to use the `each` function to iterate over large DBM files. Example:

```
    # print out history file offsets
    dbmopen(%HIST,'/usr/lib/news/history',0666);
    while (($key,$val) = each %HIST) {
        print $key, ' = ', unpack('L',$val), "\n";
    }
    dbmclose(%HIST);
```

See also AnyDBM_File for a more general description of the pros and cons of the various dbm approaches, as well as DB_File for a particularly rich implementation.

You can control which DBM library you use by loading that library before you call dbmopen():

```
use DB_File;
dbmopen(%NS_Hist, "$ENV{HOME}/.netscape/history.db")
    or die "Can't open netscape history file: $!";
```

defined EXPR

defined

Returns a Boolean value telling whether EXPR has a value other than the undefined value `undef`. If EXPR is not present, `$_` will be checked.

Many operations return `undef` to indicate failure, end of file, system error, uninitialized variable, and other exceptional conditions. This function allows you to distinguish `undef` from other values. (A simple Boolean test will not distinguish among `undef`, zero, the empty string, and `"0"`, which are all equally false.) Note that since `undef` is a valid scalar, its presence doesn't *necessarily* indicate an exceptional condition: pop returns `undef` when its argument is an empty array, *or* when the element to return happens to be `undef`.

You may also use `defined(&func)` to check whether subroutine `&func` has ever been defined. The return value is unaffected by any forward declarations of `&func`. Note that a subroutine which is not defined may still be callable: its package may have an `AUTOLOAD` method that makes it spring into existence the first time that it is called – see *perlsub*.

Use of `defined` on aggregates (hashes and arrays) is deprecated. It used to report whether memory for that aggregate has ever been allocated. This behavior may disappear in future versions of Perl. You should instead use a simple test for size:

```
if (@an_array) { print "has array elements\n" }
if (%a_hash)   { print "has hash members\n"   }
```

When used on a hash element, it tells you whether the value is defined, not whether the key exists in the hash. Use exists for the latter purpose.

Examples:

```
print if defined $switch{'D'};
print "$val\n" while defined($val = pop(@ary));
die "Can't readlink $sym: $!"
    unless defined($value = readlink $sym);
sub foo { defined &$bar ? &$bar(@_) : die "No bar"; }
$debugging = 0 unless defined $debugging;
```

Note: Many folks tend to overuse `defined`, and then are surprised to discover that the number `0` and `""` (the zero-length string) are, in fact, defined values. For example, if you say

```
"ab" =~ /a(.*)b/;
```

The pattern match succeeds, and `$1` is defined, despite the fact that it matched "nothing". But it didn't really match nothing–rather, it matched something that happened to be zero characters long. This is all very above-board and honest. When a function returns an undefined value, it's an admission that it couldn't give you an honest answer. So you should use `defined` only when you're questioning the integrity of what you're trying to do. At other times, a simple comparison to `0` or `""` is what you want.

See also undef, exists, ref.

delete EXPR

Given an expression that specifies a hash element, array element, hash slice, or array slice, deletes the specified element(s) from the hash or array. In the case of an array, if the array elements happen to be at the end, the size of the array will shrink to the highest element that tests true for exists() (or 0 if no such element exists).

Returns a list with the same number of elements as the number of elements for which deletion was attempted. Each element of that list consists of either the value of the element deleted, or the undefined value. In scalar context, this means that you get the value of the last element deleted (or the undefined value if that element did not exist).

```
    %hash = (foo => 11, bar => 22, baz => 33);
    $scalar = delete $hash{foo};             # $scalar is 11
    $scalar = delete @hash{qw(foo bar)};     # $scalar is 22
    @array  = delete @hash{qw(foo bar baz)}; # @array  is (undef,undef,33)
```

Deleting from `%ENV` modifies the environment. Deleting from a hash tied to a DBM file deletes the entry from the DBM file. Deleting from a `tied` hash or array may not necessarily return anything.

Deleting an array element effectively returns that position of the array to its initial, uninitialized state. Subsequently testing for the same element with exists() will return false. Note that deleting array elements in the middle of an array will not shift the index of the ones after them down–use splice() for that. See exists.

The following (inefficiently) deletes all the values of %HASH and @ARRAY:

```
    foreach $key (keys %HASH) {
        delete $HASH{$key};
    }

    foreach $index (0 .. $#ARRAY) {
        delete $ARRAY[$index];
    }
```

And so do these:

```
    delete @HASH{keys %HASH};

    delete @ARRAY[0 .. $#ARRAY];
```

But both of these are slower than just assigning the empty list or undefining %HASH or @ARRAY:

```
    %HASH = ();         # completely empty %HASH
    undef %HASH;        # forget %HASH ever existed

    @ARRAY = ();        # completely empty @ARRAY
    undef @ARRAY;       # forget @ARRAY ever existed
```

Note that the EXPR can be arbitrarily complicated as long as the final operation is a hash element, array element, hash slice, or array slice lookup:

```
    delete $ref->[$x][$y]{$key};
    delete @{$ref->[$x][$y]}{$key1, $key2, @morekeys};

    delete $ref->[$x][$y][$index];
    delete @{$ref->[$x][$y]}[$index1, $index2, @moreindices];
```

die LIST

Outside an `eval`, prints the value of LIST to `STDERR` and exits with the current value of `$!` (errno). If `$!` is `0`, exits with the value of `($? >> 8)` (backtick ‘command‘ status). If `($? >> 8)` is `0`, exits with `255`. Inside an `eval(),` the error message is stuffed into `$@` and the `eval` is terminated with the undefined value. This makes `die` the way to raise an exception.

Equivalent examples:

```
    die "Can't cd to spool: $!\n" unless chdir '/usr/spool/news';
    chdir '/usr/spool/news' or die "Can't cd to spool: $!\n"
```

If the last element of LIST does not end in a newline, the current script line number and input line number (if any) are also printed, and a newline is supplied. Note that the "input line number" (also known as "chunk") is subject to whatever notion of "line" happens to be currently in effect, and is also available as the special variable `$.`. See $/ in *perlvar* and $. in *perlvar*.

Hint: sometimes appending `", stopped"` to your message will cause it to make better sense when the string `"at foo line 123"` is appended. Suppose you are running script "canasta".

```
    die "/etc/games is no good";
    die "/etc/games is no good, stopped";
```

produce, respectively

```
    /etc/games is no good at canasta line 123.
    /etc/games is no good, stopped at canasta line 123.
```

See also exit(), warn(), and the Carp module.

If LIST is empty and `$@` already contains a value (typically from a previous eval) that value is reused after appending `"\t...propagated"`. This is useful for propagating exceptions:

```
    eval { ... };
    die unless $@ =~ /Expected exception/;
```

If LIST is empty and `$@` contains an object reference that has a `PROPAGATE` method, that method will be called with additional file and line number parameters. The return value replaces the value in `$@`. ie. as if `$@ = eval { $@->PROPAGATE(__FILE__, __LINE__) };` were called.

If `$@` is empty then the string `"Died"` is used.

die() can also be called with a reference argument. If this happens to be trapped within an eval(), $@ contains the reference. This behavior permits a more elaborate exception handling implementation using objects that maintain arbitrary state about the nature of the exception. Such a scheme is sometimes preferable to matching particular string values of $@ using regular expressions. Here's an example:

```
    eval { ... ; die Some::Module::Exception->new( FOO => "bar" ) };
    if ($@) {
        if (ref($@) && UNIVERSAL::isa($@,"Some::Module::Exception")) {
            # handle Some::Module::Exception
        }
        else {
            # handle all other possible exceptions
        }
    }
```

Because perl will stringify uncaught exception messages before displaying them, you may want to overload stringification operations on such custom exception objects. See *overload* for details about that.

You can arrange for a callback to be run just before the `die` does its deed, by setting the `$SIG{__DIE__}` hook. The associated handler will be called with the error text and can change the error message, if it sees fit, by calling `die` again. See $SIG{expr} in *perlvar* for details on setting `%SIG` entries, and §**??** for some examples. Although this feature was meant to be run only right before your program was to exit, this is not currently the case–the `$SIG{__DIE__}` hook is currently called even inside eval()ed blocks/strings! If one wants the hook to do nothing in such situations, put

```
        die @_ if $^S;
```

as the first line of the handler (see $ˆS in *perlvar*). Because this promotes strange action at a distance, this counterintuitive behavior may be fixed in a future release.

do BLOCK

Not really a function. Returns the value of the last command in the sequence of commands indicated by BLOCK. When modified by a loop modifier, executes the BLOCK once before testing the loop condition. (On other statements the loop modifiers test the conditional first.)

`do BLOCK` does *not* count as a loop, so the loop control statements `next`, `last`, or `redo` cannot be used to leave or restart the block. See *perlsyn* for alternative strategies.

do SUBROUTINE(LIST)

A deprecated form of subroutine call. See *perlsub*.

do EXPR

Uses the value of EXPR as a filename and executes the contents of the file as a Perl script. Its primary use is to include subroutines from a Perl subroutine library.

```
    do 'stat.pl';
```

is just like

```
    eval `cat stat.pl`;
```

except that it's more efficient and concise, keeps track of the current filename for error messages, searches the @INC libraries, and updates `%INC` if the file is found. See Predefined Names in *perlvar* for these variables. It also differs in that code evaluated with `do FILENAME` cannot see lexicals in the enclosing scope; `eval STRING` does. It's the same, however, in that it does reparse the file every time you call it, so you probably don't want to do this inside a loop.

If do cannot read the file, it returns undef and sets `$!` to the error. If do can read the file but cannot compile it, it returns undef and sets an error message in `$@`. If the file is successfully compiled, do returns the value of the last expression evaluated.

Note that inclusion of library modules is better done with the `use` and `require` operators, which also do automatic error checking and raise an exception if there's a problem.

You might like to use do to read in a program configuration file. Manual error checking can be done this way:

```
    # read in config files: system first, then user
    for $file ("/share/prog/defaults.rc",
               "$ENV{HOME}/.someprogrc")
   {
        unless ($return = do $file) {
            warn "couldn't parse $file: $@" if $@;
            warn "couldn't do $file: $!"    unless defined $return;
            warn "couldn't run $file"       unless $return;
        }
    }
```

dump LABEL

dump

This function causes an immediate core dump. See also the **-u** command-line switch in *perlrun*, which does the same thing. Primarily this is so that you can use the **undump** program (not supplied) to turn your core dump into an executable binary after having initialized all your variables at the beginning of the program. When the new binary is executed it will begin by executing a `goto LABEL` (with all the restrictions that `goto` suffers). Think of it as a goto with an intervening core dump and reincarnation. If `LABEL` is omitted, restarts the program from the top.

WARNING: Any files opened at the time of the dump will *not* be open any more when the program is reincarnated, with possible resulting confusion on the part of Perl.

This function is now largely obsolete, partly because it's very hard to convert a core file into an executable, and because the real compiler backends for generating portable bytecode and compilable C code have superseded it. That's why you should now invoke it as `CORE::dump()`, if you don't want to be warned against a possible typo.

If you're looking to use *dump* to speed up your program, consider generating bytecode or native C code as described in *perlcc*. If you're just trying to accelerate a CGI script, consider using the `mod_perl` extension to **Apache**, or the CPAN module, CGI::Fast. You might also consider autoloading or selfloading, which at least make your program *appear* to run faster.

each HASH

When called in list context, returns a 2-element list consisting of the key and value for the next element of a hash, so that you can iterate over it. When called in scalar context, returns only the key for the next element in the hash.

Entries are returned in an apparently random order. The actual random order is subject to change in future versions of perl, but it is guaranteed to be in the same order as either the `keys` or `values` function would produce on the same (unmodified) hash. Since Perl 5.8.1 the ordering is different even between different runs of Perl for security reasons (see Algorithmic Complexity Attacks in *perlsec*).

When the hash is entirely read, a null array is returned in list context (which when assigned produces a false (`0`) value), and `undef` in scalar context. The next call to `each` after that will start iterating again. There is a single iterator for each hash, shared by all `each`, `keys`, and `values` function calls in the program; it can be reset by reading all the elements from the hash, or by evaluating `keys HASH` or `values HASH`. If you add or delete elements of a hash while you're iterating over it, you may get entries skipped or duplicated, so don't. Exception: It is always safe to delete the item most recently returned by `each()`, which means that the following code will work:

```
        while (($key, $value) = each %hash) {
          print $key, "\n";
          delete $hash{$key};   # This is safe
        }
```

The following prints out your environment like the printenv(1) program, only in a different order:

```
    while (($key,$value) = each %ENV) {
        print "$key=$value\n";
    }
```

See also `keys`, `values` and `sort`.

eof FILEHANDLE

eof ()

eof

Returns 1 if the next read on FILEHANDLE will return end of file, or if FILEHANDLE is not open. FILEHANDLE may be an expression whose value gives the real filehandle. (Note that this function actually reads a character and then `ungetc`s it, so isn't very useful in an interactive context.) Do not read from a terminal file (or call `eof(FILEHANDLE)` on it) after end-of-file is reached. File types such as terminals may lose the end-of-file condition if you do.

An `eof` without an argument uses the last file read. Using `eof()` with empty parentheses is very different. It refers to the pseudo file formed from the files listed on the command line and accessed via the <> operator. Since <> isn't explicitly opened, as a normal filehandle is, an `eof()` before <> has been used will cause `@ARGV` to be examined to determine if input is available. Similarly, an `eof()` after <> has returned end-of-file will assume you are processing another `@ARGV` list, and if you haven't set `@ARGV`, will read input from `STDIN`; see I/O Operators in *perlop*.

In a `while (<>)` loop, `eof` or `eof(ARGV)` can be used to detect the end of each file, `eof()` will only detect the end of the last file. Examples:

```
# reset line numbering on each input file
while (<>) {
    next if /^\s*#/;        # skip comments
    print "$.\t$_";
} continue {
    close ARGV  if eof;     # Not eof()!
}

# insert dashes just before last line of last file
while (<>) {
    if (eof()) {            # check for end of last file
        print "--------------\n";
    }
    print;
    last if eof();          # needed if we're reading from a terminal
}
```

Practical hint: you almost never need to use `eof` in Perl, because the input operators typically return `undef` when they run out of data, or if there was an error.

eval EXPR

eval BLOCK

In the first form, the return value of EXPR is parsed and executed as if it were a little Perl program. The value of the expression (which is itself determined within scalar context) is first parsed, and if there weren't any errors, executed in the lexical context of the current Perl program, so that any variable settings or subroutine and format definitions remain afterwards. Note that the value is parsed every time the eval executes. If EXPR is omitted, evaluates `$_`. This form is typically used to delay parsing and subsequent execution of the text of EXPR until run time.

In the second form, the code within the BLOCK is parsed only once–at the same time the code surrounding the eval itself was parsed–and executed within the context of the current Perl program. This form is typically used to trap exceptions more efficiently than the first (see below), while also providing the benefit of checking the code within BLOCK at compile time.

The final semicolon, if any, may be omitted from the value of EXPR or within the BLOCK.

In both forms, the value returned is the value of the last expression evaluated inside the mini-program; a return statement may be also used, just as with subroutines. The expression providing the return value is evaluated in void, scalar, or list context, depending on the context of the eval itself. See wantarray for more on how the evaluation context can be determined.

If there is a syntax error or runtime error, or a `die` statement is executed, an undefined value is returned by `eval`, and `$@` is set to the error message. If there was no error, `$@` is guaranteed to be a null string. Beware that using `eval` neither silences perl from printing warnings to STDERR, nor does it stuff the text of warning messages into `$@`. To do either of those, you have to use the `$SIG{__WARN__}` facility, or turn off warnings inside the BLOCK or EXPR using `no warnings 'all'`. See warn, *perlvar*, *warnings* and *perllexwarn*.

Note that, because `eval` traps otherwise-fatal errors, it is useful for determining whether a particular feature (such as `socket` or `symlink`) is implemented. It is also Perl's exception trapping mechanism, where the die operator is used to raise exceptions.

If the code to be executed doesn't vary, you may use the eval-BLOCK form to trap run-time errors without incurring the penalty of recompiling each time. The error, if any, is still returned in `$@`. Examples:

```
# make divide-by-zero nonfatal
eval { $answer = $a / $b; }; warn $@ if $@;

# same thing, but less efficient
eval '$answer = $a / $b'; warn $@ if $@;

# a compile-time error
eval { $answer = };                 # WRONG

# a run-time error
eval '$answer =';   # sets $@
```

Due to the current arguably broken state of `__DIE__` hooks, when using the `eval{}` form as an exception trap in libraries, you may wish not to trigger any `__DIE__` hooks that user code may have installed. You can use the `local $SIG{__DIE__}` construct for this purpose, as shown in this example:

```
# a very private exception trap for divide-by-zero
eval { local $SIG{'__DIE__'}; $answer = $a / $b; };
warn $@ if $@;
```

This is especially significant, given that `__DIE__` hooks can call `die` again, which has the effect of changing their error messages:

```
# __DIE__ hooks may modify error messages
{
   local $SIG{'__DIE__'} =
          sub { (my $x = $_[0]) =~ s/foo/bar/g; die $x };
   eval { die "foo lives here" };
   print $@ if $@;                # prints "bar lives here"
}
```

Because this promotes action at a distance, this counterintuitive behavior may be fixed in a future release.

With an `eval`, you should be especially careful to remember what's being looked at when:

```
eval $x;            # CASE 1
eval "$x";          # CASE 2

eval '$x';          # CASE 3
eval { $x };        # CASE 4

eval "\$$x++";      # CASE 5
$$x++;              # CASE 6
```

Cases 1 and 2 above behave identically: they run the code contained in the variable $x. (Although case 2 has misleading double quotes making the reader wonder what else might be happening (nothing is).) Cases 3 and 4 likewise behave in the same way: they run the code `'$x'`, which does nothing but return the value of $x. (Case 4 is preferred for purely visual reasons, but it also has the advantage of compiling at compile-time instead of at run-time.) Case 5 is a place where normally you *would* like to use double quotes, except that in this particular situation, you can just use symbolic references instead, as in case 6.

`eval BLOCK` does *not* count as a loop, so the loop control statements `next`, `last`, or `redo` cannot be used to leave or restart the block.

Note that as a very special case, an `eval ''` executed within the `DB` package doesn't see the usual surrounding lexical scope, but rather the scope of the first non-DB piece of code that called it. You don't normally need to worry about this unless you are writing a Perl debugger.

exec LIST

exec PROGRAM LIST

The `exec` function executes a system command *and never returns*– use `system` instead of `exec` if you want it to return. It fails and returns false only if the command does not exist *and* it is executed directly instead of via your system's command shell (see below).

Since it's a common mistake to use `exec` instead of `system`, Perl warns you if there is a following statement which isn't `die`, `warn`, or `exit` (if `-w` is set - but you always do that). If you *really* want to follow an `exec` with some other statement, you can use one of these styles to avoid the warning:

```
exec ('foo')   or print STDERR "couldn't exec foo: $!";
{ exec ('foo') }; print STDERR "couldn't exec foo: $!";
```

If there is more than one argument in LIST, or if LIST is an array with more than one value, calls execvp(3) with the arguments in LIST. If there is only one scalar argument or an array with one element in it, the argument is checked for shell metacharacters, and if there are any, the entire argument is passed to the system's command shell for parsing (this is `/bin/sh -c` on Unix platforms, but varies on other platforms). If there are no shell metacharacters in the argument, it is split into words and passed directly to `execvp`, which is more efficient. Examples:

```
exec '/bin/echo', 'Your arguments are: ', @ARGV;
exec "sort $outfile | uniq";
```

If you don't really want to execute the first argument, but want to lie to the program you are executing about its own name, you can specify the program you actually want to run as an "indirect object" (without a comma) in front of the LIST. (This always forces interpretation of the LIST as a multivalued list, even if there is only a single scalar in the list.) Example:

```
$shell = '/bin/csh';
exec $shell '-sh';          # pretend it's a login shell
```

or, more directly,

```
exec {'/bin/csh'} '-sh';    # pretend it's a login shell
```

When the arguments get executed via the system shell, results will be subject to its quirks and capabilities. See 'STRING' in *perlop* for details.

Using an indirect object with `exec` or `system` is also more secure. This usage (which also works fine with system()) forces interpretation of the arguments as a multivalued list, even if the list had just one argument. That way you're safe from the shell expanding wildcards or splitting up words with whitespace in them.

```
@args = ( "echo surprise" );

exec @args;               # subject to shell escapes
                            # if @args == 1
exec { $args[0] } @args;  # safe even with one-arg list
```

The first version, the one without the indirect object, ran the *echo* program, passing it `"surprise"` an argument. The second version didn't–it tried to run a program literally called *"echo surprise"*, didn't find it, and set `$?` to a non-zero value indicating failure.

Beginning with v5.6.0, Perl will attempt to flush all files opened for output before the exec, but this may not be supported on some platforms (see *perlport*). To be safe, you may need to set `$|` ($AUTOFLUSH in English) or call the `autoflush()` method of `IO::Handle` on any open handles in order to avoid lost output.

Note that `exec` will not call your `END` blocks, nor will it call any `DESTROY` methods in your objects.

exists EXPR

Given an expression that specifies a hash element or array element, returns true if the specified element in the hash or array has ever been initialized, even if the corresponding value is undefined. The element is not autovivified if it doesn't exist.

```
    print "Exists\n"    if exists $hash{$key};
    print "Defined\n"   if defined $hash{$key};
    print "True\n"      if $hash{$key};

    print "Exists\n"    if exists $array[$index];
    print "Defined\n"   if defined $array[$index];
    print "True\n"      if $array[$index];
```

A hash or array element can be true only if it's defined, and defined if it exists, but the reverse doesn't necessarily hold true.

Given an expression that specifies the name of a subroutine, returns true if the specified subroutine has ever been declared, even if it is undefined. Mentioning a subroutine name for exists or defined does not count as declaring it. Note that a subroutine which does not exist may still be callable: its package may have an `AUTOLOAD` method that makes it spring into existence the first time that it is called – see *perlsub*.

```
    print "Exists\n"    if exists &subroutine;
    print "Defined\n"   if defined &subroutine;
```

Note that the EXPR can be arbitrarily complicated as long as the final operation is a hash or array key lookup or subroutine name:

```
    if (exists $ref->{A}->{B}->{$key})  { }
    if (exists $hash{A}{B}{$key})       { }

    if (exists $ref->{A}->{B}->[$ix])   { }
    if (exists $hash{A}{B}[$ix])        { }

    if (exists &{$ref->{A}{B}{$key}})   { }
```

Although the deepest nested array or hash will not spring into existence just because its existence was tested, any intervening ones will. Thus `$ref->{"A"}` and `$ref->{"A"}->{"B"}` will spring into existence due to the existence test for the $key element above. This happens anywhere the arrow operator is used, including even:

```
    undef $ref;
    if (exists $ref->{"Some key"})      { }
    print $ref;             # prints HASH(0x80d3d5c)
```

This surprising autovivification in what does not at first–or even second–glance appear to be an lvalue context may be fixed in a future release.

See Pseudo-hashes: Using an array as a hash in *perlref* for specifics on how exists() acts when used on a pseudo-hash.

Use of a subroutine call, rather than a subroutine name, as an argument to exists() is an error.

```
    exists &sub;        # OK
    exists &sub();      # Error
```

exit EXPR

Evaluates EXPR and exits immediately with that value. Example:

```
    $ans = <STDIN>;
    exit 0 if $ans =~ /^[Xx]/;
```

See also `die`. If EXPR is omitted, exits with `0` status. The only universally recognized values for EXPR are `0` for success and 1 for error; other values are subject to interpretation depending on the environment in which the Perl program is running. For example, exiting 69 (EX_UNAVAILABLE) from a *sendmail* incoming-mail filter will cause the mailer to return the item undelivered, but that's not true everywhere.

Don't use `exit` to abort a subroutine if there's any chance that someone might want to trap whatever error happened. Use `die` instead, which can be trapped by an `eval`.

The exit() function does not always exit immediately. It calls any defined `END` routines first, but these `END` routines may not themselves abort the exit. Likewise any object destructors that need to be called are called before the real exit. If this is a problem, you can call `POSIX:_exit($status)` to avoid END and destructor processing. See *perlmod* for details.

exp EXPR

exp

Returns *e* (the natural logarithm base) to the power of EXPR. If EXPR is omitted, gives `exp($_)`.

fcntl FILEHANDLE,FUNCTION,SCALAR

Implements the fcntl(2) function. You'll probably have to say

```
    use Fcntl;
```

first to get the correct constant definitions. Argument processing and value return works just like `ioctl` below. For example:

```
    use Fcntl;
    fcntl($filehandle, F_GETFL, $packed_return_buffer)
        or die "can't fcntl F_GETFL: $!";
```

You don't have to check for `defined` on the return from `fcntl`. Like `ioctl`, it maps a `0` return from the system call into `"0 but true"` in Perl. This string is true in boolean context and `0` in numeric context. It is also exempt from the normal **-w** warnings on improper numeric conversions.

Note that `fcntl` will produce a fatal error if used on a machine that doesn't implement fcntl(2). See the Fcntl module or your fcntl(2) manpage to learn what functions are available on your system.

Here's an example of setting a filehandle named `REMOTE` to be non-blocking at the system level. You'll have to negotiate `$|` on your own, though.

```
    use Fcntl qw(F_GETFL F_SETFL O_NONBLOCK);

    $flags = fcntl(REMOTE, F_GETFL, 0)
                or die "Can't get flags for the socket: $!\n";

    $flags = fcntl(REMOTE, F_SETFL, $flags | O_NONBLOCK)
                or die "Can't set flags for the socket: $!\n";
```

fileno FILEHANDLE

Returns the file descriptor for a filehandle, or undefined if the filehandle is not open. This is mainly useful for constructing bitmaps for `select` and low-level POSIX tty-handling operations. If FILEHANDLE is an expression, the value is taken as an indirect filehandle, generally its name.

You can use this to find out whether two handles refer to the same underlying descriptor:

```
    if (fileno(THIS) == fileno(THAT)) {
        print "THIS and THAT are dups\n";
    }
```

(Filehandles connected to memory objects via new features of `open` may return undefined even though they are open.)

flock FILEHANDLE,OPERATION

Calls flock(2), or an emulation of it, on FILEHANDLE. Returns true for success, false on failure. Produces a fatal error if used on a machine that doesn't implement flock(2), fcntl(2) locking, or lockf(3). `flock` is Perl's portable file locking interface, although it locks only entire files, not records.

Two potentially non-obvious but traditional `flock` semantics are that it waits indefinitely until the lock is granted, and that its locks **merely advisory**. Such discretionary locks are more flexible, but offer fewer guarantees. This means that files locked with `flock` may be modified by programs that do not also use `flock`. See *perlport*, your port's specific documentation, or your system-specific local manpages for details. It's best to assume traditional behavior if you're writing portable programs. (But if you're not, you should as always feel perfectly free to write for your own system's idiosyncrasies (sometimes called "features"). Slavish adherence to portability concerns shouldn't get in the way of your getting your job done.)

OPERATION is one of LOCK_SH, LOCK_EX, or LOCK_UN, possibly combined with LOCK_NB. These constants are traditionally valued 1, 2, 8 and 4, but you can use the symbolic names if you import them from the Fcntl module, either individually, or as a group using the ':flock' tag. LOCK_SH requests a shared lock, LOCK_EX requests an exclusive lock, and LOCK_UN releases a previously requested lock. If LOCK_NB is bitwise-or'ed with LOCK_SH or LOCK_EX then `flock` will return immediately rather than blocking waiting for the lock (check the return status to see if you got it).

To avoid the possibility of miscoordination, Perl now flushes FILEHANDLE before locking or unlocking it.

Note that the emulation built with lockf(3) doesn't provide shared locks, and it requires that FILEHANDLE be open with write intent. These are the semantics that lockf(3) implements. Most if not all systems implement lockf(3) in terms of fcntl(2) locking, though, so the differing semantics shouldn't bite too many people.

Note that the fcntl(2) emulation of flock(3) requires that FILEHANDLE be open with read intent to use LOCK_SH and requires that it be open with write intent to use LOCK_EX.

Note also that some versions of `flock` cannot lock things over the network; you would need to use the more system-specific `fcntl` for that. If you like you can force Perl to ignore your system's flock(2) function, and so provide its own fcntl(2)-based emulation, by passing the switch `-Ud_flock` to the *Configure* program when you configure perl.

Here's a mailbox appender for BSD systems.

```
    use Fcntl ':flock'; # import LOCK_* constants

    sub lock {
        flock(MBOX,LOCK_EX);
        # and, in case someone appended
        # while we were waiting...
        seek(MBOX, 0, 2);
    }

    sub unlock {
        flock(MBOX,LOCK_UN);
    }

    open(MBOX, ">>/usr/spool/mail/$ENV{'USER'}")
            or die "Can't open mailbox: $!";

    lock();
    print MBOX $msg,"\n\n";
    unlock();
```

On systems that support a real flock(), locks are inherited across fork() calls, whereas those that must resort to the more capricious fcntl() function lose the locks, making it harder to write servers.

See also DB_File for other flock() examples.

fork

Does a fork(2) system call to create a new process running the same program at the same point. It returns the child pid to the parent process, `0` to the child process, or `undef` if the fork is unsuccessful. File descriptors (and sometimes locks on those descriptors) are shared, while everything else is copied. On most systems supporting fork(), great care has gone into making it extremely efficient (for example, using copy-on-write technology on data pages), making it the dominant paradigm for multitasking over the last few decades.

Beginning with v5.6.0, Perl will attempt to flush all files opened for output before forking the child process, but this may not be supported on some platforms (see *perlport*). To be safe, you may need to set `$|` ($AUTOFLUSH in English) or call the `autoflush()` method of `IO::Handle` on any open handles in order to avoid duplicate output.

If you `fork` without ever waiting on your children, you will accumulate zombies. On some systems, you can avoid this by setting `$SIG{CHLD}` to `"IGNORE"`. See also *perlipc* for more examples of forking and reaping moribund children.

Note that if your forked child inherits system file descriptors like STDIN and STDOUT that are actually connected by a pipe or socket, even if you exit, then the remote server (such as, say, a CGI script or a backgrounded job launched from a remote shell) won't think you're done. You should reopen those to */dev/null* if it's any issue.

format

Declare a picture format for use by the `write` function. For example:

```
format Something =
    Test: @<<<<<<<< @||||| @>>>>>
          $str,     $%,    '$' . int($num)
.

$str = "widget";
$num = $cost/$quantity;
$~ = 'Something';
write;
```

See *perlform* for many details and examples.

formline PICTURE,LIST

This is an internal function used by `formats`, though you may call it, too. It formats (see *perlform*) a list of values according to the contents of PICTURE, placing the output into the format output accumulator, `$^A` (or `$ACCUMULATOR` in English). Eventually, when a `write` is done, the contents of `$^A` are written to some filehandle, but you could also read `$^A` yourself and then set `$^A` back to `""`. Note that a format typically does one `formline` per line of form, but the `formline` function itself doesn't care how many newlines are embedded in the PICTURE. This means that the `~` and `~~` tokens will treat the entire PICTURE as a single line. You may therefore need to use multiple formlines to implement a single record format, just like the format compiler.

Be careful if you put double quotes around the picture, because an `@` character may be taken to mean the beginning of an array name. `formline` always returns true. See *perlform* for other examples.

getc FILEHANDLE

getc

Returns the next character from the input file attached to FILEHANDLE, or the undefined value at end of file, or if there was an error (in the latter case `$!` is set). If FILEHANDLE is omitted, reads from STDIN. This is not particularly efficient. However, it cannot be used by itself to fetch single characters without waiting for the user to hit enter. For that, try something more like:

```
    if ($BSD_STYLE) {
        system "stty cbreak </dev/tty >/dev/tty 2>&1";
    }
    else {
        system "stty", '-icanon', 'eol', "\001";
    }

    $key = getc(STDIN);

    if ($BSD_STYLE) {
        system "stty -cbreak </dev/tty >/dev/tty 2>&1";
    }
    else {
        system "stty", 'icanon', 'eol', '^@'; # ASCII null
    }
    print "\n";
```

Determination of whether $BSD_STYLE should be set is left as an exercise to the reader.

The `POSIX::getattr` function can do this more portably on systems purporting POSIX compliance. See also the `Term::ReadKey` module from your nearest CPAN site; details on CPAN can be found on CPAN in *perlmodlib*.

getlogin

Implements the C library function of the same name, which on most systems returns the current login from */etc/utmp*, if any. If null, use `getpwuid`.

```
    $login = getlogin || getpwuid($<) || "Kilroy";
```

Do not consider `getlogin` for authentication: it is not as secure as `getpwuid`.

getpeername SOCKET

Returns the packed sockaddr address of other end of the SOCKET connection.

```
    use Socket;
    $hersockaddr    = getpeername(SOCK);
    ($port, $iaddr) = sockaddr_in($hersockaddr);
    $herhostname    = gethostbyaddr($iaddr, AF_INET);
    $herstraddr     = inet_ntoa($iaddr);
```

getpgrp PID

Returns the current process group for the specified PID. Use a PID of `0` to get the current process group for the current process. Will raise an exception if used on a machine that doesn't implement getpgrp(2). If PID is omitted, returns process group of current process. Note that the POSIX version of `getpgrp` does not accept a PID argument, so only `PID==0` is truly portable.

getppid

Returns the process id of the parent process.

Note for Linux users: on Linux, the C functions `getpid()` and `getppid()` return different values from different threads. In order to be portable, this behavior is not reflected by the perl-level function `getppid()`, that returns a consistent value across threads. If you want to call the underlying `getppid()`, you may use the CPAN module `Linux::Pid`.

getpriority WHICH,WHO

Returns the current priority for a process, a process group, or a user. (See *getpriority*(2).) Will raise a fatal exception if used on a machine that doesn't implement getpriority(2).

getpwnam NAME

getgrnam NAME

gethostbyname NAME

getnetbyname NAME

getprotobyname NAME

getpwuid UID

getgrgid GID

getservbyname NAME,PROTO

gethostbyaddr ADDR,ADDRTYPE

getnetbyaddr ADDR,ADDRTYPE

getprotobynumber NUMBER

getservbyport PORT,PROTO

getpwent

getgrent

gethostent

getnetent

getprotoent

getservent

setpwent

setgrent

sethostent STAYOPEN

setnetent STAYOPEN

setprotoent STAYOPEN

setservent STAYOPEN

endpwent

endgrent

endhostent

endnetent

endprotoent

endservent

These routines perform the same functions as their counterparts in the system library. In list context, the return values from the various get routines are as follows:

```
($name,$passwd,$uid,$gid,
   $quota,$comment,$gcos,$dir,$shell,$expire) = getpw*
($name,$passwd,$gid,$members) = getgr*
($name,$aliases,$addrtype,$length,@addrs) = gethost*
($name,$aliases,$addrtype,$net) = getnet*
($name,$aliases,$proto) = getproto*
($name,$aliases,$port,$proto) = getserv*
```

(If the entry doesn't exist you get a null list.)

The exact meaning of the $gcos field varies but it usually contains the real name of the user (as opposed to the login name) and other information pertaining to the user. Beware, however, that in many system users are able to change this information and therefore it cannot be trusted and therefore the $gcos is tainted (see *perlsec*). The $passwd and $shell, user's encrypted password and login shell, are also tainted, because of the same reason.

In scalar context, you get the name, unless the function was a lookup by name, in which case you get the other thing, whatever it is. (If the entry doesn't exist you get the undefined value.) For example:

```
$uid   = getpwnam($name);
$name  = getpwuid($num);
$name  = getpwent();
$gid   = getgrnam($name);
$name  = getgrgid($num);
$name  = getgrent();
#etc.
```

In *getpw*()* the fields $quota, $comment, and $expire are special cases in the sense that in many systems they are unsupported. If the $quota is unsupported, it is an empty scalar. If it is supported, it usually encodes the disk quota. If the $comment field is unsupported, it is an empty scalar. If it is supported it usually encodes some administrative comment about the user. In some systems the $quota field may be $change or $age, fields that have to do with password aging. In some systems the $comment field may be $class. The $expire field, if present, encodes the expiration period of the account or the password. For the availability and the exact meaning of these fields in your system, please consult your getpwnam(3) documentation and your *pwd.h* file. You can also find out from within Perl what your $quota and $comment fields mean and whether you have the $expire field by using the `Config` module and the values `d_pwquota`, `d_pwage`, `d_pwchange`, `d_pwcomment`, and `d_pwexpire`. Shadow password files are only supported if your vendor has implemented them in the intuitive fashion that calling the regular C library routines gets the shadow versions if you're running under privilege or if there exists the shadow(3) functions as found in System V (this includes Solaris and Linux.) Those systems which implement a proprietary shadow password facility are unlikely to be supported.

The $members value returned by *getgr*()* is a space separated list of the login names of the members of the group.

For the *gethost*()* functions, if the `h_errno` variable is supported in C, it will be returned to you via `$?` if the function call fails. The `@addrs` value returned by a successful call is a list of the raw addresses returned by the corresponding system library call. In the Internet domain, each address is four bytes long and you can unpack it by saying something like:

```
($a,$b,$c,$d) = unpack('C4',$addr[0]);
```

The Socket library makes this slightly easier:

```
use Socket;
$iaddr = inet_aton("127.1"); # or whatever address
$name  = gethostbyaddr($iaddr, AF_INET);

# or going the other way
$straddr = inet_ntoa($iaddr);
```

If you get tired of remembering which element of the return list contains which return value, by-name interfaces are provided in standard modules: `File::stat`, `Net::hostent`, `Net::netent`, `Net::protoent`, `Net::servent`, `Time::gmtime`, `Time::localtime`, and `User::grent`. These override the normal built-ins, supplying versions that return objects with the appropriate names for each field. For example:

```
use File::stat;
use User::pwent;
$is_his = (stat($filename)->uid == pwent($whoever)->uid);
```

Even though it looks like they're the same method calls (uid), they aren't, because a `File::stat` object is different from a `User::pwent` object.

getsockname SOCKET

Returns the packed sockaddr address of this end of the SOCKET connection, in case you don't know the address because you have several different IPs that the connection might have come in on.

```
use Socket;
$mysockaddr = getsockname(SOCK);
($port, $myaddr) = sockaddr_in($mysockaddr);
printf "Connect to %s [%s]\n",
   scalar gethostbyaddr($myaddr, AF_INET),
   inet_ntoa($myaddr);
```

getsockopt SOCKET,LEVEL,OPTNAME

Queries the option named OPTNAME associated with SOCKET at a given LEVEL. Options may exist at multiple protocol levels depending on the socket type, but at least the uppermost socket level SOL_SOCKET (defined in the `Socket` module) will exist. To query options at another level the protocol number of the appropriate protocol controlling the option should be supplied. For example, to indicate that an option is to be interpreted by the TCP protocol, LEVEL should be set to the protocol number of TCP, which you can get using getprotobyname.

The call returns a packed string representing the requested socket option, or `undef` if there is an error (the error reason will be in $!). What exactly is in the packed string depends in the LEVEL and OPTNAME, consult your system documentation for details. A very common case however is that the option is an integer, in which case the result will be an packed integer which you can decode using unpack with the `i` (or `I`) format.

An example testing if Nagle's algorithm is turned on on a socket:

```
use Socket;

defined(my $tcp = getprotobyname("tcp"))
    or die "Could not determine the protocol number for tcp";
# my $tcp = Socket::IPPROTO_TCP; # Alternative
my $packed = getsockopt($socket, $tcp, Socket::TCP_NODELAY)
    or die "Could not query TCP_NODELAY SOCKEt option: $!";
my $nodelay = unpack("I", $packed);
print "Nagle's algorithm is turned ", $nodelay ? "off\n" : "on\n";
```

glob EXPR

glob

In list context, returns a (possibly empty) list of filename expansions on the value of EXPR such as the standard Unix shell */bin/csh* would do. In scalar context, glob iterates through such filename expansions, returning undef when the list is exhausted. This is the internal function implementing the <`*.c`> operator, but you can use it directly. If EXPR is omitted, `$_` is used. The <`*.c`> operator is discussed in more detail in I/O Operators in *perlop*.

Beginning with v5.6.0, this operator is implemented using the standard `File::Glob` extension. See *File::Glob* for details.

gmtime EXPR

Converts a time as returned by the time function to an 8-element list with the time localized for the standard Greenwich time zone. Typically used as follows:

```
    #  0    1    2     3     4    5     6     7
    ($sec,$min,$hour,$mday,$mon,$year,$wday,$yday) =
                                            gmtime(time);
```

All list elements are numeric, and come straight out of the C 'struct tm'. $sec, $min, and $hour are the seconds, minutes, and hours of the specified time. $mday is the day of the month, and $mon is the month itself, in the range `0..11` with 0 indicating January and 11 indicating December. $year is the number of years since 1900. That is, $year is `123` in year 2023. $wday is the day of the week, with 0 indicating Sunday and 3 indicating Wednesday. $yday is the day of the year, in the range `0..364` (or `0..365` in leap years.)

Note that the $year element is *not* simply the last two digits of the year. If you assume it is, then you create non-Y2K-compliant programs–and you wouldn't want to do that, would you?

The proper way to get a complete 4-digit year is simply:

```
        $year += 1900;
```

And to get the last two digits of the year (e.g., '01' in 2001) do:

```
        $year = sprintf("%02d", $year % 100);
```

If EXPR is omitted, `gmtime()` uses the current time (`gmtime(time)`).

In scalar context, `gmtime()` returns the ctime(3) value:

```
    $now_string = gmtime;  # e.g., "Thu Oct 13 04:54:34 1994"
```

If you need local time instead of GMT use the localtime builtin. See also the `timegm` function provided by the `Time::Local` module, and the strftime(3) and mktime(3) functions available via the *POSIX* module.

This scalar value is **not** locale dependent (see *perllocale*), but is instead a Perl builtin. To get somewhat similar but locale dependent date strings, see the example in localtime.

goto LABEL

goto EXPR

goto &NAME

The `goto-LABEL` form finds the statement labeled with LABEL and resumes execution there. It may not be used to go into any construct that requires initialization, such as a subroutine or a `foreach` loop. It also can't be used to go into a construct that is optimized away, or to get out of a block or subroutine given to `sort`. It can be used to go almost anywhere else within the dynamic scope, including out of subroutines, but it's usually better to use some other construct such as `last` or `die`. The author of Perl has never felt the need to use this form of `goto` (in Perl, that is–C is another matter). (The difference being that C does not offer named loops combined with loop control. Perl does, and this replaces most structured uses of `goto` in other languages.)

The `goto-EXPR` form expects a label name, whose scope will be resolved dynamically. This allows for computed `goto`s per FORTRAN, but isn't necessarily recommended if you're optimizing for maintainability:

```
    goto ("FOO", "BAR", "GLARCH")[$i];
```

The `goto-&NAME` form is quite different from the other forms of `goto`. In fact, it isn't a goto in the normal sense at all, and doesn't have the stigma associated with other gotos. Instead, it exits the current subroutine (losing any changes set by local()) and immediately calls in its place the named subroutine using the current value of @_. This is used by `AUTOLOAD` subroutines that wish to load another subroutine and then pretend that the other subroutine had been called in the first place (except that any modifications to `@_` in the current subroutine are propagated to the other subroutine.) After the `goto`, not even `caller` will be able to tell that this routine was called first.

NAME needn't be the name of a subroutine; it can be a scalar variable containing a code reference, or a block which evaluates to a code reference.

grep BLOCK LIST

grep EXPR,LIST

This is similar in spirit to, but not the same as, grep(1) and its relatives. In particular, it is not limited to using regular expressions.

Evaluates the BLOCK or EXPR for each element of LIST (locally setting `$_` to each element) and returns the list value consisting of those elements for which the expression evaluated to true. In scalar context, returns the number of times the expression was true.

```
    @foo = grep(!/^#/, @bar);    # weed out comments
```

or equivalently,

```
    @foo = grep {!/^#/} @bar;    # weed out comments
```

Note that `$_` is an alias to the list value, so it can be used to modify the elements of the LIST. While this is useful and supported, it can cause bizarre results if the elements of LIST are not variables. Similarly, grep returns aliases into the original list, much as a for loop's index variable aliases the list elements. That is, modifying an element of a list returned by grep (for example, in a `foreach`, `map` or another `grep`) actually modifies the element in the original list. This is usually something to be avoided when writing clear code.

See also map for a list composed of the results of the BLOCK or EXPR.

hex EXPR

hex

Interprets EXPR as a hex string and returns the corresponding value. (To convert strings that might start with either 0, 0x, or 0b, see oct.) If EXPR is omitted, uses `$_`.

```
    print hex '0xAf'; # prints '175'
    print hex 'aF';   # same
```

Hex strings may only represent integers. Strings that would cause integer overflow trigger a warning. Leading whitespace is not stripped, unlike oct().

import

There is no builtin `import` function. It is just an ordinary method (subroutine) defined (or inherited) by modules that wish to export names to another module. The `use` function calls the `import` method for the package used. See also use, *perlmod*, and *Exporter*.

index STR,SUBSTR,POSITION

index STR,SUBSTR

The index function searches for one string within another, but without the wildcard-like behavior of a full regular-expression pattern match. It returns the position of the first occurrence of SUBSTR in STR at or after POSITION. If POSITION is omitted, starts searching from the beginning of the string. The return value is based at `0` (or whatever you've set the `$[` variable to–but don't do that). If the substring is not found, returns one less than the base, ordinarily `-1`.

int EXPR

int

Returns the integer portion of EXPR. If EXPR is omitted, uses `$_`. You should not use this function for rounding: one because it truncates towards `0`, and two because machine representations of floating point numbers can sometimes produce counterintuitive results. For example, `int(-6.725/0.025)` produces -268 rather than the correct -269; that's because it's really more like -268.99999999999994315658 instead. Usually, the `sprintf`, `printf`, or the `POSIX::floor` and `POSIX::ceil` functions will serve you better than will int().

ioctl FILEHANDLE,FUNCTION,SCALAR

Implements the ioctl(2) function. You'll probably first have to say

```
require "ioctl.ph"; # probably in /usr/local/lib/perl/ioctl.ph
```

to get the correct function definitions. If *ioctl.ph* doesn't exist or doesn't have the correct definitions you'll have to roll your own, based on your C header files such as *<sys/ioctl.h>*. (There is a Perl script called **h2ph** that comes with the Perl kit that may help you in this, but it's nontrivial.) SCALAR will be read and/or written depending on the FUNCTION–a pointer to the string value of SCALAR will be passed as the third argument of the actual `ioctl` call. (If SCALAR has no string value but does have a numeric value, that value will be passed rather than a pointer to the string value. To guarantee this to be true, add a `0` to the scalar before using it.) The `pack` and `unpack` functions may be needed to manipulate the values of structures used by `ioctl`.

The return value of `ioctl` (and `fcntl`) is as follows:

```
        if OS returns:          then Perl returns:
            -1                    undefined value
             0                  string "0 but true"
        anything else               that number
```

Thus Perl returns true on success and false on failure, yet you can still easily determine the actual value returned by the operating system:

```
$retval = ioctl(...) || -1;
printf "System returned %d\n", $retval;
```

The special string "`0 but true`" is exempt from **-w** complaints about improper numeric conversions.

join EXPR,LIST

Joins the separate strings of LIST into a single string with fields separated by the value of EXPR, and returns that new string. Example:

```
$rec = join(':', $login,$passwd,$uid,$gid,$gcos,$home,$shell);
```

Beware that unlike `split`, `join` doesn't take a pattern as its first argument. Compare split.

keys HASH

Returns a list consisting of all the keys of the named hash. (In scalar context, returns the number of keys.)

The keys are returned in an apparently random order. The actual random order is subject to change in future versions of perl, but it is guaranteed to be the same order as either the `values` or `each` function produces (given that the hash has not been modified). Since Perl 5.8.1 the ordering is different even between different runs of Perl for security reasons (see Algorithmic Complexity Attacks in *perlsec*).

As a side effect, calling keys() resets the HASH's internal iterator, see each. (In particular, calling keys() in void context resets the iterator with no other overhead.)

Here is yet another way to print your environment:

```
@keys = keys %ENV;
@values = values %ENV;
while (@keys) {
    print pop(@keys), '=', pop(@values), "\n";
}
```

or how about sorted by key:

```
foreach $key (sort(keys %ENV)) {
    print $key, '=', $ENV{$key}, "\n";
}
```

The returned values are copies of the original keys in the hash, so modifying them will not affect the original hash. Compare values.

To sort a hash by value, you'll need to use a `sort` function. Here's a descending numeric sort of a hash by its values:

```
foreach $key (sort { $hash{$b} <=> $hash{$a} } keys %hash) {
    printf "%4d %s\n", $hash{$key}, $key;
}
```

As an lvalue `keys` allows you to increase the number of hash buckets allocated for the given hash. This can gain you a measure of efficiency if you know the hash is going to get big. (This is similar to pre-extending an array by assigning a larger number to $#array.) If you say

```
keys %hash = 200;
```

then `%hash` will have at least 200 buckets allocated for it–256 of them, in fact, since it rounds up to the next power of two. These buckets will be retained even if you do `%hash = ()`, use `undef %hash` if you want to free the storage while `%hash` is still in scope. You can't shrink the number of buckets allocated for the hash using `keys` in this way (but you needn't worry about doing this by accident, as trying has no effect).

See also `each`, `values` and `sort`.

kill SIGNAL, LIST

Sends a signal to a list of processes. Returns the number of processes successfully signaled (which is not necessarily the same as the number actually killed).

```
$cnt = kill 1, $child1, $child2;
kill 9, @goners;
```

If SIGNAL is zero, no signal is sent to the process. This is a useful way to check that a child process is alive and hasn't changed its UID. See *perlport* for notes on the portability of this construct.

Unlike in the shell, if SIGNAL is negative, it kills process groups instead of processes. (On System V, a negative *PROCESS* number will also kill process groups, but that's not portable.) That means you usually want to use positive not negative signals. You may also use a signal name in quotes.

See Signals in *perlipc* for more details.

last LABEL

last

The `last` command is like the `break` statement in C (as used in loops); it immediately exits the loop in question. If the LABEL is omitted, the command refers to the innermost enclosing loop. The `continue` block, if any, is not executed:

```
LINE: while (<STDIN>) {
    last LINE if /^$/;      # exit when done with header
    #...
}
```

`last` cannot be used to exit a block which returns a value such as `eval {}`, `sub {}` or `do {}`, and should not be used to exit a grep() or map() operation.

Note that a block by itself is semantically identical to a loop that executes once. Thus `last` can be used to effect an early exit out of such a block.

See also continue for an illustration of how `last`, `next`, and `redo` work.

lc EXPR

lc

Returns a lowercased version of EXPR. This is the internal function implementing the `\L` escape in double-quoted strings. Respects current LC_CTYPE locale if `use locale` in force. See *perllocale* and *perlunicode* for more details about locale and Unicode support.

If EXPR is omitted, uses `$_`.

lcfirst EXPR

lcfirst

Returns the value of EXPR with the first character lowercased. This is the internal function implementing the `\l` escape in double-quoted strings. Respects current LC_CTYPE locale if `use locale` in force. See *perllocale* and *perlunicode* for more details about locale and Unicode support.

If EXPR is omitted, uses `$_`.

length EXPR

length

Returns the length in *characters* of the value of EXPR. If EXPR is omitted, returns length of `$_`. Note that this cannot be used on an entire array or hash to find out how many elements these have. For that, use `scalar @array` and `scalar keys %hash` respectively.

Note the *characters*: if the EXPR is in Unicode, you will get the number of characters, not the number of bytes. To get the length in bytes, use `do { use bytes; length(EXPR) }`, see *bytes*.

link OLDFILE,NEWFILE

Creates a new filename linked to the old filename. Returns true for success, false otherwise.

listen SOCKET,QUEUESIZE

Does the same thing that the listen system call does. Returns true if it succeeded, false otherwise. See the example in Sockets: Client/Server Communication in *perlipc*.

local EXPR

You really probably want to be using `my` instead, because `local` isn't what most people think of as "local". See Private Variables via my() in *perlsub* for details.

A local modifies the listed variables to be local to the enclosing block, file, or eval. If more than one value is listed, the list must be placed in parentheses. See Temporary Values via local() in *perlsub* for details, including issues with tied arrays and hashes.

localtime EXPR

Converts a time as returned by the time function to a 9-element list with the time analyzed for the local time zone. Typically used as follows:

```
#  0    1    2     3     4    5     6     7     8
($sec,$min,$hour,$mday,$mon,$year,$wday,$yday,$isdst) =
                                            localtime(time);
```

All list elements are numeric, and come straight out of the C 'struct tm'. $sec, $min, and $hour are the seconds, minutes, and hours of the specified time. $mday is the day of the month, and $mon is the month itself, in the range `0..11` with 0 indicating January and 11 indicating December. $year is the number of years since 1900. That is, $year is `123` in year 2023. $wday is the day of the week, with 0 indicating Sunday and 3 indicating Wednesday. $yday is the day of the year, in the range `0..364` (or `0..365` in leap years.) $isdst is true if the specified time occurs during daylight savings time, false otherwise.

Note that the $year element is *not* simply the last two digits of the year. If you assume it is, then you create non-Y2K-compliant programs–and you wouldn't want to do that, would you?

The proper way to get a complete 4-digit year is simply:

```
        $year += 1900;
```

And to get the last two digits of the year (e.g., ’01’ in 2001) do:

```
        $year = sprintf("%02d", $year % 100);
```

If EXPR is omitted, `localtime()` uses the current time (`localtime(time)`).

In scalar context, `localtime()` returns the ctime(3) value:

```
    $now_string = localtime;  # e.g., "Thu Oct 13 04:54:34 1994"
```

This scalar value is **not** locale dependent but is a Perl builtin. For GMT instead of local time use the gmtime builtin. See also the `Time::Local` module (to convert the second, minutes, hours, ... back to the integer value returned by time()), and the *POSIX* module’s strftime(3) and mktime(3) functions.

To get somewhat similar but locale dependent date strings, set up your locale environment variables appropriately (please see *perllocale*) and try for example:

```
    use POSIX qw(strftime);
    $now_string = strftime "%a %b %e %H:%M:%S %Y", localtime;
    # or for GMT formatted appropriately for your locale:
    $now_string = strftime "%a %b %e %H:%M:%S %Y", gmtime;
```

Note that the `%a` and `%b`, the short forms of the day of the week and the month of the year, may not necessarily be three characters wide.

lock THING

This function places an advisory lock on a shared variable, or referenced object contained in *THING* until the lock goes out of scope.

lock() is a "weak keyword" : this means that if you’ve defined a function by this name (before any calls to it), that function will be called instead. (However, if you’ve said `use threads`, lock() is always a keyword.) See *threads*.

log EXPR

log

Returns the natural logarithm (base *e*) of EXPR. If EXPR is omitted, returns log of `$_`. To get the log of another base, use basic algebra: The base-N log of a number is equal to the natural log of that number divided by the natural log of N. For example:

```
    sub log10 {
        my $n = shift;
        return log($n)/log(10);
    }
```

See also exp for the inverse operation.

lstat EXPR

lstat

Does the same thing as the `stat` function (including setting the special `_` filehandle) but stats a symbolic link instead of the file the symbolic link points to. If symbolic links are unimplemented on your system, a normal `stat` is done. For much more detailed information, please see the documentation for stat.

If EXPR is omitted, stats `$_`.

m//

The match operator. See *perlop*.

map BLOCK LIST

map EXPR,LIST

Evaluates the BLOCK or EXPR for each element of LIST (locally setting `$_` to each element) and returns the list value composed of the results of each such evaluation. In scalar context, returns the total number of elements so generated. Evaluates BLOCK or EXPR in list context, so each element of LIST may produce zero, one, or more elements in the returned value.

```
    @chars = map(chr, @nums);
```

translates a list of numbers to the corresponding characters. And

```
    %hash = map { getkey($_) => $_ } @array;
```

is just a funny way to write

```
    %hash = ();
    foreach $_ (@array) {
        $hash{getkey($_)} = $_;
    }
```

Note that `$_` is an alias to the list value, so it can be used to modify the elements of the LIST. While this is useful and supported, it can cause bizarre results if the elements of LIST are not variables. Using a regular `foreach` loop for this purpose would be clearer in most cases. See also grep for an array composed of those items of the original list for which the BLOCK or EXPR evaluates to true.

`{` starts both hash references and blocks, so `map { ...` could be either the start of map BLOCK LIST or map EXPR, LIST. Because perl doesn't look ahead for the closing `}` it has to take a guess at which its dealing with based what it finds just after the `{`. Usually it gets it right, but if it doesn't it won't realize something is wrong until it gets to the `}` and encounters the missing (or unexpected) comma. The syntax error will be reported close to the `}` but you'll need to change something near the `{` such as using a unary + to give perl some help:

```
    %hash = map {  "\L$_", 1  } @array  # perl guesses EXPR.  wrong
    %hash = map { +"\L$_", 1  } @array  # perl guesses BLOCK. right
    %hash = map { ("\L$_", 1) } @array  # this also works
    %hash = map {  lc($_), 1  } @array  # as does this.
    %hash = map +( lc($_), 1 ), @array  # this is EXPR and works!

    %hash = map  ( lc($_), 1 ), @array  # evaluates to (1, @array)
```

or to force an anon hash constructor use +{

```
   @hashes = map +{ lc($_), 1 }, @array # EXPR, so needs , at end
```

and you get list of anonymous hashes each with only 1 entry.

mkdir FILENAME,MASK

mkdir FILENAME

Creates the directory specified by FILENAME, with permissions specified by MASK (as modified by `umask`). If it succeeds it returns true, otherwise it returns false and sets `$!` (errno). If omitted, MASK defaults to 0777.

In general, it is better to create directories with permissive MASK, and let the user modify that with their `umask`, than it is to supply a restrictive MASK and give the user no way to be more permissive. The exceptions to this rule are when the file or directory should be kept private (mail files, for instance). The perlfunc(1) entry on `umask` discusses the choice of MASK in more detail.

Note that according to the POSIX 1003.1-1996 the FILENAME may have any number of trailing slashes. Some operating and filesystems do not get this right, so Perl automatically removes all trailing slashes to keep everyone happy.

msgctl ID,CMD,ARG

Calls the System V IPC function msgctl(2). You'll probably have to say

```
    use IPC::SysV;
```

first to get the correct constant definitions. If CMD is `IPC_STAT`, then ARG must be a variable which will hold the returned `msqid_ds` structure. Returns like `ioctl`: the undefined value for error, `"0 but true"` for zero, or the actual return value otherwise. See also SysV IPC in *perlipc*, `IPC::SysV`, and `IPC::Semaphore` documentation.

msgget KEY,FLAGS

Calls the System V IPC function msgget(2). Returns the message queue id, or the undefined value if there is an error. See also SysV IPC in *perlipc* and `IPC::SysV` and `IPC::Msg` documentation.

msgrcv ID,VAR,SIZE,TYPE,FLAGS

Calls the System V IPC function msgrcv to receive a message from message queue ID into variable VAR with a maximum message size of SIZE. Note that when a message is received, the message type as a native long integer will be the first thing in VAR, followed by the actual message. This packing may be opened with `unpack("l! a*")`. Taints the variable. Returns true if successful, or false if there is an error. See also SysV IPC in *perlipc*, `IPC::SysV`, and `IPC::SysV::Msg` documentation.

msgsnd ID,MSG,FLAGS

Calls the System V IPC function msgsnd to send the message MSG to the message queue ID. MSG must begin with the native long integer message type, and be followed by the length of the actual message, and finally the message itself. This kind of packing can be achieved with `pack("l! a*", $type, $message)`. Returns true if successful, or false if there is an error. See also `IPC::SysV` and `IPC::SysV::Msg` documentation.

my EXPR

my TYPE EXPR

my EXPR : ATTRS

my TYPE EXPR : ATTRS

A `my` declares the listed variables to be local (lexically) to the enclosing block, file, or `eval`. If more than one value is listed, the list must be placed in parentheses.

The exact semantics and interface of TYPE and ATTRS are still evolving. TYPE is currently bound to the use of `fields` pragma, and attributes are handled using the `attributes` pragma, or starting from Perl 5.8.0 also via the `Attribute::Handlers` module. See Private Variables via my() in *perlsub* for details, and *fields*, *attributes*, and *Attribute::Handlers*.

next LABEL

next

The `next` command is like the `continue` statement in C; it starts the next iteration of the loop:

```
    LINE: while (<STDIN>) {
        next LINE if /^#/;      # discard comments
        #...
    }
```

Note that if there were a `continue` block on the above, it would get executed even on discarded lines. If the LABEL is omitted, the command refers to the innermost enclosing loop.

`next` cannot be used to exit a block which returns a value such as `eval {}`, `sub {}` or `do {}`, and should not be used to exit a grep() or map() operation.

Note that a block by itself is semantically identical to a loop that executes once. Thus `next` will exit such a block early.

See also continue for an illustration of how `last`, `next`, and `redo` work.

no Module VERSION LIST

no Module VERSION

no Module LIST

no Module

See the `use` function, which `no` is the opposite of.

oct EXPR

oct

Interprets EXPR as an octal string and returns the corresponding value. (If EXPR happens to start off with `0x`, interprets it as a hex string. If EXPR starts off with `0b`, it is interpreted as a binary string. Leading whitespace is ignored in all three cases.) The following will handle decimal, binary, octal, and hex in the standard Perl or C notation:

```
    $val = oct($val) if $val =~ /^0/;
```

If EXPR is omitted, uses `$_`. To go the other way (produce a number in octal), use sprintf() or printf():

```
    $perms = (stat("filename"))[2] & 07777;
    $oct_perms = sprintf "%lo", $perms;
```

The oct() function is commonly used when a string such as `644` needs to be converted into a file mode, for example. (Although perl will automatically convert strings into numbers as needed, this automatic conversion assumes base 10.)

open FILEHANDLE,EXPR

open FILEHANDLE,MODE,EXPR

open FILEHANDLE,MODE,EXPR,LIST

open FILEHANDLE,MODE,REFERENCE

open FILEHANDLE

Opens the file whose filename is given by EXPR, and associates it with FILEHANDLE.

(The following is a comprehensive reference to open(): for a gentler introduction you may consider *perlopentut*.)

If FILEHANDLE is an undefined scalar variable (or array or hash element) the variable is assigned a reference to a new anonymous filehandle, otherwise if FILEHANDLE is an expression, its value is used as the name of the real filehandle wanted. (This is considered a symbolic reference, so `use strict 'refs'` should *not* be in effect.)

If EXPR is omitted, the scalar variable of the same name as the FILEHANDLE contains the filename. (Note that lexical variables–those declared with `my`–will not work for this purpose; so if you're using `my`, specify EXPR in your call to open.)

If three or more arguments are specified then the mode of opening and the file name are separate. If MODE is `'<'` or nothing, the file is opened for input. If MODE is `'>'`, the file is truncated and opened for output, being created if necessary. If MODE is `'>>'`, the file is opened for appending, again being created if necessary.

You can put a `'+'` in front of the `'>'` or `'<'` to indicate that you want both read and write access to the file; thus `'+<'` is almost always preferred for read/write updates–the `'+>'` mode would clobber the file first. You can't usually use either read-write mode for updating textfiles, since they have variable length records. See the **-i** switch in *perlrun* for a better approach. The file is created with permissions of `0666` modified by the process' `umask` value.

These various prefixes correspond to the fopen(3) modes of `'r'`, `'r+'`, `'w'`, `'w+'`, `'a'`, and `'a+'`.

In the 2-arguments (and 1-argument) form of the call the mode and filename should be concatenated (in this order), possibly separated by spaces. It is possible to omit the mode in these forms if the mode is `'<'`.

If the filename begins with `'|'`, the filename is interpreted as a command to which output is to be piped, and if the filename ends with a `'|'`, the filename is interpreted as a command which pipes output to us. See Using open() for IPC in *perlipc* for more examples of this. (You are not allowed to `open` to a command that pipes both in *and* out, but see *IPC::Open2*, *IPC::Open3*, and Bidirectional Communication with Another Process in *perlipc* for alternatives.)

For three or more arguments if MODE is `'|-'`, the filename is interpreted as a command to which output is to be piped, and if MODE is `'-|'`, the filename is interpreted as a command which pipes output to us. In the 2-arguments (and 1-argument) form one should replace dash (`'-'`) with the command. See Using open() for IPC in *perlipc* for more examples of this. (You are not allowed to `open` to a command that pipes both in *and* out, but see *IPC::Open2*, *IPC::Open3*, and Bidirectional Communication in *perlipc* for alternatives.)

In the three-or-more argument form of pipe opens, if LIST is specified (extra arguments after the command name) then LIST becomes arguments to the command invoked if the platform supports it. The meaning of `open` with more than three arguments for non-pipe modes is not yet specified. Experimental "layers" may give extra LIST arguments meaning.

In the 2-arguments (and 1-argument) form opening `'-'` opens STDIN and opening `'>-'` opens STDOUT.

You may use the three-argument form of open to specify IO "layers" (sometimes also referred to as "disciplines") to be applied to the handle that affect how the input and output are processed (see *open* and *PerlIO* for more details). For example

```
open(FH, "<:utf8", "file")
```

will open the UTF-8 encoded file containing Unicode characters, see *perluniintro*. (Note that if layers are specified in the three-arg form then default layers set by the `open` pragma are ignored.)

Open returns nonzero upon success, the undefined value otherwise. If the `open` involved a pipe, the return value happens to be the pid of the subprocess.

If you're running Perl on a system that distinguishes between text files and binary files, then you should check out binmode for tips for dealing with this. The key distinction between systems that need `binmode` and those that don't is their text file formats. Systems like Unix, Mac OS, and Plan 9, which delimit lines with a single character, and which encode that character in C as `"\n"`, do not need `binmode`. The rest need it.

When opening a file, it's usually a bad idea to continue normal execution if the request failed, so `open` is frequently used in connection with `die`. Even if `die` won't do what you want (say, in a CGI script, where you want to make a nicely formatted error message (but there are modules that can help with that problem)) you should always check the return value from opening a file. The infrequent exception is when working with an unopened filehandle is actually what you want to do.

As a special case the 3 arg form with a read/write mode and the third argument being `undef`:

```
    open(TMP, "+>", undef) or die ...
```

opens a filehandle to an anonymous temporary file. Also using "+<" works for symmetry, but you really should consider writing something to the temporary file first. You will need to seek() to do the reading.

File handles can be opened to "in memory" files held in Perl scalars via:

```
    open($fh, '>', \$variable) || ..
```

Though if you try to re-open `STDOUT` or `STDERR` as an "in memory" file, you have to close it first:

```
    close STDOUT;
    open STDOUT, '>', \$variable or die "Can't open STDOUT: $!";
```

Examples:

```
    $ARTICLE = 100;
    open ARTICLE or die "Can't find article $ARTICLE: $!\n";
    while (<ARTICLE>) {...
    open(LOG, '>>/usr/spool/news/twitlog');     # (log is reserved)
    # if the open fails, output is discarded

    open(DBASE, '+<', 'dbase.mine')             # open for update
        or die "Can't open 'dbase.mine' for update: $!";

    open(DBASE, '+<dbase.mine')                 # ditto
        or die "Can't open 'dbase.mine' for update: $!";

    open(ARTICLE, '-|', "caesar <$article")     # decrypt article
        or die "Can't start caesar: $!";

    open(ARTICLE, "caesar <$article |")         # ditto
        or die "Can't start caesar: $!";

    open(EXTRACT, "|sort >Tmp$$")               # $$ is our process id
        or die "Can't start sort: $!";

    # in memory files
    open(MEMORY,'>', \$var)
        or die "Can't open memory file: $!";
    print MEMORY "foo!\n";                      # output will end up in $var

    # process argument list of files along with any includes

    foreach $file (@ARGV) {
        process($file, 'fh00');
    }

    sub process {
        my($filename, $input) = @_;
        $input++;               # this is a string increment
        unless (open($input, $filename)) {
            print STDERR "Can't open $filename: $!\n";
            return;
        }

        local $_;
        while (<$input>) {              # note use of indirection
            if (/^#include "(.*)"/) {
                process($1, $input);
                next;
            }
            #...                 # whatever
        }
    }
```

You may also, in the Bourne shell tradition, specify an EXPR beginning with `'>&'`, in which case the rest of the string is interpreted as the name of a filehandle (or file descriptor, if numeric) to be duped (as *dup*(2)) and opened. You may use & after >, >>, <, +>, +>>, and +<. The mode you specify should match the mode of the original filehandle. (Duping a filehandle does not take into account any existing contents of IO buffers.) If you use the 3 arg form then you can pass either a number, the name of a filehandle or the normal "reference to a glob".

Here is a script that saves, redirects, and restores `STDOUT` and `STDERR` using various methods:

```
#!/usr/bin/perl
open my $oldout, ">&STDOUT"     or die "Can't dup STDOUT: $!";
open OLDERR,     ">&", \*STDERR or die "Can't dup STDERR: $!";

open STDOUT, '>', "foo.out" or die "Can't redirect STDOUT: $!";
open STDERR, ">&STDOUT"     or die "Can't dup STDOUT: $!";

select STDERR; $| = 1;      # make unbuffered
select STDOUT; $| = 1;      # make unbuffered

print STDOUT "stdout 1\n";  # this works for
print STDERR "stderr 1\n";  # subprocesses too

open STDOUT, ">&", $oldout or die "Can't dup \$oldout: $!";
open STDERR, ">&OLDERR"    or die "Can't dup OLDERR: $!";

print STDOUT "stdout 2\n";
print STDERR "stderr 2\n";
```

If you specify `'<&=X'`, where `X` is a file descriptor number or a filehandle, then Perl will do an equivalent of C's `fdopen` of that file descriptor (and not call *dup*(2)); this is more parsimonious of file descriptors. For example:

```
# open for input, reusing the fileno of $fd
open(FILEHANDLE, "<&=$fd")
```

or

```
open(FILEHANDLE, "<&=", $fd)
```

or

```
# open for append, using the fileno of OLDFH
open(FH, ">>&=", OLDFH)
```

or

```
open(FH, ">>&=OLDFH")
```

Being parsimonious on filehandles is also useful (besides being parsimonious) for example when something is dependent on file descriptors, like for example locking using flock(). If you do just `open(A, '>>&B')`, the filehandle A will not have the same file descriptor as B, and therefore flock(A) will not flock(B), and vice versa. But with `open(A, '>>&=B')` the filehandles will share the same file descriptor.

Note that if you are using Perls older than 5.8.0, Perl will be using the standard C libraries' fdopen() to implement the "=" functionality. On many UNIX systems fdopen() fails when file descriptors exceed a certain value, typically 255. For Perls 5.8.0 and later, PerlIO is most often the default.

You can see whether Perl has been compiled with PerlIO or not by running `perl -V` and looking for `useperlio=` line. If `useperlio` is `define`, you have PerlIO, otherwise you don't.

If you open a pipe on the command `'-'`, i.e., either `'|-'` or `'-|'` with 2-arguments (or 1-argument) form of open(), then there is an implicit fork done, and the return value of open is the pid of the child within the parent process, and `0` within the child process. (Use `defined($pid)` to determine whether the open was successful.) The filehandle behaves normally for the parent, but i/o to that filehandle is piped from/to the STDOUT/STDIN of the child process. In the child process the filehandle isn't opened–i/o happens from/to the new STDOUT or STDIN. Typically this is used like the normal piped open when you want to exercise more control over just how the pipe command gets executed, such as when you are running setuid, and don't want to have to scan shell commands for metacharacters. The following triples are more or less equivalent:

```
    open(FOO, "|tr '[a-z]' '[A-Z]'");
    open(FOO, '|-', "tr '[a-z]' '[A-Z]'");
    open(FOO, '|-') || exec 'tr', '[a-z]', '[A-Z]';
    open(FOO, '|-', "tr", '[a-z]', '[A-Z]');

    open(FOO, "cat -n '$file'|");
    open(FOO, '-|', "cat -n '$file'");
    open(FOO, '-|') || exec 'cat', '-n', $file;
    open(FOO, '-|', "cat", '-n', $file);
```

The last example in each block shows the pipe as "list form", which is not yet supported on all platforms. A good rule of thumb is that if your platform has true `fork()` (in other words, if your platform is UNIX) you can use the list form.

See Safe Pipe Opens in *perlipc* for more examples of this.

Beginning with v5.6.0, Perl will attempt to flush all files opened for output before any operation that may do a fork, but this may not be supported on some platforms (see *perlport*). To be safe, you may need to set `$|` ($AUTOFLUSH in English) or call the `autoflush()` method of `IO::Handle` on any open handles.

On systems that support a close-on-exec flag on files, the flag will be set for the newly opened file descriptor as determined by the value of $^F. See `$^F` in *perlvar*.

Closing any piped filehandle causes the parent process to wait for the child to finish, and returns the status value in `$?`.

The filename passed to 2-argument (or 1-argument) form of open() will have leading and trailing whitespace deleted, and the normal redirection characters honored. This property, known as "magic open", can often be used to good effect. A user could specify a filename of *"rsh cat file |"*, or you could change certain filenames as needed:

```
    $filename =~ s/(.*\.gz)\s*$/gzip -dc < $1|/;
    open(FH, $filename) or die "Can't open $filename: $!";
```

Use 3-argument form to open a file with arbitrary weird characters in it,

```
    open(FOO, '<', $file);
```

otherwise it's necessary to protect any leading and trailing whitespace:

```
    $file =~ s#^(\s)#./$1#;
    open(FOO, "< $file\0");
```

(this may not work on some bizarre filesystems). One should conscientiously choose between the *magic* and 3-arguments form of open():

```
    open IN, $ARGV[0];
```

will allow the user to specify an argument of the form "`rsh cat file |`", but will not work on a filename which happens to have a trailing space, while

```
    open IN, '<', $ARGV[0];
```

will have exactly the opposite restrictions.

If you want a "real" C `open` (see *open*(2) on your system), then you should use the `sysopen` function, which involves no such magic (but may use subtly different filemodes than Perl open(), which is mapped to C fopen()). This is another way to protect your filenames from interpretation. For example:

```
    use IO::Handle;
    sysopen(HANDLE, $path, O_RDWR|O_CREAT|O_EXCL)
        or die "sysopen $path: $!";
    $oldfh = select(HANDLE); $| = 1; select($oldfh);
    print HANDLE "stuff $$\n";
    seek(HANDLE, 0, 0);
    print "File contains: ", <HANDLE>;
```

Using the constructor from the `IO::Handle` package (or one of its subclasses, such as `IO::File` or `IO::Socket`), you can generate anonymous filehandles that have the scope of whatever variables hold references to them, and automatically close whenever and however you leave that scope:

```
    use IO::File;
    #...
    sub read_myfile_munged {
        my $ALL = shift;
        my $handle = new IO::File;
        open($handle, "myfile") or die "myfile: $!";
        $first = <$handle>
            or return ();     # Automatically closed here.
        mung $first or die "mung failed";       # Or here.
        return $first, <$handle> if $ALL;       # Or here.
        $first;                                 # Or here.
    }
```

See seek for some details about mixing reading and writing.

opendir DIRHANDLE,EXPR

Opens a directory named EXPR for processing by `readdir`, `telldir`, `seekdir`, `rewinddir`, and `closedir`. Returns true if successful. DIRHANDLE may be an expression whose value can be used as an indirect dirhandle, usually the real dirhandle name. If DIRHANDLE is an undefined scalar variable (or array or hash element), the variable is assigned a reference to a new anonymous dirhandle. DIRHANDLEs have their own namespace separate from FILEHANDLEs.

ord EXPR

ord

Returns the numeric (the native 8-bit encoding, like ASCII or EBCDIC, or Unicode) value of the first character of EXPR. If EXPR is omitted, uses `$_`.

For the reverse, see chr. See *perlunicode* and *encoding* for more about Unicode.

our EXPR

our EXPR TYPE

our EXPR : ATTRS

our TYPE EXPR : ATTRS

An `our` declares the listed variables to be valid globals within the enclosing block, file, or `eval`. That is, it has the same scoping rules as a "my" declaration, but does not create a local variable. If more than one value is listed, the list must be placed in parentheses. The `our` declaration has no semantic effect unless "use strict vars" is in effect, in which case it lets you use the declared global variable without qualifying it with a package name. (But only within the lexical scope of the `our` declaration. In this it differs from "use vars", which is package scoped.)

An `our` declaration declares a global variable that will be visible across its entire lexical scope, even across package boundaries. The package in which the variable is entered is determined at the point of the declaration, not at the point of use. This means the following behavior holds:

```
    package Foo;
    our $bar;           # declares $Foo::bar for rest of lexical scope
    $bar = 20;

    package Bar;
    print $bar;         # prints 20
```

Multiple `our` declarations in the same lexical scope are allowed if they are in different packages. If they happened to be in the same package, Perl will emit warnings if you have asked for them.

```
    use warnings;
    package Foo;
    our $bar;           # declares $Foo::bar for rest of lexical scope
    $bar = 20;

    package Bar;
    our $bar = 30;      # declares $Bar::bar for rest of lexical scope
    print $bar;         # prints 30

    our $bar;           # emits warning
```

An `our` declaration may also have a list of attributes associated with it.

The exact semantics and interface of TYPE and ATTRS are still evolving. TYPE is currently bound to the use of `fields` pragma, and attributes are handled using the `attributes` pragma, or starting from Perl 5.8.0 also via the `Attribute::Handlers` module. See Private Variables via my() in *perlsub* for details, and *fields*, *attributes*, and *Attribute::Handlers*.

The only currently recognized `our()` attribute is `unique` which indicates that a single copy of the global is to be used by all interpreters should the program happen to be running in a multi-interpreter environment. (The default behaviour would be for each interpreter to have its own copy of the global.) Examples:

```
    our @EXPORT : unique = qw(foo);
    our %EXPORT_TAGS : unique = (bar => [qw(aa bb cc)]);
    our $VERSION : unique = "1.00";
```

Note that this attribute also has the effect of making the global readonly when the first new interpreter is cloned (for example, when the first new thread is created).

Multi-interpreter environments can come to being either through the fork() emulation on Windows platforms, or by embedding perl in a multi-threaded application. The `unique` attribute does nothing in all other environments.

Warning: the current implementation of this attribute operates on the typeglob associated with the variable; this means that `our $x : unique` also has the effect of `our @x : unique; our %x : unique`. This may be subject to change.

pack TEMPLATE,LIST

Takes a LIST of values and converts it into a string using the rules given by the TEMPLATE. The resulting string is the concatenation of the converted values. Typically, each converted value looks like its machine-level representation. For example, on 32-bit machines a converted integer may be represented by a sequence of 4 bytes.

The TEMPLATE is a sequence of characters that give the order and type of values, as follows:

```
    a   A string with arbitrary binary data, will be null padded.
    A   A text (ASCII) string, will be space padded.
    Z   A null terminated (ASCIZ) string, will be null padded.
```

```
b   A bit string (ascending bit order inside each byte, like vec()).
B   A bit string (descending bit order inside each byte).
h   A hex string (low nybble first).
H   A hex string (high nybble first).

c   A signed char value.
C   An unsigned char value.  Only does bytes.  See U for Unicode.

s   A signed short value.
S   An unsigned short value.
      (This 'short' is _exactly_ 16 bits, which may differ from
       what a local C compiler calls 'short'.  If you want
       native-length shorts, use the '!' suffix.)

i   A signed integer value.
I   An unsigned integer value.
      (This 'integer' is _at_least_ 32 bits wide.  Its exact
       size depends on what a local C compiler calls 'int',
       and may even be larger than the 'long' described in
       the next item.)

l   A signed long value.
L   An unsigned long value.
      (This 'long' is _exactly_ 32 bits, which may differ from
       what a local C compiler calls 'long'.  If you want
       native-length longs, use the '!' suffix.)

n   An unsigned short in "network" (big-endian) order.
N   An unsigned long in "network" (big-endian) order.
v   An unsigned short in "VAX" (little-endian) order.
V   An unsigned long in "VAX" (little-endian) order.
      (These 'shorts' and 'longs' are _exactly_ 16 bits and
       _exactly_ 32 bits, respectively.)

q   A signed quad (64-bit) value.
Q   An unsigned quad value.
      (Quads are available only if your system supports 64-bit
       integer values _and_ if Perl has been compiled to support those.
       Causes a fatal error otherwise.)

j   A signed integer value (a Perl internal integer, IV).
J   An unsigned integer value (a Perl internal unsigned integer, UV).

f   A single-precision float in the native format.
d   A double-precision float in the native format.

F   A floating point value in the native native format
       (a Perl internal floating point value, NV).
D   A long double-precision float in the native format.
      (Long doubles are available only if your system supports long
       double values _and_ if Perl has been compiled to support those.
       Causes a fatal error otherwise.)

p   A pointer to a null-terminated string.
P   A pointer to a structure (fixed-length string).
```

```
u   A uuencoded string.
U   A Unicode character number.  Encodes to UTF-8 internally
    (or UTF-EBCDIC in EBCDIC platforms).

w   A BER compressed integer.  Its bytes represent an unsigned
    integer in base 128, most significant digit first, with as
    few digits as possible.  Bit eight (the high bit) is set
    on each byte except the last.

x   A null byte.
X   Back up a byte.
@   Null fill to absolute position, counted from the start of
    the innermost ()-group.
(   Start of a ()-group.
```

The following rules apply:

- Each letter may optionally be followed by a number giving a repeat count. With all types except `a`, `A`, `Z`, `b`, `B`, `h`, `H`, `@`, `x`, `X` and `P` the pack function will gobble up that many values from the LIST. A * for the repeat count means to use however many items are left, except for `@`, `x`, `X`, where it is equivalent to `0`, and `u`, where it is equivalent to 1 (or 45, what is the same). A numeric repeat count may optionally be enclosed in brackets, as in `pack 'C[80]', @arr`.

  One can replace the numeric repeat count by a template enclosed in brackets; then the packed length of this template in bytes is used as a count. For example, `x[L]` skips a long (it skips the number of bytes in a long); the template `$t X[$t] $t` unpack()s twice what $t unpacks. If the template in brackets contains alignment commands (such as `x![d]`), its packed length is calculated as if the start of the template has the maximal possible alignment.

  When used with `Z`, * results in the addition of a trailing null byte (so the packed result will be one longer than the byte `length` of the item).

  The repeat count for `u` is interpreted as the maximal number of bytes to encode per line of output, with 0 and 1 replaced by 45.

- The `a`, `A`, and `Z` types gobble just one value, but pack it as a string of length count, padding with nulls or spaces as necessary. When unpacking, `A` strips trailing spaces and nulls, `Z` strips everything after the first null, and `a` returns data verbatim. When packing, `a`, and `Z` are equivalent.

  If the value-to-pack is too long, it is truncated. If too long and an explicit count is provided, `Z` packs only `$count-1` bytes, followed by a null byte. Thus `Z` always packs a trailing null byte under all circumstances.

- Likewise, the `b` and `B` fields pack a string that many bits long. Each byte of the input field of pack() generates 1 bit of the result. Each result bit is based on the least-significant bit of the corresponding input byte, i.e., on `ord($byte)%2`. In particular, bytes `"0"` and `"1"` generate bits 0 and 1, as do bytes `"\0"` and `"\1"`.

  Starting from the beginning of the input string of pack(), each 8-tuple of bytes is converted to 1 byte of output. With format `b` the first byte of the 8-tuple determines the least-significant bit of a byte, and with format `B` it determines the most-significant bit of a byte.

  If the length of the input string is not exactly divisible by 8, the remainder is packed as if the input string were padded by null bytes at the end. Similarly, during unpack()ing the "extra" bits are ignored.

  If the input string of pack() is longer than needed, extra bytes are ignored. A * for the repeat count of pack() means to use all the bytes of the input field. On unpack()ing the bits are converted to a string of `"0"`s and `"1"`s.

- The `h` and `H` fields pack a string that many nybbles (4-bit groups, representable as hexadecimal digits, 0-9a-f) long.

  Each byte of the input field of pack() generates 4 bits of the result. For non-alphabetical bytes the result is based on the 4 least-significant bits of the input byte, i.e., on `ord($byte)%16`. In particular, bytes `"0"` and `"1"` generate nybbles 0 and 1, as do bytes `"\0"` and `"\1"`. For bytes `"a".."f"` and `"A".."F"` the result is compatible with the usual hexadecimal digits, so that `"a"` and `"A"` both generate the nybble `0xa==10`. The result for bytes `"g".."z"` and `"G".."Z"` is not well-defined.

Starting from the beginning of the input string of pack(), each pair of bytes is converted to 1 byte of output. With format `h` the first byte of the pair determines the least-significant nybble of the output byte, and with format `H` it determines the most-significant nybble.

If the length of the input string is not even, it behaves as if padded by a null byte at the end. Similarly, during unpack()ing the "extra" nybbles are ignored.

If the input string of pack() is longer than needed, extra bytes are ignored. A `*` for the repeat count of pack() means to use all the bytes of the input field. On unpack()ing the bits are converted to a string of hexadecimal digits.

- The `p` type packs a pointer to a null-terminated string. You are responsible for ensuring the string is not a temporary value (which can potentially get deallocated before you get around to using the packed result). The `P` type packs a pointer to a structure of the size indicated by the length. A NULL pointer is created if the corresponding value for `p` or `P` is `undef`, similarly for unpack().
- The `/` template character allows packing and unpacking of strings where the packed structure contains a byte count followed by the string itself. You write *length-item*`/`*string-item*.

  The *length-item* can be any `pack` template letter, and describes how the length value is packed. The ones likely to be of most use are integer-packing ones like `n` (for Java strings), `w` (for ASN.1 or SNMP) and `N` (for Sun XDR).

  For `pack`, the *string-item* must, at present, be `"A*"`, `"a*"` or `"Z*"`. For `unpack` the length of the string is obtained from the *length-item*, but if you put in the '*' it will be ignored. For all other codes, `unpack` applies the length value to the next item, which must not have a repeat count.

```
    unpack 'C/a', "\04Gurusamy";        gives 'Guru'
    unpack 'a3/A* A*', '007 Bond  J ';  gives (' Bond','J')
    pack 'n/a* w/a*','hello,','world';  gives "\000\006hello,\005world"
```

  The *length-item* is not returned explicitly from `unpack`.

  Adding a count to the *length-item* letter is unlikely to do anything useful, unless that letter is `A`, `a` or `Z`. Packing with a *length-item* of `a` or `Z` may introduce `"\000"` characters, which Perl does not regard as legal in numeric strings.
- The integer types `s`, `S`, `l`, and `L` may be immediately followed by a `!` suffix to signify native shorts or longs–as you can see from above for example a bare `l` does mean exactly 32 bits, the native `long` (as seen by the local C compiler) may be larger. This is an issue mainly in 64-bit platforms. You can see whether using `!` makes any difference by

```
        print length(pack("s")), " ", length(pack("s!")), "\n";
        print length(pack("l")), " ", length(pack("l!")), "\n";
```

  `i!` and `I!` also work but only because of completeness; they are identical to `i` and `I`.

  The actual sizes (in bytes) of native shorts, ints, longs, and long longs on the platform where Perl was built are also available via *Config*:

```
        use Config;
        print $Config{shortsize},    "\n";
        print $Config{intsize},      "\n";
        print $Config{longsize},     "\n";
        print $Config{longlongsize}, "\n";
```

  (The `$Config{longlongsize}` will be undefined if your system does not support long longs.)
- The integer formats `s`, `S`, `i`, `I`, `l`, `L`, `j`, and `J` are inherently non-portable between processors and operating systems because they obey the native byteorder and endianness. For example a 4-byte integer 0x12345678 (305419896 decimal) would be ordered natively (arranged in and handled by the CPU registers) into bytes as

```
        0x12 0x34 0x56 0x78     # big-endian
        0x78 0x56 0x34 0x12     # little-endian
```

Basically, the Intel and VAX CPUs are little-endian, while everybody else, for example Motorola m68k/88k, PPC, Sparc, HP PA, Power, and Cray are big-endian. Alpha and MIPS can be either: Digital/Compaq used/uses them in little-endian mode; SGI/Cray uses them in big-endian mode.

The names 'big-endian' and 'little-endian' are comic references to the classic "Gulliver's Travels" (via the paper "On Holy Wars and a Plea for Peace" by Danny Cohen, USC/ISI IEN 137, April 1, 1980) and the egg-eating habits of the Lilliputians.

Some systems may have even weirder byte orders such as

```
0x56 0x78 0x12 0x34
0x34 0x12 0x78 0x56
```

You can see your system's preference with

```
print join(" ", map { sprintf "%#02x", $_ }
                    unpack("C*",pack("L",0x12345678))), "\n";
```

The byteorder on the platform where Perl was built is also available via *Config*:

```
use Config;
print $Config{byteorder}, "\n";
```

Byteorders `'1234'` and `'12345678'` are little-endian, `'4321'` and `'87654321'` are big-endian.

If you want portable packed integers use the formats `n`, `N`, `v`, and `V`, their byte endianness and size are known. See also *perlport*.

- Real numbers (floats and doubles) are in the native machine format only; due to the multiplicity of floating formats around, and the lack of a standard "network" representation, no facility for interchange has been made. This means that packed floating point data written on one machine may not be readable on another - even if both use IEEE floating point arithmetic (as the endian-ness of the memory representation is not part of the IEEE spec). See also *perlport*.

  Note that Perl uses doubles internally for all numeric calculation, and converting from double into float and thence back to double again will lose precision (i.e., `unpack("f", pack("f", $foo))` will not in general equal $foo).

- If the pattern begins with a `U`, the resulting string will be treated as UTF-8-encoded Unicode. You can force UTF-8 encoding on in a string with an initial `U0`, and the bytes that follow will be interpreted as Unicode characters. If you don't want this to happen, you can begin your pattern with `C0` (or anything else) to force Perl not to UTF-8 encode your string, and then follow this with a `U*` somewhere in your pattern.

- You must yourself do any alignment or padding by inserting for example enough `'x'`es while packing. There is no way to pack() and unpack() could know where the bytes are going to or coming from. Therefore `pack` (and `unpack`) handle their output and input as flat sequences of bytes.

- A ()-group is a sub-TEMPLATE enclosed in parentheses. A group may take a repeat count, both as postfix, and for unpack() also via the `/` template character. Within each repetition of a group, positioning with `@` starts again at 0. Therefore, the result of

  ```
  pack( '@1A((@2A)@3A)', 'a', 'b', 'c' )
  ```

  is the string "\0a\0\0bc".

- `x` and `X` accept `!` modifier. In this case they act as alignment commands: they jump forward/back to the closest position aligned at a multiple of `count` bytes. For example, to pack() or unpack() C's `struct {char c; double d; char cc[2]}` one may need to use the template `C x![d] d C[2]`; this assumes that doubles must be aligned on the double's size.

  For alignment commands `count` of 0 is equivalent to `count` of 1; both result in no-ops.

- A comment in a TEMPLATE starts with `#` and goes to the end of line. White space may be used to separate pack codes from each other, but a `!` modifier and a repeat count must follow immediately.

- If TEMPLATE requires more arguments to pack() than actually given, pack() assumes additional `""` arguments. If TEMPLATE requires less arguments to pack() than actually given, extra arguments are ignored.

Examples:

```
$foo = pack("CCCC",65,66,67,68);
# foo eq "ABCD"
$foo = pack("C4",65,66,67,68);
# same thing
$foo = pack("U4",0x24b6,0x24b7,0x24b8,0x24b9);
# same thing with Unicode circled letters

$foo = pack("ccxxcc",65,66,67,68);
# foo eq "AB\0\0CD"

# note: the above examples featuring "C" and "c" are true
# only on ASCII and ASCII-derived systems such as ISO Latin 1
# and UTF-8.  In EBCDIC the first example would be
# $foo = pack("CCCC",193,194,195,196);

$foo = pack("s2",1,2);
# "\1\0\2\0" on little-endian
# "\0\1\0\2" on big-endian

$foo = pack("a4","abcd","x","y","z");
# "abcd"

$foo = pack("aaaa","abcd","x","y","z");
# "axyz"

$foo = pack("a14","abcdefg");
# "abcdefg\0\0\0\0\0\0\0"

$foo = pack("i9pl", gmtime);
# a real struct tm (on my system anyway)

$utmp_template = "Z8 Z8 Z16 L";
$utmp = pack($utmp_template, @utmp1);
# a struct utmp (BSDish)

@utmp2 = unpack($utmp_template, $utmp);
# "@utmp1" eq "@utmp2"

sub bintodec {
    unpack("N", pack("B32", substr("0" x 32 . shift, -32)));
}

$foo = pack('sx2l', 12, 34);
# short 12, two zero bytes padding, long 34
$bar = pack('s@4l', 12, 34);
# short 12, zero fill to position 4, long 34
# $foo eq $bar
```

The same template may generally also be used in unpack().

package NAMESPACE

package

Declares the compilation unit as being in the given namespace. The scope of the package declaration is from the declaration itself through the end of the enclosing block, file, or eval (the same as the `my` operator). All further unqualified dynamic identifiers will be in this namespace. A package statement affects only dynamic variables–including those you've used `local` on–but *not* lexical variables, which are created with `my`. Typically it would be the first declaration in a file to be included by the `require` or `use` operator. You can switch into a package in more than one place; it merely influences which symbol table is used by the compiler for the rest of that block. You can refer to variables and filehandles in other packages by prefixing the identifier with the package name and a double colon: `$Package::Variable`. If the package name is null, the `main` package as assumed. That is, `$::sail` is equivalent to `$main::sail` (as well as to `$main'sail`, still seen in older code).

If NAMESPACE is omitted, then there is no current package, and all identifiers must be fully qualified or lexicals. However, you are strongly advised not to make use of this feature. Its use can cause unexpected behaviour, even crashing some versions of Perl. It is deprecated, and will be removed from a future release.

See Packages in *perlmod* for more information about packages, modules, and classes. See *perlsub* for other scoping issues.

pipe READHANDLE,WRITEHANDLE

Opens a pair of connected pipes like the corresponding system call. Note that if you set up a loop of piped processes, deadlock can occur unless you are very careful. In addition, note that Perl's pipes use IO buffering, so you may need to set $| to flush your WRITEHANDLE after each command, depending on the application.

See *IPC::Open2*, *IPC::Open3*, and Bidirectional Communication in *perlipc* for examples of such things.

On systems that support a close-on-exec flag on files, the flag will be set for the newly opened file descriptors as determined by the value of $^F. See $^F in *perlvar*.

pop ARRAY

pop

Pops and returns the last value of the array, shortening the array by one element. Has an effect similar to

```
$ARRAY[$#ARRAY--]
```

If there are no elements in the array, returns the undefined value (although this may happen at other times as well). If ARRAY is omitted, pops the `@ARGV` array in the main program, and the `@_` array in subroutines, just like `shift`.

pos SCALAR

pos

Returns the offset of where the last `m//g` search left off for the variable in question (`$_` is used when the variable is not specified). May be modified to change that offset. Such modification will also influence the `\G` zero-width assertion in regular expressions. See *perlre* and *perlop*.

print FILEHANDLE LIST

print LIST

print

Prints a string or a list of strings. Returns true if successful. FILEHANDLE may be a scalar variable name, in which case the variable contains the name of or a reference to the filehandle, thus introducing one level of indirection. (NOTE: If FILEHANDLE is a variable and the next token is a term, it may be misinterpreted as an operator unless you interpose a + or put parentheses around the arguments.) If FILEHANDLE is omitted, prints by default to standard output (or to the last selected output channel–see select). If LIST is also omitted, prints `$_` to the currently selected output channel. To set the default output channel to something other than STDOUT use the select operation. The current value of `$,` (if any) is printed between each LIST item. The current value of `$\` (if any) is printed after the entire LIST has been printed. Because print takes a LIST, anything in the LIST is evaluated in list context, and any subroutine that you call will have one or more of its expressions evaluated in list context. Also be careful not to follow the print keyword with a left parenthesis unless you want the corresponding right parenthesis to terminate the arguments to the print–interpose a + or put parentheses around all the arguments.

Note that if you're storing FILEHANDLES in an array or other expression, you will have to use a block returning its value instead:

```
    print { $files[$i] } "stuff\n";
    print { $OK ? STDOUT : STDERR } "stuff\n";
```

printf FILEHANDLE FORMAT, LIST

printf FORMAT, LIST

Equivalent to `print FILEHANDLE sprintf(FORMAT, LIST)`, except that `$\` (the output record separator) is not appended. The first argument of the list will be interpreted as the `printf` format. See `sprintf` for an explanation of the format argument. If `use locale` is in effect, the character used for the decimal point in formatted real numbers is affected by the LC_NUMERIC locale. See *perllocale*.

Don't fall into the trap of using a `printf` when a simple `print` would do. The `print` is more efficient and less error prone.

prototype FUNCTION

Returns the prototype of a function as a string (or `undef` if the function has no prototype). FUNCTION is a reference to, or the name of, the function whose prototype you want to retrieve.

If FUNCTION is a string starting with `CORE::`, the rest is taken as a name for Perl builtin. If the builtin is not *overridable* (such as `qw//`) or its arguments cannot be expressed by a prototype (such as `system`) returns `undef` because the builtin does not really behave like a Perl function. Otherwise, the string describing the equivalent prototype is returned.

push ARRAY,LIST

Treats ARRAY as a stack, and pushes the values of LIST onto the end of ARRAY. The length of ARRAY increases by the length of LIST. Has the same effect as

```
    for $value (LIST) {
        $ARRAY[++$#ARRAY] = $value;
    }
```

but is more efficient. Returns the new number of elements in the array.

q/STRING/

qq/STRING/

qr/STRING/

qx/STRING/

qw/STRING/

Generalized quotes. See Regexp Quote-Like Operators in *perlop*.

quotemeta EXPR

quotemeta

Returns the value of EXPR with all non-"word" characters backslashed. (That is, all characters not matching `/[A-Za-z_0-9]/` will be preceded by a backslash in the returned string, regardless of any locale settings.) This is the internal function implementing the `\Q` escape in double-quoted strings.

If EXPR is omitted, uses `$_`.

rand EXPR

rand

Returns a random fractional number greater than or equal to `0` and less than the value of EXPR. (EXPR should be positive.) If EXPR is omitted, the value `1` is used. Currently EXPR with the value `0` is also special-cased as `1` - this has not been documented before perl 5.8.0 and is subject to change in future versions of perl. Automatically calls `srand` unless `srand` has already been called. See also `srand`.

Apply `int()` to the value returned by `rand()` if you want random integers instead of random fractional numbers. For example,

```
    int(rand(10))
```

returns a random integer between `0` and `9`, inclusive.

(Note: If your rand function consistently returns numbers that are too large or too small, then your version of Perl was probably compiled with the wrong number of RANDBITS.)

read FILEHANDLE,SCALAR,LENGTH,OFFSET

read FILEHANDLE,SCALAR,LENGTH

Attempts to read LENGTH *characters* of data into variable SCALAR from the specified FILEHANDLE. Returns the number of characters actually read, `0` at end of file, or undef if there was an error (in the latter case `$!` is also set). SCALAR will be grown or shrunk so that the last character actually read is the last character of the scalar after the read.

An OFFSET may be specified to place the read data at some place in the string other than the beginning. A negative OFFSET specifies placement at that many characters counting backwards from the end of the string. A positive OFFSET greater than the length of SCALAR results in the string being padded to the required size with `"\0"` bytes before the result of the read is appended.

The call is actually implemented in terms of either Perl's or system's fread() call. To get a true read(2) system call, see `sysread`.

Note the *characters*: depending on the status of the filehandle, either (8-bit) bytes or characters are read. By default all filehandles operate on bytes, but for example if the filehandle has been opened with the `:utf8` I/O layer (see open, and the `open` pragma, *open*), the I/O will operate on UTF-8 encoded Unicode characters, not bytes. Similarly for the `:encoding` pragma: in that case pretty much any characters can be read.

readdir DIRHANDLE

Returns the next directory entry for a directory opened by `opendir`. If used in list context, returns all the rest of the entries in the directory. If there are no more entries, returns an undefined value in scalar context or a null list in list context.

If you're planning to filetest the return values out of a `readdir`, you'd better prepend the directory in question. Otherwise, because we didn't `chdir` there, it would have been testing the wrong file.

```
    opendir(DIR, $some_dir) || die "can't opendir $some_dir: $!";
    @dots = grep { /^\./ && -f "$some_dir/$_" } readdir(DIR);
    closedir DIR;
```

readline EXPR

Reads from the filehandle whose typeglob is contained in EXPR. In scalar context, each call reads and returns the next line, until end-of-file is reached, whereupon the subsequent call returns undef. In list context, reads until end-of-file is reached and returns a list of lines. Note that the notion of "line" used here is however you may have defined it with `$/` or `$INPUT_RECORD_SEPARATOR`). See $/ in *perlvar*.

When `$/` is set to `undef`, when readline() is in scalar context (i.e. file slurp mode), and when an empty file is read, it returns '' the first time, followed by `undef` subsequently.

This is the internal function implementing the `<EXPR>` operator, but you can use it directly. The `<EXPR>` operator is discussed in more detail in I/O Operators in *perlop*.

```
    $line = <STDIN>;
    $line = readline(*STDIN);           # same thing
```

If readline encounters an operating system error, `$!` will be set with the corresponding error message. It can be helpful to check `$!` when you are reading from filehandles you don't trust, such as a tty or a socket. The following example uses the operator form of `readline`, and takes the necessary steps to ensure that `readline` was successful.

```
    for (;;) {
        undef $!;
        unless (defined( $line = <> )) {
            die $! if $!;
            last; # reached EOF
        }
        # ...
    }
```

readlink EXPR

readlink

Returns the value of a symbolic link, if symbolic links are implemented. If not, gives a fatal error. If there is some system error, returns the undefined value and sets `$!` (errno). If EXPR is omitted, uses `$_`.

readpipe EXPR

EXPR is executed as a system command. The collected standard output of the command is returned. In scalar context, it comes back as a single (potentially multi-line) string. In list context, returns a list of lines (however you've defined lines with `$/` or `$INPUT_RECORD_SEPARATOR`). This is the internal function implementing the `qx/EXPR/` operator, but you can use it directly. The `qx/EXPR/` operator is discussed in more detail in I/O Operators in *perlop*.

recv SOCKET,SCALAR,LENGTH,FLAGS

Receives a message on a socket. Attempts to receive LENGTH characters of data into variable SCALAR from the specified SOCKET filehandle. SCALAR will be grown or shrunk to the length actually read. Takes the same flags as the system call of the same name. Returns the address of the sender if SOCKET's protocol supports this; returns an empty string otherwise. If there's an error, returns the undefined value. This call is actually implemented in terms of recvfrom(2) system call. See UDP: Message Passing in *perlipc* for examples.

Note the *characters*: depending on the status of the socket, either (8-bit) bytes or characters are received. By default all sockets operate on bytes, but for example if the socket has been changed using binmode() to operate with the `:utf8` I/O layer (see the `open` pragma, *open*), the I/O will operate on UTF-8 encoded Unicode characters, not bytes. Similarly for the `:encoding` pragma: in that case pretty much any characters can be read.

redo LABEL

redo

The `redo` command restarts the loop block without evaluating the conditional again. The `continue` block, if any, is not executed. If the LABEL is omitted, the command refers to the innermost enclosing loop. This command is normally used by programs that want to lie to themselves about what was just input:

```
    # a simpleminded Pascal comment stripper
    # (warning: assumes no { or } in strings)
    LINE: while (<STDIN>) {
        while (s|({.*}.*){.*}|$1 |) {}
        s|{.*}| |;
        if (s|{.*| |) {
            $front = $_;
            while (<STDIN>) {
                if (/}/) {      # end of comment?
                    s|^|$front\{|;
                    redo LINE;
                }
            }
        }
        print;
    }
```

`redo` cannot be used to retry a block which returns a value such as `eval {}`, `sub {}` or `do {}`, and should not be used to exit a grep() or map() operation.

Note that a block by itself is semantically identical to a loop that executes once. Thus `redo` inside such a block will effectively turn it into a looping construct.

See also continue for an illustration of how `last`, `next`, and `redo` work.

ref EXPR

ref

Returns a non-empty string if EXPR is a reference, the empty string otherwise. If EXPR is not specified, `$_` will be used. The value returned depends on the type of thing the reference is a reference to. Builtin types include:

```
    SCALAR
    ARRAY
    HASH
    CODE
    REF
    GLOB
    LVALUE
```

If the referenced object has been blessed into a package, then that package name is returned instead. You can think of `ref` as a `typeof` operator.

```
    if (ref($r) eq "HASH") {
        print "r is a reference to a hash.\n";
    }
    unless (ref($r)) {
        print "r is not a reference at all.\n";
    }
    if (UNIVERSAL::isa($r, "HASH")) {  # for subclassing
        print "r is a reference to something that isa hash.\n";
    }
```

See also *perlref*.

rename OLDNAME,NEWNAME

Changes the name of a file; an existing file NEWNAME will be clobbered. Returns true for success, false otherwise.

Behavior of this function varies wildly depending on your system implementation. For example, it will usually not work across file system boundaries, even though the system *mv* command sometimes compensates for this. Other restrictions include whether it works on directories, open files, or pre-existing files. Check *perlport* and either the rename(2) manpage or equivalent system documentation for details.

require VERSION

require EXPR

require

Demands a version of Perl specified by VERSION, or demands some semantics specified by EXPR or by `$_` if EXPR is not supplied.

VERSION may be either a numeric argument such as 5.006, which will be compared to `$]`, or a literal of the form v5.6.1, which will be compared to `$^V` (aka $PERL_VERSION). A fatal error is produced at run time if VERSION is greater than the version of the current Perl interpreter. Compare with use, which can do a similar check at compile time.

Specifying VERSION as a literal of the form v5.6.1 should generally be avoided, because it leads to misleading error messages under earlier versions of Perl which do not support this syntax. The equivalent numeric version should be used instead.

```
require v5.6.1;     # run time version check
require 5.6.1;      # ditto
require 5.006_001;  # ditto; preferred for backwards compatibility
```

Otherwise, demands that a library file be included if it hasn't already been included. The file is included via the do-FILE mechanism, which is essentially just a variety of `eval`. Has semantics similar to the following subroutine:

```
sub require {
   my ($filename) = @_;
   if (exists $INC{$filename}) {
       return 1 if $INC{$filename};
       die "Compilation failed in require";
   }
   my ($realfilename,$result);
   ITER: {
       foreach $prefix (@INC) {
           $realfilename = "$prefix/$filename";
           if (-f $realfilename) {
               $INC{$filename} = $realfilename;
               $result = do $realfilename;
               last ITER;
           }
       }
       die "Can't find $filename in \@INC";
   }
   if ($@) {
       $INC{$filename} = undef;
       die $@;
   } elsif (!$result) {
       delete $INC{$filename};
       die "$filename did not return true value";
   } else {
       return $result;
   }
}
```

Note that the file will not be included twice under the same specified name.

The file must return true as the last statement to indicate successful execution of any initialization code, so it's customary to end such a file with `1;` unless you're sure it'll return true otherwise. But it's better just to put the `1;`, in case you add more statements.

If EXPR is a bareword, the require assumes a "*.pm*" extension and replaces "*::*" with "*/*" in the filename for you, to make it easy to load standard modules. This form of loading of modules does not risk altering your namespace.

In other words, if you try this:

```
        require Foo::Bar;    # a splendid bareword
```

The require function will actually look for the "*Foo/Bar.pm*" file in the directories specified in the `@INC` array.

But if you try this:

```
        $class = 'Foo::Bar';
        require $class;      # $class is not a bareword
    #or
        require "Foo::Bar";  # not a bareword because of the ""
```

The require function will look for the "*Foo::Bar*" file in the @INC array and will complain about not finding "*Foo::Bar*" there. In this case you can do:

```
        eval "require $class";
```

Now that you understand how `require` looks for files in the case of a bareword argument, there is a little extra functionality going on behind the scenes. Before `require` looks for a "*.pm*" extension, it will first look for a filename with a "*.pmc*" extension. A file with this extension is assumed to be Perl bytecode generated by B::Bytecode. If this file is found, and it's modification time is newer than a coinciding "*.pm*" non-compiled file, it will be loaded in place of that non-compiled file ending in a "*.pm*" extension.

You can also insert hooks into the import facility, by putting directly Perl code into the @INC array. There are three forms of hooks: subroutine references, array references and blessed objects.

Subroutine references are the simplest case. When the inclusion system walks through @INC and encounters a subroutine, this subroutine gets called with two parameters, the first being a reference to itself, and the second the name of the file to be included (e.g. "*Foo/Bar.pm*"). The subroutine should return `undef` or a filehandle, from which the file to include will be read. If `undef` is returned, `require` will look at the remaining elements of @INC.

If the hook is an array reference, its first element must be a subroutine reference. This subroutine is called as above, but the first parameter is the array reference. This enables to pass indirectly some arguments to the subroutine.

In other words, you can write:

```
    push @INC, \&my_sub;
    sub my_sub {
        my ($coderef, $filename) = @_;  # $coderef is \&my_sub
        ...
    }
```

or:

```
    push @INC, [ \&my_sub, $x, $y, ... ];
    sub my_sub {
        my ($arrayref, $filename) = @_;
        # Retrieve $x, $y, ...
        my @parameters = @$arrayref[1..$#$arrayref];
        ...
    }
```

If the hook is an object, it must provide an INC method, that will be called as above, the first parameter being the object itself. (Note that you must fully qualify the sub's name, as it is always forced into package `main`.) Here is a typical code layout:

```
    # In Foo.pm
    package Foo;
    sub new { ... }
    sub Foo::INC {
        my ($self, $filename) = @_;
        ...
    }
    # In the main program
    push @INC, new Foo(...);
```

Note that these hooks are also permitted to set the %INC entry corresponding to the files they have loaded. See %INC in *perlvar*.

For a yet-more-powerful import facility, see use and *perlmod*.

reset EXPR

reset

Generally used in a `continue` block at the end of a loop to clear variables and reset `??` searches so that they work again. The expression is interpreted as a list of single characters (hyphens allowed for ranges). All variables and arrays beginning with one of those letters are reset to their pristine state. If the expression is omitted, one-match searches (`?pattern?`) are reset to match again. Resets only variables or searches in the current package. Always returns 1. Examples:

```
    reset 'X';          # reset all X variables
    reset 'a-z';        # reset lower case variables
    reset;              # just reset ?one-time? searches
```

Resetting `"A-Z"` is not recommended because you'll wipe out your `@ARGV` and `@INC` arrays and your `%ENV` hash. Resets only package variables–lexical variables are unaffected, but they clean themselves up on scope exit anyway, so you'll probably want to use them instead. See my.

return EXPR

return

Returns from a subroutine, `eval`, or `do FILE` with the value given in EXPR. Evaluation of EXPR may be in list, scalar, or void context, depending on how the return value will be used, and the context may vary from one execution to the next (see `wantarray`). If no EXPR is given, returns an empty list in list context, the undefined value in scalar context, and (of course) nothing at all in a void context.

(Note that in the absence of an explicit `return`, a subroutine, eval, or do FILE will automatically return the value of the last expression evaluated.)

reverse LIST

In list context, returns a list value consisting of the elements of LIST in the opposite order. In scalar context, concatenates the elements of LIST and returns a string value with all characters in the opposite order.

```
    print reverse <>;           # line tac, last line first

    undef $/;                   # for efficiency of <>
    print scalar reverse <>;    # character tac, last line tsrif
```

Used without arguments in scalar context, reverse() reverses `$_`.

This operator is also handy for inverting a hash, although there are some caveats. If a value is duplicated in the original hash, only one of those can be represented as a key in the inverted hash. Also, this has to unwind one hash and build a whole new one, which may take some time on a large hash, such as from a DBM file.

```
    %by_name = reverse %by_address;     # Invert the hash
```

rewinddir DIRHANDLE

Sets the current position to the beginning of the directory for the `readdir` routine on DIRHANDLE.

rindex STR,SUBSTR,POSITION

rindex STR,SUBSTR

Works just like index() except that it returns the position of the LAST occurrence of SUBSTR in STR. If POSITION is specified, returns the last occurrence at or before that position.

rmdir FILENAME

rmdir

Deletes the directory specified by FILENAME if that directory is empty. If it succeeds it returns true, otherwise it returns false and sets `$!` (errno). If FILENAME is omitted, uses `$_`.

s///

The substitution operator. See *perlop*.

scalar EXPR

Forces EXPR to be interpreted in scalar context and returns the value of EXPR.

```
    @counts = ( scalar @a, scalar @b, scalar @c );
```

There is no equivalent operator to force an expression to be interpolated in list context because in practice, this is never needed. If you really wanted to do so, however, you could use the construction `@{[ (some expression) ]}`, but usually a simple `(some expression)` suffices.

Because `scalar` is unary operator, if you accidentally use for EXPR a parenthesized list, this behaves as a scalar comma expression, evaluating all but the last element in void context and returning the final element evaluated in scalar context. This is seldom what you want.

The following single statement:

```
        print uc(scalar(&foo,$bar)),$baz;
```

is the moral equivalent of these two:

```
        &foo;
        print(uc($bar),$baz);
```

See *perlop* for more details on unary operators and the comma operator.

seek FILEHANDLE,POSITION,WHENCE

Sets FILEHANDLE's position, just like the `fseek` call of `stdio`. FILEHANDLE may be an expression whose value gives the name of the filehandle. The values for WHENCE are `0` to set the new position *in bytes* to POSITION, `1` to set it to the current position plus POSITION, and `2` to set it to EOF plus POSITION (typically negative). For WHENCE you may use the constants `SEEK_SET`, `SEEK_CUR`, and `SEEK_END` (start of the file, current position, end of the file) from the Fcntl module. Returns `1` upon success, `0` otherwise.

Note the *in bytes*: even if the filehandle has been set to operate on characters (for example by using the `:utf8` open layer), tell() will return byte offsets, not character offsets (because implementing that would render seek() and tell() rather slow).

If you want to position file for `sysread` or `syswrite`, don't use `seek`–buffering makes its effect on the file's system position unpredictable and non-portable. Use `sysseek` instead.

Due to the rules and rigors of ANSI C, on some systems you have to do a seek whenever you switch between reading and writing. Amongst other things, this may have the effect of calling stdio's clearerr(3). A WHENCE of `1` (`SEEK_CUR`) is useful for not moving the file position:

```
    seek(TEST,0,1);
```

This is also useful for applications emulating `tail -f`. Once you hit EOF on your read, and then sleep for a while, you might have to stick in a seek() to reset things. The `seek` doesn't change the current position, but it *does* clear the end-of-file condition on the handle, so that the next `<FILE>` makes Perl try again to read something. We hope.

If that doesn't work (some IO implementations are particularly cantankerous), then you may need something more like this:

```
    for (;;) {
        for ($curpos = tell(FILE); $_ = <FILE>;
             $curpos = tell(FILE)) {
            # search for some stuff and put it into files
        }
        sleep($for_a_while);
        seek(FILE, $curpos, 0);
    }
```

seekdir DIRHANDLE,POS

Sets the current position for the `readdir` routine on DIRHANDLE. POS must be a value returned by `telldir`. Has the same caveats about possible directory compaction as the corresponding system library routine.

select FILEHANDLE

select

Returns the currently selected filehandle. Sets the current default filehandle for output, if FILEHANDLE is supplied. This has two effects: first, a `write` or a `print` without a filehandle will default to this FILEHANDLE. Second, references to variables related to output will refer to this output channel. For example, if you have to set the top of form format for more than one output channel, you might do the following:

```
    select(REPORT1);
    $^ = 'report1_top';
    select(REPORT2);
    $^ = 'report2_top';
```

FILEHANDLE may be an expression whose value gives the name of the actual filehandle. Thus:

```
    $oldfh = select(STDERR); $| = 1; select($oldfh);
```

Some programmers may prefer to think of filehandles as objects with methods, preferring to write the last example as:

```
    use IO::Handle;
    STDERR->autoflush(1);
```

select RBITS,WBITS,EBITS,TIMEOUT

This calls the select(2) system call with the bit masks specified, which can be constructed using `fileno` and `vec`, along these lines:

```
    $rin = $win = $ein = '';
    vec($rin,fileno(STDIN),1) = 1;
    vec($win,fileno(STDOUT),1) = 1;
    $ein = $rin | $win;
```

If you want to select on many filehandles you might wish to write a subroutine:

```
    sub fhbits {
        my(@fhlist) = split(' ',$_[0]);
        my($bits);
        for (@fhlist) {
            vec($bits,fileno($_),1) = 1;
        }
        $bits;
    }
    $rin = fhbits('STDIN TTY SOCK');
```

The usual idiom is:

```
    ($nfound,$timeleft) =
      select($rout=$rin, $wout=$win, $eout=$ein, $timeout);
```

or to block until something becomes ready just do this

```
    $nfound = select($rout=$rin, $wout=$win, $eout=$ein, undef);
```

Most systems do not bother to return anything useful in $timeleft, so calling select() in scalar context just returns $nfound.

Any of the bit masks can also be undef. The timeout, if specified, is in seconds, which may be fractional. Note: not all implementations are capable of returning the $timeleft. If not, they always return $timeleft equal to the supplied $timeout.

You can effect a sleep of 250 milliseconds this way:

```
    select(undef, undef, undef, 0.25);
```

Note that whether `select` gets restarted after signals (say, SIGALRM) is implementation-dependent. See also *perlport* for notes on the portability of `select`.

WARNING: One should not attempt to mix buffered I/O (like `read` or <FH>) with `select`, except as permitted by POSIX, and even then only on POSIX systems. You have to use `sysread` instead.

semctl ID,SEMNUM,CMD,ARG

Calls the System V IPC function `semctl`. You'll probably have to say

```
    use IPC::SysV;
```

first to get the correct constant definitions. If CMD is IPC_STAT or GETALL, then ARG must be a variable which will hold the returned semid_ds structure or semaphore value array. Returns like `ioctl`: the undefined value for error, "`0 but true`" for zero, or the actual return value otherwise. The ARG must consist of a vector of native short integers, which may be created with `pack("s!",(0)x$nsem)`. See also SysV IPC in *perlipc*, `IPC::SysV`, `IPC::Semaphore` documentation.

semget KEY,NSEMS,FLAGS

Calls the System V IPC function semget. Returns the semaphore id, or the undefined value if there is an error. See also SysV IPC in *perlipc*, `IPC::SysV`, `IPC::SysV::Semaphore` documentation.

semop KEY,OPSTRING

Calls the System V IPC function semop to perform semaphore operations such as signalling and waiting. OPSTRING must be a packed array of semop structures. Each semop structure can be generated with `pack("s!3", $semnum, $semop, $semflag)`. The number of semaphore operations is implied by the length of OPSTRING. Returns true if successful, or false if there is an error. As an example, the following code waits on semaphore $semnum of semaphore id $semid:

```
    $semop = pack("s!3", $semnum, -1, 0);
    die "Semaphore trouble: $!\n" unless semop($semid, $semop);
```

To signal the semaphore, replace -1 with 1. See also SysV IPC in *perlipc*, IPC::SysV, and IPC::SysV::Semaphore documentation.

send SOCKET,MSG,FLAGS,TO

send SOCKET,MSG,FLAGS

Sends a message on a socket. Attempts to send the scalar MSG to the SOCKET filehandle. Takes the same flags as the system call of the same name. On unconnected sockets you must specify a destination to send TO, in which case it does a C sendto. Returns the number of characters sent, or the undefined value if there is an error. The C system call sendmsg(2) is currently unimplemented. See UDP: Message Passing in *perlipc* for examples.

Note the *characters*: depending on the status of the socket, either (8-bit) bytes or characters are sent. By default all sockets operate on bytes, but for example if the socket has been changed using binmode() to operate with the :utf8 I/O layer (see open, or the open pragma, *open*), the I/O will operate on UTF-8 encoded Unicode characters, not bytes. Similarly for the :encoding pragma: in that case pretty much any characters can be sent.

setpgrp PID,PGRP

Sets the current process group for the specified PID, 0 for the current process. Will produce a fatal error if used on a machine that doesn't implement POSIX setpgid(2) or BSD setpgrp(2). If the arguments are omitted, it defaults to 0,0. Note that the BSD 4.2 version of setpgrp does not accept any arguments, so only setpgrp(0,0) is portable. See also POSIX::setsid().

setpriority WHICH,WHO,PRIORITY

Sets the current priority for a process, a process group, or a user. (See setpriority(2).) Will produce a fatal error if used on a machine that doesn't implement setpriority(2).

setsockopt SOCKET,LEVEL,OPTNAME,OPTVAL

Sets the socket option requested. Returns undefined if there is an error. OPTVAL may be specified as undef if you don't want to pass an argument.

shift ARRAY

shift

Shifts the first value of the array off and returns it, shortening the array by 1 and moving everything down. If there are no elements in the array, returns the undefined value. If ARRAY is omitted, shifts the @_ array within the lexical scope of subroutines and formats, and the @ARGV array at file scopes or within the lexical scopes established by the eval '', BEGIN {}, INIT {}, CHECK {}, and END {} constructs.

See also unshift, push, and pop. shift and unshift do the same thing to the left end of an array that pop and push do to the right end.

shmctl ID,CMD,ARG

Calls the System V IPC function shmctl. You'll probably have to say

```
    use IPC::SysV;
```

first to get the correct constant definitions. If CMD is IPC_STAT, then ARG must be a variable which will hold the returned shmid_ds structure. Returns like ioctl: the undefined value for error, "0 but true" for zero, or the actual return value otherwise. See also SysV IPC in *perlipc* and IPC::SysV documentation.

shmget KEY,SIZE,FLAGS

Calls the System V IPC function shmget. Returns the shared memory segment id, or the undefined value if there is an error. See also SysV IPC in *perlipc* and IPC::SysV documentation.

shmread ID,VAR,POS,SIZE

shmwrite ID,STRING,POS,SIZE

Reads or writes the System V shared memory segment ID starting at position POS for size SIZE by attaching to it, copying in/out, and detaching from it. When reading, VAR must be a variable that will hold the data read. When writing, if STRING is too long, only SIZE bytes are used; if STRING is too short, nulls are written to fill out SIZE bytes. Return true if successful, or false if there is an error. shmread() taints the variable. See also SysV IPC in *perlipc*, `IPC::SysV` documentation, and the `IPC::Shareable` module from CPAN.

shutdown SOCKET,HOW

Shuts down a socket connection in the manner indicated by HOW, which has the same interpretation as in the system call of the same name.

```
    shutdown(SOCKET, 0);    # I/we have stopped reading data
    shutdown(SOCKET, 1);    # I/we have stopped writing data
    shutdown(SOCKET, 2);    # I/we have stopped using this socket
```

This is useful with sockets when you want to tell the other side you're done writing but not done reading, or vice versa. It's also a more insistent form of close because it also disables the file descriptor in any forked copies in other processes.

sin EXPR

sin

Returns the sine of EXPR (expressed in radians). If EXPR is omitted, returns sine of `$_`.

For the inverse sine operation, you may use the `Math::Trig::asin` function, or use this relation:

```
    sub asin { atan2($_[0], sqrt(1 - $_[0] * $_[0])) }
```

sleep EXPR

sleep

Causes the script to sleep for EXPR seconds, or forever if no EXPR. May be interrupted if the process receives a signal such as `SIGALRM`. Returns the number of seconds actually slept. You probably cannot mix `alarm` and `sleep` calls, because `sleep` is often implemented using `alarm`.

On some older systems, it may sleep up to a full second less than what you requested, depending on how it counts seconds. Most modern systems always sleep the full amount. They may appear to sleep longer than that, however, because your process might not be scheduled right away in a busy multitasking system.

For delays of finer granularity than one second, you may use Perl's `syscall` interface to access setitimer(2) if your system supports it, or else see select above. The Time::HiRes module (from CPAN, and starting from Perl 5.8 part of the standard distribution) may also help.

See also the POSIX module's `pause` function.

socket SOCKET,DOMAIN,TYPE,PROTOCOL

Opens a socket of the specified kind and attaches it to filehandle SOCKET. DOMAIN, TYPE, and PROTOCOL are specified the same as for the system call of the same name. You should `use Socket` first to get the proper definitions imported. See the examples in Sockets: Client/Server Communication in *perlipc*.

On systems that support a close-on-exec flag on files, the flag will be set for the newly opened file descriptor, as determined by the value of $^F. See `$^F` in *perlvar*.

socketpair SOCKET1,SOCKET2,DOMAIN,TYPE,PROTOCOL

Creates an unnamed pair of sockets in the specified domain, of the specified type. DOMAIN, TYPE, and PROTOCOL are specified the same as for the system call of the same name. If unimplemented, yields a fatal error. Returns true if successful.

On systems that support a close-on-exec flag on files, the flag will be set for the newly opened file descriptors, as determined by the value of $^F. See `$^F` in *perlvar*.

Some systems defined `pipe` in terms of `socketpair`, in which a call to `pipe(Rdr, Wtr)` is essentially:

```
    use Socket;
    socketpair(Rdr, Wtr, AF_UNIX, SOCK_STREAM, PF_UNSPEC);
    shutdown(Rdr, 1);        # no more writing for reader
    shutdown(Wtr, 0);        # no more reading for writer
```

See *perlipc* for an example of socketpair use. Perl 5.8 and later will emulate socketpair using IP sockets to localhost if your system implements sockets but not socketpair.

sort SUBNAME LIST

sort BLOCK LIST

sort LIST

In list context, this sorts the LIST and returns the sorted list value. In scalar context, the behaviour of `sort()` is undefined.

If SUBNAME or BLOCK is omitted, `sort`s in standard string comparison order. If SUBNAME is specified, it gives the name of a subroutine that returns an integer less than, equal to, or greater than `0`, depending on how the elements of the list are to be ordered. (The <=> and `cmp` operators are extremely useful in such routines.) SUBNAME may be a scalar variable name (unsubscripted), in which case the value provides the name of (or a reference to) the actual subroutine to use. In place of a SUBNAME, you can provide a BLOCK as an anonymous, in-line sort subroutine.

If the subroutine's prototype is `($$)`, the elements to be compared are passed by reference in `@_`, as for a normal subroutine. This is slower than unprototyped subroutines, where the elements to be compared are passed into the subroutine as the package global variables $a and $b (see example below). Note that in the latter case, it is usually counter-productive to declare $a and $b as lexicals.

In either case, the subroutine may not be recursive. The values to be compared are always passed by reference, so don't modify them.

You also cannot exit out of the sort block or subroutine using any of the loop control operators described in *perlsyn* or with `goto`.

When `use locale` is in effect, `sort LIST` sorts LIST according to the current collation locale. See *perllocale*.

Perl 5.6 and earlier used a quicksort algorithm to implement sort. That algorithm was not stable, and *could* go quadratic. (A *stable* sort preserves the input order of elements that compare equal. Although quicksort's run time is O(NlogN) when averaged over all arrays of length N, the time can be O(N**2), *quadratic* behavior, for some inputs.) In 5.7, the quicksort implementation was replaced with a stable mergesort algorithm whose worst case behavior is O(NlogN). But benchmarks indicated that for some inputs, on some platforms, the original quicksort was faster. 5.8 has a sort pragma for limited control of the sort. Its rather blunt control of the underlying algorithm may not persist into future perls, but the ability to characterize the input or output in implementation independent ways quite probably will. See *sort*.

Examples:

```
    # sort lexically
    @articles = sort @files;

    # same thing, but with explicit sort routine
    @articles = sort {$a cmp $b} @files;

    # now case-insensitively
    @articles = sort {uc($a) cmp uc($b)} @files;

    # same thing in reversed order
    @articles = sort {$b cmp $a} @files;

    # sort numerically ascending
    @articles = sort {$a <=> $b} @files;
```

```
# sort numerically descending
@articles = sort {$b <=> $a} @files;

# this sorts the %age hash by value instead of key
# using an in-line function
@eldest = sort { $age{$b} <=> $age{$a} } keys %age;

# sort using explicit subroutine name
sub byage {
    $age{$a} <=> $age{$b};  # presuming numeric
}
@sortedclass = sort byage @class;

sub backwards { $b cmp $a }
@harry  = qw(dog cat x Cain Abel);
@george = qw(gone chased yz Punished Axed);
print sort @harry;
        # prints AbelCaincatdogx
print sort backwards @harry;
        # prints xdogcatCainAbel
print sort @george, 'to', @harry;
        # prints AbelAxedCainPunishedcatchaseddoggonetoxyz

# inefficiently sort by descending numeric compare using
# the first integer after the first = sign, or the
# whole record case-insensitively otherwise

@new = sort {
    ($b =~ /=(\d+)/)[0] <=> ($a =~ /=(\d+)/)[0]
                        ||
                uc($a)  cmp  uc($b)
} @old;

# same thing, but much more efficiently;
# we'll build auxiliary indices instead
# for speed
@nums = @caps = ();
for (@old) {
    push @nums, /=(\d+)/;
    push @caps, uc($_);
}

@new = @old[ sort {
                    $nums[$b] <=> $nums[$a]
                             ||
                    $caps[$a] cmp $caps[$b]
                   } 0..$#old
           ];

# same thing, but without any temps
@new = map { $_->[0] }
       sort { $b->[1] <=> $a->[1]
                       ||
              $a->[2] cmp $b->[2]
       } map { [$_, /=(\d+)/, uc($_)] } @old;
```

```
# using a prototype allows you to use any comparison subroutine
# as a sort subroutine (including other package's subroutines)
package other;
sub backwards ($$) { $_[1] cmp $_[0]; }     # $a and $b are not set here

package main;
@new = sort other::backwards @old;

# guarantee stability, regardless of algorithm
use sort 'stable';
@new = sort { substr($a, 3, 5) cmp substr($b, 3, 5) } @old;

# force use of mergesort (not portable outside Perl 5.8)
use sort '_mergesort';  # note discouraging _
@new = sort { substr($a, 3, 5) cmp substr($b, 3, 5) } @old;
```

If you're using strict, you *must not* declare $a and $b as lexicals. They are package globals. That means if you're in the `main` package and type

```
@articles = sort {$b <=> $a} @files;
```

then `$a` and `$b` are `$main::a` and `$main::b` (or `$::a` and `$::b`), but if you're in the `FooPack` package, it's the same as typing

```
@articles = sort {$FooPack::b <=> $FooPack::a} @files;
```

The comparison function is required to behave. If it returns inconsistent results (sometimes saying `$x[1]` is less than `$x[2]` and sometimes saying the opposite, for example) the results are not well-defined.

Because <=> returns `undef` when either operand is `NaN` (not-a-number), and because `sort` will trigger a fatal error unless the result of a comparison is defined, when sorting with a comparison function like `$a <=> $b`, be careful about lists that might contain a `NaN`. The following example takes advantage of the fact that `NaN != NaN` to eliminate any `NaN`s from the input.

```
@result = sort { $a <=> $b } grep { $_ == $_ } @input;
```

splice ARRAY,OFFSET,LENGTH,LIST

splice ARRAY,OFFSET,LENGTH

splice ARRAY,OFFSET

splice ARRAY

Removes the elements designated by OFFSET and LENGTH from an array, and replaces them with the elements of LIST, if any. In list context, returns the elements removed from the array. In scalar context, returns the last element removed, or `undef` if no elements are removed. The array grows or shrinks as necessary. If OFFSET is negative then it starts that far from the end of the array. If LENGTH is omitted, removes everything from OFFSET onward. If LENGTH is negative, removes the elements from OFFSET onward except for -LENGTH elements at the end of the array. If both OFFSET and LENGTH are omitted, removes everything. If OFFSET is past the end of the array, perl issues a warning, and splices at the end of the array.

The following equivalences hold (assuming `$[ == 0 and $#a >= $i`)

```
push(@a,$x,$y)      splice(@a,@a,0,$x,$y)
pop(@a)             splice(@a,-1)
shift(@a)           splice(@a,0,1)
unshift(@a,$x,$y)   splice(@a,0,0,$x,$y)
$a[$i] = $y         splice(@a,$i,1,$y)
```

Example, assuming array lengths are passed before arrays:

```
    sub aeq {   # compare two list values
        my(@a) = splice(@_,0,shift);
        my(@b) = splice(@_,0,shift);
        return 0 unless @a == @b;       # same len?
        while (@a) {
            return 0 if pop(@a) ne pop(@b);
        }
        return 1;
    }
    if (&aeq($len,@foo[1..$len],0+@bar,@bar)) { ... }
```

split /PATTERN/,EXPR,LIMIT

split /PATTERN/,EXPR

split /PATTERN/

split

Splits the string EXPR into a list of strings and returns that list. By default, empty leading fields are preserved, and empty trailing ones are deleted. (If all fields are empty, they are considered to be trailing.)

In scalar context, returns the number of fields found and splits into the `@_` array. Use of split in scalar context is deprecated, however, because it clobbers your subroutine arguments.

If EXPR is omitted, splits the `$_` string. If PATTERN is also omitted, splits on whitespace (after skipping any leading whitespace). Anything matching PATTERN is taken to be a delimiter separating the fields. (Note that the delimiter may be longer than one character.)

If LIMIT is specified and positive, it represents the maximum number of fields the EXPR will be split into, though the actual number of fields returned depends on the number of times PATTERN matches within EXPR. If LIMIT is unspecified or zero, trailing null fields are stripped (which potential users of `pop` would do well to remember). If LIMIT is negative, it is treated as if an arbitrarily large LIMIT had been specified. Note that splitting an EXPR that evaluates to the empty string always returns the empty list, regardless of the LIMIT specified.

A pattern matching the null string (not to be confused with a null pattern `//`, which is just one member of the set of patterns matching a null string) will split the value of EXPR into separate characters at each point it matches that way. For example:

```
    print join(':', split(/ */, 'hi there'));
```

produces the output 'h:i:t:h:e:r:e'.

Using the empty pattern `//` specifically matches the null string, and is not be confused with the use of `//` to mean "the last successful pattern match".

Empty leading (or trailing) fields are produced when there are positive width matches at the beginning (or end) of the string; a zero-width match at the beginning (or end) of the string does not produce an empty field. For example:

```
   print join(':', split(/(?=\w)/, 'hi there!'));
```

produces the output 'h:i :t:h:e:r:e!'.

The LIMIT parameter can be used to split a line partially

```
    ($login, $passwd, $remainder) = split(/:/, $_, 3);
```

When assigning to a list, if LIMIT is omitted, or zero, Perl supplies a LIMIT one larger than the number of variables in the list, to avoid unnecessary work. For the list above LIMIT would have been 4 by default. In time critical applications it behooves you not to split into more fields than you really need.

If the PATTERN contains parentheses, additional list elements are created from each matching substring in the delimiter.

```
    split(/([,-])/, "1-10,20", 3);
```

produces the list value

```
    (1, '-', 10, ',', 20)
```

If you had the entire header of a normal Unix email message in $header, you could split it up into fields and their values this way:

```
    $header =~ s/\n\s+/ /g;  # fix continuation lines
    %hdrs   =  (UNIX_FROM => split /^(\S*?):\s*/m, $header);
```

The pattern `/PATTERN/` may be replaced with an expression to specify patterns that vary at runtime. (To do runtime compilation only once, use `/$variable/o`.)

As a special case, specifying a PATTERN of space (`' '`) will split on white space just as `split` with no arguments does. Thus, `split(' ')` can be used to emulate **awk**'s default behavior, whereas `split(/ /)` will give you as many null initial fields as there are leading spaces. A `split` on `/\s+/` is like a `split(' ')` except that any leading whitespace produces a null first field. A `split` with no arguments really does a `split(' ', $_)` internally.

A PATTERN of `/^/` is treated as if it were `/^/m`, since it isn't much use otherwise.

Example:

```
    open(PASSWD, '/etc/passwd');
    while (<PASSWD>) {
        chomp;
        ($login, $passwd, $uid, $gid,
         $gcos, $home, $shell) = split(/:/);
        #...
    }
```

As with regular pattern matching, any capturing parentheses that are not matched in a `split()` will be set to `undef` when returned:

```
    @fields = split /(A)|B/, "1A2B3";
    # @fields is (1, 'A', 2, undef, 3)
```

sprintf FORMAT, LIST

Returns a string formatted by the usual `printf` conventions of the C library function `sprintf`. See below for more details and see *sprintf*(3) or *printf*(3) on your system for an explanation of the general principles.

For example:

```
        # Format number with up to 8 leading zeroes
        $result = sprintf("%08d", $number);

        # Round number to 3 digits after decimal point
        $rounded = sprintf("%.3f", $number);
```

Perl does its own `sprintf` formatting–it emulates the C function `sprintf`, but it doesn't use it (except for floating-point numbers, and even then only the standard modifiers are allowed). As a result, any non-standard extensions in your local `sprintf` are not available from Perl.

Unlike `printf`, `sprintf` does not do what you probably mean when you pass it an array as your first argument. The array is given scalar context, and instead of using the 0th element of the array as the format, Perl will use the count of elements in the array as the format, which is almost never useful.

Perl's `sprintf` permits the following universally-known conversions:

```
   %%   a percent sign
   %c   a character with the given number
   %s   a string
   %d   a signed integer, in decimal
   %u   an unsigned integer, in decimal
   %o   an unsigned integer, in octal
   %x   an unsigned integer, in hexadecimal
   %e   a floating-point number, in scientific notation
   %f   a floating-point number, in fixed decimal notation
   %g   a floating-point number, in %e or %f notation
```

In addition, Perl permits the following widely-supported conversions:

```
   %X   like %x, but using upper-case letters
   %E   like %e, but using an upper-case "E"
   %G   like %g, but with an upper-case "E" (if applicable)
   %b   an unsigned integer, in binary
   %p   a pointer (outputs the Perl value's address in hexadecimal)
   %n   special: *stores* the number of characters output so far
        into the next variable in the parameter list
```

Finally, for backward (and we do mean "backward") compatibility, Perl permits these unnecessary but widely-supported conversions:

```
   %i   a synonym for %d
   %D   a synonym for %ld
   %U   a synonym for %lu
   %O   a synonym for %lo
   %F   a synonym for %f
```

Note that the number of exponent digits in the scientific notation produced by `%e`, `%E`, `%g` and `%G` for numbers with the modulus of the exponent less than 100 is system-dependent: it may be three or less (zero-padded as necessary). In other words, 1.23 times ten to the 99th may be either "1.23e99" or "1.23e099".

Between the `%` and the format letter, you may specify a number of additional attributes controlling the interpretation of the format. In order, these are:

format parameter index

An explicit format parameter index, such as `2$`. By default sprintf will format the next unused argument in the list, but this allows you to take the arguments out of order. Eg:

```
  printf '%2$d %1$d', 12, 34;      # prints "34 12"
  printf '%3$d %d %1$d', 1, 2, 3;  # prints "3 1 1"
```

flags

one or more of: space prefix positive number with a space + prefix positive number with a plus sign - left-justify within the field 0 use zeros, not spaces, to right-justify # prefix non-zero octal with "0", non-zero hex with "0x", non-zero binary with "0b"

For example:

```
  printf '<% d>', 12;   # prints "< 12>"
  printf '<%+d>', 12;   # prints "<+12>"
  printf '<%6s>', 12;   # prints "<    12>"
  printf '<%-6s>', 12;  # prints "<12    >"
  printf '<%06s>', 12;  # prints "<000012>"
  printf '<%#x>', 12;   # prints "<0xc>"
```

vector flag

The vector flag v, optionally specifying the join string to use. This flag tells perl to interpret the supplied string as a vector of integers, one for each character in the string, separated by a given string (a dot . by default). This can be useful for displaying ordinal values of characters in arbitrary strings:

```
printf "version is v%vd\n", $^V;     # Perl's version
```

Put an asterisk * before the v to override the string to use to separate the numbers:

```
printf "address is %*vX\n", ":", $addr;   # IPv6 address
printf "bits are %0*v8b\n", " ", $bits;   # random bitstring
```

You can also explicitly specify the argument number to use for the join string using eg *2$v:

```
printf '%*4$vX %*4$vX %*4$vX', @addr[1..3], ":";   # 3 IPv6 addresses
```

(minimum) width

Arguments are usually formatted to be only as wide as required to display the given value. You can override the width by putting a number here, or get the width from the next argument (with *) or from a specified argument (with eg *2$):

```
printf '<%s>', "a";       # prints "<a>"
printf '<%6s>', "a";      # prints "<     a>"
printf '<%*s>', 6, "a";   # prints "<     a>"
printf '<%*2$s>', "a", 6; # prints "<     a>"
printf '<%2s>', "long";   # prints "<long>" (does not truncate)
```

If a field width obtained through * is negative, it has the same effect as the - flag: left-justification.

precision, or maximum width

You can specify a precision (for numeric conversions) or a maximum width (for string conversions) by specifying a . followed by a number. For floating point formats, with the exception of 'g' and 'G', this specifies the number of decimal places to show (the default being 6), eg:

```
# these examples are subject to system-specific variation
printf '<%f>', 1;    # prints "<1.000000>"
printf '<%.1f>', 1;  # prints "<1.0>"
printf '<%.0f>', 1;  # prints "<1>"
printf '<%e>', 10;   # prints "<1.000000e+01>"
printf '<%.1e>', 10; # prints "<1.0e+01>"
```

For 'g' and 'G', this specifies the maximum number of digits to show, including prior to the decimal point as well as after it, eg:

```
# these examples are subject to system-specific variation
printf '<%g>', 1;        # prints "<1>"
printf '<%.10g>', 1;     # prints "<1>"
printf '<%g>', 100;      # prints "<100>"
printf '<%.1g>', 100;    # prints "<1e+02>"
printf '<%.2g>', 100.01; # prints "<1e+02>"
printf '<%.5g>', 100.01; # prints "<100.01>"
printf '<%.4g>', 100.01; # prints "<100>"
```

For integer conversions, specifying a precision implies that the output of the number itself should be zero-padded to this width:

```
printf '<%.6x>', 1;      # prints "<000001>"
printf '<%#.6x>', 1;     # prints "<0x000001>"
printf '<%-10.6x>', 1;   # prints "<000001    >"
```

For string conversions, specifying a precision truncates the string to fit in the specified width:

```
printf '<%.5s>', "truncated";   # prints "<trunc>"
printf '<%10.5s>', "truncated"; # prints "<     trunc>"
```

You can also get the precision from the next argument using `.*`:

```
printf '<%.6x>', 1;       # prints "<000001>"
printf '<%.*x>', 6, 1;    # prints "<000001>"
```

You cannot currently get the precision from a specified number, but it is intended that this will be possible in the future using eg `.*2$`:

```
printf '<%.*2$x>', 1, 6;   # INVALID, but in future will print "<000001>"
```

size

For numeric conversions, you can specify the size to interpret the number as using `l`, `h`, `V`, `q`, `L`, or `ll`. For integer conversions (`d u o x X b i D U O`), numbers are usually assumed to be whatever the default integer size is on your platform (usually 32 or 64 bits), but you can override this to use instead one of the standard C types, as supported by the compiler used to build Perl:

```
l           interpret integer as C type "long" or "unsigned long"
h           interpret integer as C type "short" or "unsigned short"
q, L or ll  interpret integer as C type "long long", "unsigned long long".
            or "quads" (typically 64-bit integers)
```

The last will produce errors if Perl does not understand "quads" in your installation. (This requires that either the platform natively supports quads or Perl was specifically compiled to support quads.) You can find out whether your Perl supports quads via *Config*:

```
use Config;
($Config{use64bitint} eq 'define' || $Config{longsize} >= 8) &&
        print "quads\n";
```

For floating point conversions (`e f g E F G`), numbers are usually assumed to be the default floating point size on your platform (double or long double), but you can force 'long double' with `q`, `L`, or `ll` if your platform supports them. You can find out whether your Perl supports long doubles via *Config*:

```
use Config;
$Config{d_longdbl} eq 'define' && print "long doubles\n";
```

You can find out whether Perl considers 'long double' to be the default floating point size to use on your platform via *Config*:

```
use Config;
($Config{uselongdouble} eq 'define') &&
        print "long doubles by default\n";
```

It can also be the case that long doubles and doubles are the same thing:

```
use Config;
($Config{doublesize} == $Config{longdblsize}) &&
        print "doubles are long doubles\n";
```

The size specifier `V` has no effect for Perl code, but it is supported for compatibility with XS code; it means 'use the standard size for a Perl integer (or floating-point number)', which is already the default for Perl code.

order of arguments

Normally, sprintf takes the next unused argument as the value to format for each format specification. If the format specification uses * to require additional arguments, these are consumed from the argument list in the order in which they appear in the format specification *before* the value to format. Where an argument is specified using an explicit index, this does not affect the normal order for the arguments (even when the explicitly specified index would have been the next argument in any case).

So:

```
printf '<%*.*s>', $a, $b, $c;
```

would use `$a` for the width, `$b` for the precision and `$c` as the value to format, while:

```
print '<%*1$.*s>', $a, $b;
```

would use `$a` for the width and the precision, and `$b` as the value to format.

Here are some more examples - beware that when using an explicit index, the `$` may need to be escaped:

```
printf "%2\$d %d\n",    12, 34;               # will print "34 12\n"
printf "%2\$d %d %d\n", 12, 34;               # will print "34 12 34\n"
printf "%3\$d %d %d\n", 12, 34, 56;           # will print "56 12 34\n"
printf "%2\$*3\$d %d\n", 12, 34, 3;           # will print " 34 12\n"
```

If `use locale` is in effect, the character used for the decimal point in formatted real numbers is affected by the LC_NUMERIC locale. See *perllocale*.

sqrt EXPR

sqrt

Return the square root of EXPR. If EXPR is omitted, returns square root of `$_`. Only works on non-negative operands, unless you've loaded the standard Math::Complex module.

```
use Math::Complex;
print sqrt(-2);    # prints 1.4142135623731i
```

srand EXPR

srand

Sets the random number seed for the `rand` operator.

The point of the function is to "seed" the `rand` function so that `rand` can produce a different sequence each time you run your program.

If srand() is not called explicitly, it is called implicitly at the first use of the `rand` operator. However, this was not the case in versions of Perl before 5.004, so if your script will run under older Perl versions, it should call `srand`.

Most programs won't even call srand() at all, except those that need a cryptographically-strong starting point rather than the generally acceptable default, which is based on time of day, process ID, and memory allocation, or the */dev/urandom* device, if available.

You can call srand($seed) with the same $seed to reproduce the *same* sequence from rand(), but this is usually reserved for generating predictable results for testing or debugging. Otherwise, don't call srand() more than once in your program.

Do **not** call srand() (i.e. without an argument) more than once in a script. The internal state of the random number generator should contain more entropy than can be provided by any seed, so calling srand() again actually *loses* randomness.

Most implementations of `srand` take an integer and will silently truncate decimal numbers. This means `srand(42)` will usually produce the same results as `srand(42.1)`. To be safe, always pass `srand` an integer.

In versions of Perl prior to 5.004 the default seed was just the current `time`. This isn't a particularly good seed, so many old programs supply their own seed value (often `time ^ $$` or `time ^ ($$ + ($$ << 15))`), but that isn't necessary any more.

Note that you need something much more random than the default seed for cryptographic purposes. Checksumming the compressed output of one or more rapidly changing operating system status programs is the usual method. For example:

```
srand (time ^ $$ ^ unpack "%L*", `ps axww | gzip`);
```

If you're particularly concerned with this, see the `Math::TrulyRandom` module in CPAN.

Frequently called programs (like CGI scripts) that simply use

```
    time ^ $$
```

for a seed can fall prey to the mathematical property that

```
    a^b == (a+1)^(b+1)
```

one-third of the time. So don't do that.

stat FILEHANDLE

stat EXPR

stat

Returns a 13-element list giving the status info for a file, either the file opened via FILEHANDLE, or named by EXPR. If EXPR is omitted, it stats `$_`. Returns a null list if the stat fails. Typically used as follows:

```
    ($dev,$ino,$mode,$nlink,$uid,$gid,$rdev,$size,
       $atime,$mtime,$ctime,$blksize,$blocks)
           = stat($filename);
```

Not all fields are supported on all filesystem types. Here are the meanings of the fields:

```
  0 dev      device number of filesystem
  1 ino      inode number
  2 mode     file mode  (type and permissions)
  3 nlink    number of (hard) links to the file
  4 uid      numeric user ID of file's owner
  5 gid      numeric group ID of file's owner
  6 rdev     the device identifier (special files only)
  7 size     total size of file, in bytes
  8 atime    last access time in seconds since the epoch
  9 mtime    last modify time in seconds since the epoch
 10 ctime    inode change time in seconds since the epoch (*)
 11 blksize  preferred block size for file system I/O
 12 blocks   actual number of blocks allocated
```

(The epoch was at 00:00 January 1, 1970 GMT.)

(*) The ctime field is non-portable. In particular, you cannot expect it to be a "creation time", see Files and Filesystems in *perlport* for details.

If `stat` is passed the special filehandle consisting of an underline, no stat is done, but the current contents of the stat structure from the last `stat`, `lstat`, or filetest are returned. Example:

```
    if (-x $file && (($d) = stat(_)) && $d < 0) {
        print "$file is executable NFS file\n";
    }
```

(This works on machines only for which the device number is negative under NFS.)

Because the mode contains both the file type and its permissions, you should mask off the file type portion and (s)printf using a `"%o"` if you want to see the real permissions.

```
    $mode = (stat($filename))[2];
    printf "Permissions are %04o\n", $mode & 07777;
```

In scalar context, `stat` returns a boolean value indicating success or failure, and, if successful, sets the information associated with the special filehandle `_`.

The File::stat module provides a convenient, by-name access mechanism:

```
    use File::stat;
    $sb = stat($filename);
    printf "File is %s, size is %s, perm %04o, mtime %s\n",
        $filename, $sb->size, $sb->mode & 07777,
        scalar localtime $sb->mtime;
```

You can import symbolic mode constants (S_IF*) and functions (S_IS*) from the Fcntl module:

```
    use Fcntl ':mode';

    $mode = (stat($filename))[2];

    $user_rwx      = ($mode & S_IRWXU) >> 6;
    $group_read    = ($mode & S_IRGRP) >> 3;
    $other_execute =  $mode & S_IXOTH;

    printf "Permissions are %04o\n", S_IMODE($mode), "\n";

    $is_setuid     =  $mode & S_ISUID;
    $is_setgid     =  S_ISDIR($mode);
```

You could write the last two using the -u and -d operators. The commonly available S_IF* constants are

```
    # Permissions: read, write, execute, for user, group, others.

    S_IRWXU S_IRUSR S_IWUSR S_IXUSR
    S_IRWXG S_IRGRP S_IWGRP S_IXGRP
    S_IRWXO S_IROTH S_IWOTH S_IXOTH

    # Setuid/Setgid/Stickiness/SaveText.
    # Note that the exact meaning of these is system dependent.

    S_ISUID S_ISGID S_ISVTX S_ISTXT

    # File types.  Not necessarily all are available on your system.

    S_IFREG S_IFDIR S_IFLNK S_IFBLK S_ISCHR S_IFIFO S_IFSOCK S_IFWHT S_ENFMT

    # The following are compatibility aliases for S_IRUSR, S_IWUSR, S_IXUSR.

    S_IREAD S_IWRITE S_IEXEC
```

and the S_IF* functions are

```
    S_IMODE($mode)      the part of $mode containing the permission bits
                        and the setuid/setgid/sticky bits

    S_IFMT($mode)       the part of $mode containing the file type
                        which can be bit-anded with e.g. S_IFREG
                        or with the following functions

    # The operators -f, -d, -l, -b, -c, -p, and -S.
    S_ISREG($mode) S_ISDIR($mode) S_ISLNK($mode)
    S_ISBLK($mode) S_ISCHR($mode) S_ISFIFO($mode) S_ISSOCK($mode)

    # No direct -X operator counterpart, but for the first one
    # the -g operator is often equivalent.  The ENFMT stands for
    # record flocking enforcement, a platform-dependent feature.

    S_ISENFMT($mode) S_ISWHT($mode)
```

See your native chmod(2) and stat(2) documentation for more details about the `S_*` constants. To get status info for a symbolic link instead of the target file behind the link, use the `lstat` function.

study SCALAR

study

Takes extra time to study SCALAR (`$_` if unspecified) in anticipation of doing many pattern matches on the string before it is next modified. This may or may not save time, depending on the nature and number of patterns you are searching on, and on the distribution of character frequencies in the string to be searched–you probably want to compare run times with and without it to see which runs faster. Those loops which scan for many short constant strings (including the constant parts of more complex patterns) will benefit most. You may have only one `study` active at a time–if you study a different scalar the first is "unstudied". (The way `study` works is this: a linked list of every character in the string to be searched is made, so we know, for example, where all the `'k'` characters are. From each search string, the rarest character is selected, based on some static frequency tables constructed from some C programs and English text. Only those places that contain this "rarest" character are examined.)

For example, here is a loop that inserts index producing entries before any line containing a certain pattern:

```
    while (<>) {
        study;
        print ".IX foo\n"       if /\bfoo\b/;
        print ".IX bar\n"       if /\bbar\b/;
        print ".IX blurfl\n"    if /\bblurfl\b/;
        # ...
        print;
    }
```

In searching for `/\bfoo\b/`, only those locations in `$_` that contain `f` will be looked at, because `f` is rarer than `o`. In general, this is a big win except in pathological cases. The only question is whether it saves you more time than it took to build the linked list in the first place.

Note that if you have to look for strings that you don't know till runtime, you can build an entire loop as a string and `eval` that to avoid recompiling all your patterns all the time. Together with undefining `$/` to input entire files as one record, this can be very fast, often faster than specialized programs like fgrep(1). The following scans a list of files (`@files`) for a list of words (`@words`), and prints out the names of those files that contain a match:

```
    $search = 'while (<>) { study;';
    foreach $word (@words) {
        $search .= "++\$seen{\$ARGV} if /\\b$word\\b/;\n";
    }
    $search .= "}";
    @ARGV = @files;
    undef $/;
    eval $search;               # this screams
    $/ = "\n";          # put back to normal input delimiter
    foreach $file (sort keys(%seen)) {
        print $file, "\n";
    }
```

sub NAME BLOCK

sub NAME (PROTO) BLOCK

sub NAME : ATTRS BLOCK

sub NAME (PROTO) : ATTRS BLOCK

This is subroutine definition, not a real function *per se*. Without a BLOCK it's just a forward declaration. Without a NAME, it's an anonymous function declaration, and does actually return a value: the CODE ref of the closure you just created.

See *perlsub* and *perlref* for details about subroutines and references, and *attributes* and *Attribute::Handlers* for more information about attributes.

substr EXPR,OFFSET,LENGTH,REPLACEMENT

substr EXPR,OFFSET,LENGTH

substr EXPR,OFFSET

Extracts a substring out of EXPR and returns it. First character is at offset `0`, or whatever you've set `$[` to (but don't do that). If OFFSET is negative (or more precisely, less than `$[`), starts that far from the end of the string. If LENGTH is omitted, returns everything to the end of the string. If LENGTH is negative, leaves that many characters off the end of the string.

You can use the substr() function as an lvalue, in which case EXPR must itself be an lvalue. If you assign something shorter than LENGTH, the string will shrink, and if you assign something longer than LENGTH, the string will grow to accommodate it. To keep the string the same length you may need to pad or chop your value using `sprintf`.

If OFFSET and LENGTH specify a substring that is partly outside the string, only the part within the string is returned. If the substring is beyond either end of the string, substr() returns the undefined value and produces a warning. When used as an lvalue, specifying a substring that is entirely outside the string is a fatal error. Here's an example showing the behavior for boundary cases:

```
my $name = 'fred';
substr($name, 4) = 'dy';          # $name is now 'freddy'
my $null = substr $name, 6, 2;    # returns '' (no warning)
my $oops = substr $name, 7;       # returns undef, with warning
substr($name, 7) = 'gap';         # fatal error
```

An alternative to using substr() as an lvalue is to specify the replacement string as the 4th argument. This allows you to replace parts of the EXPR and return what was there before in one operation, just as you can with splice().

If the lvalue returned by substr is used after the EXPR is changed in any way, the behaviour may not be as expected and is subject to change. This caveat includes code such as `print(substr($foo,$a,$b)=$bar)` or `(substr($foo,$a,$b)=$bar)=$fud` (where $foo is changed via the substring assignment, and then the substr is used again), or where a substr() is aliased via a `foreach` loop or passed as a parameter or a reference to it is taken and then the alias, parameter, or deref'd reference either is used after the original EXPR has been changed or is assigned to and then used a second time.

symlink OLDFILE,NEWFILE

Creates a new filename symbolically linked to the old filename. Returns `1` for success, `0` otherwise. On systems that don't support symbolic links, produces a fatal error at run time. To check for that, use eval:

```
$symlink_exists = eval { symlink("",""); 1 };
```

syscall NUMBER, LIST

Calls the system call specified as the first element of the list, passing the remaining elements as arguments to the system call. If unimplemented, produces a fatal error. The arguments are interpreted as follows: if a given argument is numeric, the argument is passed as an int. If not, the pointer to the string value is passed. You are responsible to make sure a string is pre-extended long enough to receive any result that might be written into a string. You can't use a string literal (or other read-only string) as an argument to `syscall` because Perl has to assume that any string pointer might be written through. If your integer arguments are not literals and have never been interpreted in a numeric context, you may need to add `0` to them to force them to look like numbers. This emulates the `syswrite` function (or vice versa):

```
    require 'syscall.ph';              # may need to run h2ph
    $s = "hi there\n";
    syscall(&SYS_write, fileno(STDOUT), $s, length $s);
```

Note that Perl supports passing of up to only 14 arguments to your system call, which in practice should usually suffice.

Syscall returns whatever value returned by the system call it calls. If the system call fails, `syscall` returns `-1` and sets `$!` (errno). Note that some system calls can legitimately return `-1`. The proper way to handle such calls is to assign `$!=0;` before the call and check the value of `$!` if syscall returns `-1`.

There's a problem with `syscall(&SYS_pipe)`: it returns the file number of the read end of the pipe it creates. There is no way to retrieve the file number of the other end. You can avoid this problem by using `pipe` instead.

sysopen FILEHANDLE,FILENAME,MODE

sysopen FILEHANDLE,FILENAME,MODE,PERMS

Opens the file whose filename is given by FILENAME, and associates it with FILEHANDLE. If FILEHANDLE is an expression, its value is used as the name of the real filehandle wanted. This function calls the underlying operating system's `open` function with the parameters FILENAME, MODE, PERMS.

The possible values and flag bits of the MODE parameter are system-dependent; they are available via the standard module `Fcntl`. See the documentation of your operating system's `open` to see which values and flag bits are available. You may combine several flags using the |-operator.

Some of the most common values are `O_RDONLY` for opening the file in read-only mode, `O_WRONLY` for opening the file in write-only mode, and `O_RDWR` for opening the file in read-write mode.

For historical reasons, some values work on almost every system supported by perl: zero means read-only, one means write-only, and two means read/write. We know that these values do *not* work under OS/390 & VM/ESA Unix and on the Macintosh; you probably don't want to use them in new code.

If the file named by FILENAME does not exist and the `open` call creates it (typically because MODE includes the `O_CREAT` flag), then the value of PERMS specifies the permissions of the newly created file. If you omit the PERMS argument to `sysopen`, Perl uses the octal value `0666`. These permission values need to be in octal, and are modified by your process's current `umask`.

In many systems the `O_EXCL` flag is available for opening files in exclusive mode. This is **not** locking: exclusiveness means here that if the file already exists, sysopen() fails. `O_EXCL` may not work on network filesystems, and has no effect unless the `O_CREAT` flag is set as well. Setting `O_CREAT|O_EXCL` prevents the file from being opened if it is a symbolic link. It does not protect against symbolic links in the file's path.

Sometimes you may want to truncate an already-existing file. This can be done using the `O_TRUNC` flag. The behavior of `O_TRUNC` with `O_RDONLY` is undefined.

You should seldom if ever use `0644` as argument to `sysopen`, because that takes away the user's option to have a more permissive umask. Better to omit it. See the perlfunc(1) entry on `umask` for more on this.

Note that `sysopen` depends on the fdopen() C library function. On many UNIX systems, fdopen() is known to fail when file descriptors exceed a certain value, typically 255. If you need more file descriptors than that, consider rebuilding Perl to use the `sfio` library, or perhaps using the POSIX::open() function.

See *perlopentut* for a kinder, gentler explanation of opening files.

sysread FILEHANDLE,SCALAR,LENGTH,OFFSET

sysread FILEHANDLE,SCALAR,LENGTH

Attempts to read LENGTH bytes of data into variable SCALAR from the specified FILEHANDLE, using the system call read(2). It bypasses buffered IO, so mixing this with other kinds of reads, `print`, `write`, `seek`, `tell`, or `eof` can cause confusion because the perlio or stdio layers usually buffers data. Returns the number of bytes actually read, `0` at end of file, or undef if there was an error (in the latter case `$!` is also set). SCALAR will be grown or shrunk so that the last byte actually read is the last byte of the scalar after the read.

An OFFSET may be specified to place the read data at some place in the string other than the beginning. A negative OFFSET specifies placement at that many characters counting backwards from the end of the string. A positive OFFSET greater than the length of SCALAR results in the string being padded to the required size with `"\0"` bytes before the result of the read is appended.

There is no syseof() function, which is ok, since eof() doesn't work very well on device files (like ttys) anyway. Use sysread() and check for a return value for 0 to decide whether you're done.

Note that if the filehandle has been marked as `:utf8` Unicode characters are read instead of bytes (the LENGTH, OFFSET, and the return value of sysread() are in Unicode characters). The `:encoding(...)` layer implicitly introduces the `:utf8` layer. See binmode, open, and the `open` pragma, *open*.

sysseek FILEHANDLE,POSITION,WHENCE

Sets FILEHANDLE's system position in bytes using the system call lseek(2). FILEHANDLE may be an expression whose value gives the name of the filehandle. The values for WHENCE are `0` to set the new position to POSITION, `1` to set the it to the current position plus POSITION, and `2` to set it to EOF plus POSITION (typically negative).

Note the *in bytes*: even if the filehandle has been set to operate on characters (for example by using the `:utf8` I/O layer), tell() will return byte offsets, not character offsets (because implementing that would render sysseek() very slow).

sysseek() bypasses normal buffered IO, so mixing this with reads (other than `sysread`, for example &gt;&lt or read()) `print`, `write`, `seek`, `tell`, or `eof` may cause confusion.

For WHENCE, you may also use the constants `SEEK_SET`, `SEEK_CUR`, and `SEEK_END` (start of the file, current position, end of the file) from the Fcntl module. Use of the constants is also more portable than relying on 0, 1, and 2. For example to define a "systell" function:

```
    use Fcntl 'SEEK_CUR';
    sub systell { sysseek($_[0], 0, SEEK_CUR) }
```

Returns the new position, or the undefined value on failure. A position of zero is returned as the string `"0 but true"`; thus `sysseek` returns true on success and false on failure, yet you can still easily determine the new position.

system LIST

system PROGRAM LIST

Does exactly the same thing as `exec LIST`, except that a fork is done first, and the parent process waits for the child process to complete. Note that argument processing varies depending on the number of arguments. If there is more than one argument in LIST, or if LIST is an array with more than one value, starts the program given by the first element of the list with arguments given by the rest of the list. If there is only one scalar argument, the argument is checked for shell metacharacters, and if there are any, the entire argument is passed to the system's command shell for parsing (this is `/bin/sh -c` on Unix platforms, but varies on other platforms). If there are no shell metacharacters in the argument, it is split into words and passed directly to `execvp`, which is more efficient.

Beginning with v5.6.0, Perl will attempt to flush all files opened for output before any operation that may do a fork, but this may not be supported on some platforms (see *perlport*). To be safe, you may need to set $| ($AUTOFLUSH in English) or call the `autoflush()` method of `IO::Handle` on any open handles.

The return value is the exit status of the program as returned by the `wait` call. To get the actual exit value shift right by eight (see below). See also exec. This is *not* what you want to use to capture the output from a command, for that you should use merely backticks or `qx//`, as described in 'STRING' in *perlop*. Return value of -1 indicates a failure to start the program (inspect $! for the reason).

Like `exec`, `system` allows you to lie to a program about its name if you use the `system PROGRAM LIST` syntax. Again, see exec.

Since `SIGINT` and `SIGQUIT` are ignored during the execution of `system`, if you expect your program to terminate on receipt of these signals you will need to arrange to do so yourself based on the return value.

```
@args = ("command", "arg1", "arg2");
system(@args) == 0
     or die "system @args failed: $?"
```

You can check all the failure possibilities by inspecting `$?` like this:

```
if ($? == -1) {
    print "failed to execute: $!\n";
}
elsif ($? & 127) {
    printf "child died with signal %d, %s coredump\n",
        ($? & 127),  ($? & 128) ? 'with' : 'without';
}
else {
    printf "child exited with value %d\n", $? >> 8;
}
```

or more portably by using the W*() calls of the POSIX extension; see *perlport* for more information.

When the arguments get executed via the system shell, results and return codes will be subject to its quirks and capabilities. See 'STRING' in *perlop* and exec for details.

syswrite FILEHANDLE,SCALAR,LENGTH,OFFSET

syswrite FILEHANDLE,SCALAR,LENGTH

syswrite FILEHANDLE,SCALAR

Attempts to write LENGTH bytes of data from variable SCALAR to the specified FILEHANDLE, using the system call write(2). If LENGTH is not specified, writes whole SCALAR. It bypasses buffered IO, so mixing this with reads (other than `sysread()`), `print`, `write`, `seek`, `tell`, or `eof` may cause confusion because the perlio and stdio layers usually buffers data. Returns the number of bytes actually written, or `undef` if there was an error (in this case the errno variable `$!` is also set). If the LENGTH is greater than the available data in the SCALAR after the OFFSET, only as much data as is available will be written.

An OFFSET may be specified to write the data from some part of the string other than the beginning. A negative OFFSET specifies writing that many characters counting backwards from the end of the string. In the case the SCALAR is empty you can use OFFSET but only zero offset.

Note that if the filehandle has been marked as `:utf8`, Unicode characters are written instead of bytes (the LENGTH, OFFSET, and the return value of syswrite() are in UTF-8 encoded Unicode characters). The `:encoding(...)` layer implicitly introduces the `:utf8` layer. See binmode, open, and the `open` pragma, *open*.

tell FILEHANDLE

tell

Returns the current position *in bytes* for FILEHANDLE, or -1 on error. FILEHANDLE may be an expression whose value gives the name of the actual filehandle. If FILEHANDLE is omitted, assumes the file last read.

Note the *in bytes*: even if the filehandle has been set to operate on characters (for example by using the `:utf8` open layer), tell() will return byte offsets, not character offsets (because that would render seek() and tell() rather slow).

The return value of tell() for the standard streams like the STDIN depends on the operating system: it may return -1 or something else. tell() on pipes, fifos, and sockets usually returns -1.

There is no `systell` function. Use `sysseek(FH, 0, 1)` for that.

Do not use tell() on a filehandle that has been opened using sysopen(), use sysseek() for that as described above. Why? Because sysopen() creates unbuffered, "raw", filehandles, while open() creates buffered filehandles. sysseek() make sense only on the first kind, tell() only makes sense on the second kind.

telldir DIRHANDLE

Returns the current position of the `readdir` routines on DIRHANDLE. Value may be given to `seekdir` to access a particular location in a directory. Has the same caveats about possible directory compaction as the corresponding system library routine.

tie VARIABLE,CLASSNAME,LIST

This function binds a variable to a package class that will provide the implementation for the variable. VARIABLE is the name of the variable to be enchanted. CLASSNAME is the name of a class implementing objects of correct type. Any additional arguments are passed to the `new` method of the class (meaning `TIESCALAR`, `TIEHANDLE`, `TIEARRAY`, or `TIEHASH`). Typically these are arguments such as might be passed to the `dbm_open()` function of C. The object returned by the `new` method is also returned by the `tie` function, which would be useful if you want to access other methods in CLASSNAME.

Note that functions such as `keys` and `values` may return huge lists when used on large objects, like DBM files. You may prefer to use the `each` function to iterate over such. Example:

```
# print out history file offsets
use NDBM_File;
tie(%HIST, 'NDBM_File', '/usr/lib/news/history', 1, 0);
while (($key,$val) = each %HIST) {
    print $key, ' = ', unpack('L',$val), "\n";
}
untie(%HIST);
```

A class implementing a hash should have the following methods:

```
TIEHASH classname, LIST
FETCH this, key
STORE this, key, value
DELETE this, key
CLEAR this
EXISTS this, key
FIRSTKEY this
NEXTKEY this, lastkey
SCALAR this
DESTROY this
UNTIE this
```

A class implementing an ordinary array should have the following methods:

```
TIEARRAY classname, LIST
FETCH this, key
STORE this, key, value
FETCHSIZE this
STORESIZE this, count
CLEAR this
PUSH this, LIST
POP this
SHIFT this
UNSHIFT this, LIST
SPLICE this, offset, length, LIST
EXTEND this, count
DESTROY this
UNTIE this
```

A class implementing a file handle should have the following methods:

```
    TIEHANDLE classname, LIST
    READ this, scalar, length, offset
    READLINE this
    GETC this
    WRITE this, scalar, length, offset
    PRINT this, LIST
    PRINTF this, format, LIST
    BINMODE this
    EOF this
    FILENO this
    SEEK this, position, whence
    TELL this
    OPEN this, mode, LIST
    CLOSE this
    DESTROY this
    UNTIE this
```

A class implementing a scalar should have the following methods:

```
    TIESCALAR classname, LIST
    FETCH this,
    STORE this, value
    DESTROY this
    UNTIE this
```

Not all methods indicated above need be implemented. See *perltie, Tie::Hash*, *Tie::Array, Tie::Scalar*, and *Tie::Handle*.

Unlike `dbmopen`, the `tie` function will not use or require a module for you–you need to do that explicitly yourself. See DB_File or the *Config* module for interesting `tie` implementations.

For further details see *perltie*, §**??**.

tied VARIABLE

Returns a reference to the object underlying VARIABLE (the same value that was originally returned by the `tie` call that bound the variable to a package.) Returns the undefined value if VARIABLE isn't tied to a package.

time

Returns the number of non-leap seconds since whatever time the system considers to be the epoch, suitable for feeding to `gmtime` and `localtime`. On most systems the epoch is 00:00:00 UTC, January 1, 1970; a prominent exception being Mac OS Classic which uses 00:00:00, January 1, 1904 in the current local time zone for its epoch.

For measuring time in better granularity than one second, you may use either the Time::HiRes module (from CPAN, and starting from Perl 5.8 part of the standard distribution), or if you have gettimeofday(2), you may be able to use the `syscall` interface of Perl. See *perlfaq8* for details.

times

Returns a four-element list giving the user and system times, in seconds, for this process and the children of this process.

```
    ($user,$system,$cuser,$csystem) = times;
```

In scalar context, `times` returns `$user`.

tr///

The transliteration operator. Same as `y///`. See *perlop*.

truncate FILEHANDLE,LENGTH

truncate EXPR,LENGTH

Truncates the file opened on FILEHANDLE, or named by EXPR, to the specified length. Produces a fatal error if truncate isn't implemented on your system. Returns true if successful, the undefined value otherwise.

The behavior is undefined if LENGTH is greater than the length of the file.

uc EXPR

uc

Returns an uppercased version of EXPR. This is the internal function implementing the `\U` escape in double-quoted strings. Respects current LC_CTYPE locale if `use locale` in force. See *perllocale* and *perlunicode* for more details about locale and Unicode support. It does not attempt to do titlecase mapping on initial letters. See `ucfirst` for that.

If EXPR is omitted, uses `$_`.

ucfirst EXPR

ucfirst

Returns the value of EXPR with the first character in uppercase (titlecase in Unicode). This is the internal function implementing the `\u` escape in double-quoted strings. Respects current LC_CTYPE locale if `use locale` in force. See *perllocale* and *perlunicode* for more details about locale and Unicode support.

If EXPR is omitted, uses `$_`.

umask EXPR

umask

Sets the umask for the process to EXPR and returns the previous value. If EXPR is omitted, merely returns the current umask.

The Unix permission `rwxr-x-` is represented as three sets of three bits, or three octal digits: `0750` (the leading 0 indicates octal and isn't one of the digits). The `umask` value is such a number representing disabled permissions bits. The permission (or "mode") values you pass `mkdir` or `sysopen` are modified by your umask, so even if you tell `sysopen` to create a file with permissions `0777`, if your umask is `0022` then the file will actually be created with permissions `0755`. If your `umask` were `0027` (group can't write; others can't read, write, or execute), then passing `sysopen` `0666` would create a file with mode `0640` (`0666 &~ 027` is `0640`).

Here's some advice: supply a creation mode of `0666` for regular files (in `sysopen`) and one of `0777` for directories (in `mkdir`) and executable files. This gives users the freedom of choice: if they want protected files, they might choose process umasks of `022`, `027`, or even the particularly antisocial mask of `077`. Programs should rarely if ever make policy decisions better left to the user. The exception to this is when writing files that should be kept private: mail files, web browser cookies, *.rhosts* files, and so on.

If umask(2) is not implemented on your system and you are trying to restrict access for *yourself* (i.e., (EXPR & 0700) > 0), produces a fatal error at run time. If umask(2) is not implemented and you are not trying to restrict access for yourself, returns `undef`.

Remember that a umask is a number, usually given in octal; it is *not* a string of octal digits. See also oct, if all you have is a string.

undef EXPR

undef

Undefines the value of EXPR, which must be an lvalue. Use only on a scalar value, an array (using `@`), a hash (using `%`), a subroutine (using `&`), or a typeglob (using `*`). (Saying `undef $hash{$key}` will probably not do what you expect on most predefined variables or DBM list values, so don't do that; see *delete*.) Always returns the undefined value. You can omit the EXPR, in which case nothing is undefined, but you still get an undefined value that you could, for instance, return from a subroutine, assign to a variable or pass as a parameter. Examples:

```
    undef $foo;
    undef $bar{'blurfl'};      # Compare to: delete $bar{'blurfl'};
    undef @ary;
    undef %hash;
    undef &mysub;
    undef *xyz;       # destroys $xyz, @xyz, %xyz, &xyz, etc.
    return (wantarray ? (undef, $errmsg) : undef) if $they_blew_it;
    select undef, undef, undef, 0.25;
    ($a, $b, undef, $c) = &foo;       # Ignore third value returned
```

Note that this is a unary operator, not a list operator.

unlink LIST

unlink

Deletes a list of files. Returns the number of files successfully deleted.

```
    $cnt = unlink 'a', 'b', 'c';
    unlink @goners;
    unlink <*.bak>;
```

Note: `unlink` will not delete directories unless you are superuser and the **-U** flag is supplied to Perl. Even if these conditions are met, be warned that unlinking a directory can inflict damage on your filesystem. Use `rmdir` instead.

If LIST is omitted, uses `$_`.

unpack TEMPLATE,EXPR

`unpack` does the reverse of `pack`: it takes a string and expands it out into a list of values. (In scalar context, it returns merely the first value produced.)

The string is broken into chunks described by the TEMPLATE. Each chunk is converted separately to a value. Typically, either the string is a result of `pack`, or the bytes of the string represent a C structure of some kind.

The TEMPLATE has the same format as in the `pack` function. Here's a subroutine that does substring:

```
    sub substr {
        my($what,$where,$howmuch) = @_;
        unpack("x$where a$howmuch", $what);
    }
```

and then there's

```
    sub ordinal { unpack("c",$_[0]); } # same as ord()
```

In addition to fields allowed in pack(), you may prefix a field with a %<number> to indicate that you want a <number>-bit checksum of the items instead of the items themselves. Default is a 16-bit checksum. Checksum is calculated by summing numeric values of expanded values (for string fields the sum of `ord($char)` is taken, for bit fields the sum of zeroes and ones).

For example, the following computes the same number as the System V sum program:

```
    $checksum = do {
        local $/;  # slurp!
        unpack("%32C*",<>) % 65535;
    };
```

The following efficiently counts the number of set bits in a bit vector:

```
    $setbits = unpack("%32b*", $selectmask);
```

The `p` and `P` formats should be used with care. Since Perl has no way of checking whether the value passed to `unpack()` corresponds to a valid memory location, passing a pointer value that's not known to be valid is likely to have disastrous consequences.

If there are more pack codes or if the repeat count of a field or a group is larger than what the remainder of the input string allows, the result is not well defined: in some cases, the repeat count is decreased, or `unpack()` will produce null strings or zeroes, or terminate with an error. If the input string is longer than one described by the TEMPLATE, the rest is ignored.

See pack for more examples and notes.

untie VARIABLE

Breaks the binding between a variable and a package. (See `tie`.) Has no effect if the variable is not tied.

unshift ARRAY,LIST

Does the opposite of a `shift`. Or the opposite of a `push`, depending on how you look at it. Prepends list to the front of the array, and returns the new number of elements in the array.

```
    unshift(@ARGV, '-e') unless $ARGV[0] =~ /^-/;
```

Note the LIST is prepended whole, not one element at a time, so the prepended elements stay in the same order. Use `reverse` to do the reverse.

use Module VERSION LIST

use Module VERSION

use Module LIST

use Module

use VERSION

Imports some semantics into the current package from the named module, generally by aliasing certain subroutine or variable names into your package. It is exactly equivalent to

```
    BEGIN { require Module; import Module LIST; }
```

except that Module *must* be a bareword.

VERSION may be either a numeric argument such as 5.006, which will be compared to `$]`, or a literal of the form v5.6.1, which will be compared to `$^V` (aka $PERL_VERSION. A fatal error is produced if VERSION is greater than the version of the current Perl interpreter; Perl will not attempt to parse the rest of the file. Compare with require, which can do a similar check at run time.

Specifying VERSION as a literal of the form v5.6.1 should generally be avoided, because it leads to misleading error messages under earlier versions of Perl which do not support this syntax. The equivalent numeric version should be used instead.

```
    use v5.6.1;         # compile time version check
    use 5.6.1;          # ditto
    use 5.006_001;      # ditto; preferred for backwards compatibility
```

This is often useful if you need to check the current Perl version before `use`ing library modules that have changed in incompatible ways from older versions of Perl. (We try not to do this more than we have to.)

The `BEGIN` forces the `require` and `import` to happen at compile time. The `require` makes sure the module is loaded into memory if it hasn't been yet. The `import` is not a builtin–it's just an ordinary static method call into the `Module` package to tell the module to import the list of features back into the current package. The module can implement its `import` method any way it likes, though most modules just choose to derive their `import` method via inheritance from the `Exporter` class that is defined in the `Exporter` module. See *Exporter*. If no `import` method can be found then the call is skipped.

If you do not want to call the package's `import` method (for instance, to stop your namespace from being altered), explicitly supply the empty list:

```
use Module ();
```

That is exactly equivalent to

```
BEGIN { require Module }
```

If the VERSION argument is present between Module and LIST, then the `use` will call the VERSION method in class Module with the given version as an argument. The default VERSION method, inherited from the UNIVERSAL class, croaks if the given version is larger than the value of the variable `$Module::VERSION`.

Again, there is a distinction between omitting LIST (`import` called with no arguments) and an explicit empty LIST `()` (`import` not called). Note that there is no comma after VERSION!

Because this is a wide-open interface, pragmas (compiler directives) are also implemented this way. Currently implemented pragmas are:

```
use constant;
use diagnostics;
use integer;
use sigtrap  qw(SEGV BUS);
use strict   qw(subs vars refs);
use subs     qw(afunc blurfl);
use warnings qw(all);
use sort     qw(stable _quicksort _mergesort);
```

Some of these pseudo-modules import semantics into the current block scope (like `strict` or `integer`, unlike ordinary modules, which import symbols into the current package (which are effective through the end of the file).

There's a corresponding `no` command that unimports meanings imported by `use`, i.e., it calls `unimport Module LIST` instead of `import`.

```
no integer;
no strict 'refs';
no warnings;
```

See *perlmodlib* for a list of standard modules and pragmas. See *perlrun* for the `-M` and `-m` command-line options to perl that give `use` functionality from the command-line.

utime LIST

Changes the access and modification times on each file of a list of files. The first two elements of the list must be the NUMERICAL access and modification times, in that order. Returns the number of files successfully changed. The inode change time of each file is set to the current time. For example, this code has the same effect as the Unix touch(1) command when the files *already exist*.

```
#!/usr/bin/perl
$atime = $mtime = time;
utime $atime, $mtime, @ARGV;
```

Since perl 5.7.2, if the first two elements of the list are `undef`, then the utime(2) function in the C library will be called with a null second argument. On most systems, this will set the file's access and modification times to the current time (i.e. equivalent to the example above.)

```
utime undef, undef, @ARGV;
```

Under NFS this will use the time of the NFS server, not the time of the local machine. If there is a time synchronization problem, the NFS server and local machine will have different times. The Unix touch(1) command will in fact normally use this form instead of the one shown in the first example.

Note that only passing one of the first two elements as `undef` will be equivalent of passing it as 0 and will not have the same effect as described when they are both `undef`. This case will also trigger an uninitialized warning.

values HASH

Returns a list consisting of all the values of the named hash. (In a scalar context, returns the number of values.)

The values are returned in an apparently random order. The actual random order is subject to change in future versions of perl, but it is guaranteed to be the same order as either the `keys` or `each` function would produce on the same (unmodified) hash. Since Perl 5.8.1 the ordering is different even between different runs of Perl for security reasons (see Algorithmic Complexity Attacks in *perlsec*).

As a side effect, calling values() resets the HASH's internal iterator, see each. (In particular, calling values() in void context resets the iterator with no other overhead.)

Note that the values are not copied, which means modifying them will modify the contents of the hash:

```
for (values %hash)      { s/foo/bar/g }   # modifies %hash values
for (@hash{keys %hash}) { s/foo/bar/g }   # same
```

See also `keys`, `each`, and `sort`.

vec EXPR,OFFSET,BITS

Treats the string in EXPR as a bit vector made up of elements of width BITS, and returns the value of the element specified by OFFSET as an unsigned integer. BITS therefore specifies the number of bits that are reserved for each element in the bit vector. This must be a power of two from 1 to 32 (or 64, if your platform supports that).

If BITS is 8, "elements" coincide with bytes of the input string.

If BITS is 16 or more, bytes of the input string are grouped into chunks of size BITS/8, and each group is converted to a number as with pack()/unpack() with big-endian formats `n`/`N` (and analogously for BITS==64). See §**??** for details.

If bits is 4 or less, the string is broken into bytes, then the bits of each byte are broken into 8/BITS groups. Bits of a byte are numbered in a little-endian-ish way, as in `0x01`, `0x02`, `0x04`, `0x08`, `0x10`, `0x20`, `0x40`, `0x80`. For example, breaking the single input byte `chr(0x36)` into two groups gives a list `(0x6, 0x3)`; breaking it into 4 groups gives `(0x2, 0x1, 0x3, 0x0)`.

`vec` may also be assigned to, in which case parentheses are needed to give the expression the correct precedence as in

```
vec($image, $max_x * $x + $y, 8) = 3;
```

If the selected element is outside the string, the value 0 is returned. If an element off the end of the string is written to, Perl will first extend the string with sufficiently many zero bytes. It is an error to try to write off the beginning of the string (i.e. negative OFFSET).

The string should not contain any character with the value > 255 (which can only happen if you're using UTF-8 encoding). If it does, it will be treated as something which is not UTF-8 encoded. When the `vec` was assigned to, other parts of your program will also no longer consider the string to be UTF-8 encoded. In other words, if you do have such characters in your string, vec() will operate on the actual byte string, and not the conceptual character string.

Strings created with `vec` can also be manipulated with the logical operators |, &, ^, and ~. These operators will assume a bit vector operation is desired when both operands are strings. See Bitwise String Operators in *perlop*.

The following code will build up an ASCII string saying `'PerlPerlPerl'`. The comments show the string after each step. Note that this code works in the same way on big-endian or little-endian machines.

```
my $foo = '';
vec($foo,  0, 32) = 0x5065726C;     # 'Perl'

# $foo eq "Perl" eq "\x50\x65\x72\x6C", 32 bits
print vec($foo, 0, 8);              # prints 80 == 0x50 == ord('P')
```

```
    vec($foo,  2, 16) = 0x5065;         # 'PerlPe'
    vec($foo,  3, 16) = 0x726C;         # 'PerlPerl'
    vec($foo,  8,  8) = 0x50;           # 'PerlPerlP'
    vec($foo,  9,  8) = 0x65;           # 'PerlPerlPe'
    vec($foo, 20,  4) = 2;              # 'PerlPerlPe'   . "\x02"
    vec($foo, 21,  4) = 7;              # 'PerlPerlPer'
                                        # 'r' is "\x72"
    vec($foo, 45,  2) = 3;              # 'PerlPerlPer'  . "\x0c"
    vec($foo, 93,  1) = 1;              # 'PerlPerlPer'  . "\x2c"
    vec($foo, 94,  1) = 1;              # 'PerlPerlPerl'
                                        # 'l' is "\x6c"
```

To transform a bit vector into a string or list of 0's and 1's, use these:

```
    $bits = unpack("b*", $vector);
    @bits = split(//, unpack("b*", $vector));
```

If you know the exact length in bits, it can be used in place of the *.

Here is an example to illustrate how the bits actually fall in place:

```
    #!/usr/bin/perl -wl

    print <<'EOT';
                                      0         1         2         3
                       unpack("V",$_) 01234567890123456789012345678901
    ------------------------------------------------------------------
    EOT

    for $w (0..3) {
        $width = 2**$w;
        for ($shift=0; $shift < $width; ++$shift) {
            for ($off=0; $off < 32/$width; ++$off) {
                $str = pack("B*", "0"x32);
                $bits = (1<<$shift);
                vec($str, $off, $width) = $bits;
                $res = unpack("b*",$str);
                $val = unpack("V", $str);
                write;
            }
        }
    }

    format STDOUT =
    vec($_,@#,@#) = @<< == @######### @>>>>>>>>>>>>>>>>>>>>>>>>>>>>>>>
    $off, $width, $bits, $val, $res
    .
    __END__
```

Regardless of the machine architecture on which it is run, the above example should print the following table:

```
                                      0         1         2         3
                       unpack("V",$_) 01234567890123456789012345678901
    ------------------------------------------------------------------
    vec($_, 0, 1) = 1   ==          1 10000000000000000000000000000000
    vec($_, 1, 1) = 1   ==          2 01000000000000000000000000000000
```

```
vec($_, 2, 1) = 1    ==          4 00100000000000000000000000000000

```

wait

Behaves like the wait(2) system call on your system: it waits for a child process to terminate and returns the pid of the deceased process, or `-1` if there are no child processes. The status is returned in `$?`. Note that a return value of `-1` could mean that child processes are being automatically reaped, as described in *perlipc*.

waitpid PID,FLAGS

Waits for a particular child process to terminate and returns the pid of the deceased process, or `-1` if there is no such child process. On some systems, a value of 0 indicates that there are processes still running. The status is returned in `$?`. If you say

```
use POSIX ":sys_wait_h";
#...
do {
    $kid = waitpid(-1, WNOHANG);
} until $kid > 0;
```

then you can do a non-blocking wait for all pending zombie processes. Non-blocking wait is available on machines supporting either the waitpid(2) or wait4(2) system calls. However, waiting for a particular pid with FLAGS of `0` is implemented everywhere. (Perl emulates the system call by remembering the status values of processes that have exited but have not been harvested by the Perl script yet.)

Note that on some systems, a return value of `-1` could mean that child processes are being automatically reaped. See *perlipc* for details, and for other examples.

wantarray

Returns true if the context of the currently executing subroutine or eval() block is looking for a list value. Returns false if the context is looking for a scalar. Returns the undefined value if the context is looking for no value (void context).

```
return unless defined wantarray;    # don't bother doing more
my @a = complex_calculation();
return wantarray ? @a : "@a";
```

This function should have been named wantlist() instead.

warn LIST

Produces a message on STDERR just like `die`, but doesn't exit or throw an exception.

If LIST is empty and `$@` already contains a value (typically from a previous eval) that value is used after appending `"\t...caught"` to `$@`. This is useful for staying almost, but not entirely similar to `die`.

If `$@` is empty then the string `"Warning:  Something's wrong"` is used.

No message is printed if there is a `$SIG{__WARN__}` handler installed. It is the handler's responsibility to deal with the message as it sees fit (like, for instance, converting it into a `die`). Most handlers must therefore make arrangements to actually display the warnings that they are not prepared to deal with, by calling `warn` again in the handler. Note that this is quite safe and will not produce an endless loop, since `__WARN__` hooks are not called from inside one.

You will find this behavior is slightly different from that of `$SIG{__DIE__}` handlers (which don't suppress the error text, but can instead call `die` again to change it).

Using a `__WARN__` handler provides a powerful way to silence all warnings (even the so-called mandatory ones). An example:

```
    # wipe out *all* compile-time warnings
    BEGIN { $SIG{'__WARN__'} = sub { warn $_[0] if $DOWARN } }
    my $foo = 10;
    my $foo = 20;          # no warning about duplicate my $foo,
                           # but hey, you asked for it!
    # no compile-time or run-time warnings before here
    $DOWARN = 1;

    # run-time warnings enabled after here
    warn "\$foo is alive and $foo!";     # does show up
```

See *perlvar* for details on setting `%SIG` entries, and for more examples. See the Carp module for other kinds of warnings using its carp() and cluck() functions.

write FILEHANDLE

write EXPR

write

Writes a formatted record (possibly multi-line) to the specified FILEHANDLE, using the format associated with that file. By default the format for a file is the one having the same name as the filehandle, but the format for the current output channel (see the `select` function) may be set explicitly by assigning the name of the format to the `$~` variable.

Top of form processing is handled automatically: if there is insufficient room on the current page for the formatted record, the page is advanced by writing a form feed, a special top-of-page format is used to format the new page header, and then the record is written. By default the top-of-page format is the name of the filehandle with "_TOP" appended, but it may be dynamically set to the format of your choice by assigning the name to the `$^` variable while the filehandle is selected. The number of lines remaining on the current page is in variable `$-`, which can be set to `0` to force a new page.

If FILEHANDLE is unspecified, output goes to the current default output channel, which starts out as STDOUT but may be changed by the `select` operator. If the FILEHANDLE is an EXPR, then the expression is evaluated and the resulting string is used to look up the name of the FILEHANDLE at run time. For more on formats, see *perlform*.

Note that write is *not* the opposite of `read`. Unfortunately.

y///

The transliteration operator. Same as `tr///`. See *perlop*.

Chapter 31

perlopentut

Tutorial on opening things in Perl

31.1 DESCRIPTION

Perl has two simple, built-in ways to open files: the shell way for convenience, and the C way for precision. The shell way also has 2- and 3-argument forms, which have different semantics for handling the filename. The choice is yours.

31.2 Open à la shell

Perl's `open` function was designed to mimic the way command-line redirection in the shell works. Here are some basic examples from the shell:

```
    $ myprogram file1 file2 file3
    $ myprogram    <  inputfile
    $ myprogram    >  outputfile
    $ myprogram    >> outputfile
    $ myprogram    |  otherprogram
    $ otherprogram |  myprogram
```

And here are some more advanced examples:

```
    $ otherprogram      | myprogram f1 - f2
    $ otherprogram 2>&1 | myprogram -
    $ myprogram     <&3
    $ myprogram     >&4
```

Programmers accustomed to constructs like those above can take comfort in learning that Perl directly supports these familiar constructs using virtually the same syntax as the shell.

31.2.1 Simple Opens

The `open` function takes two arguments: the first is a filehandle, and the second is a single string comprising both what to open and how to open it. `open` returns true when it works, and when it fails, returns a false value and sets the special variable `$!` to reflect the system error. If the filehandle was previously opened, it will be implicitly closed first.

For example:

```
open(INFO,      "datafile") || die("can't open datafile: $!");
open(INFO,   "<  datafile") || die("can't open datafile: $!");
open(RESULTS,">  runstats") || die("can't open runstats: $!");
open(LOG,    ">> logfile ") || die("can't open logfile:  $!");
```

If you prefer the low-punctuation version, you could write that this way:

```
open INFO,   "<  datafile"  or die "can't open datafile: $!";
open RESULTS,">  runstats"  or die "can't open runstats: $!";
open LOG,    ">> logfile "  or die "can't open logfile:  $!";
```

A few things to notice. First, the leading less-than is optional. If omitted, Perl assumes that you want to open the file for reading.

Note also that the first example uses the || logical operator, and the second uses `or`, which has lower precedence. Using || in the latter examples would effectively mean

```
open INFO, ( "<  datafile"  || die "can't open datafile: $!" );
```

which is definitely not what you want.

The other important thing to notice is that, just as in the shell, any white space before or after the filename is ignored. This is good, because you wouldn't want these to do different things:

```
open INFO,   "<datafile"
open INFO,   "< datafile"
open INFO,   "<  datafile"
```

Ignoring surrounding whitespace also helps for when you read a filename in from a different file, and forget to trim it before opening:

```
$filename = <INFO>;         # oops, \n still there
open(EXTRA, "< $filename") || die "can't open $filename: $!";
```

This is not a bug, but a feature. Because `open` mimics the shell in its style of using redirection arrows to specify how to open the file, it also does so with respect to extra white space around the filename itself as well. For accessing files with naughty names, see §31.4.2.

There is also a 3-argument version of `open`, which lets you put the special redirection characters into their own argument:

```
open( INFO, ">", $datafile ) || die "Can't create $datafile: $!";
```

In this case, the filename to open is the actual string in `$datafile`, so you don't have to worry about `$datafile` containing characters that might influence the open mode, or whitespace at the beginning of the filename that would be absorbed in the 2-argument version. Also, any reduction of unnecessary string interpolation is a good thing.

31.2.2 Indirect Filehandles

`open`'s first argument can be a reference to a filehandle. As of perl 5.6.0, if the argument is uninitialized, Perl will automatically create a filehandle and put a reference to it in the first argument, like so:

```
open( my $in, $infile )   or die "Couldn't read $infile: $!";
while ( <$in> ) {
    # do something with $_
}
close $in;
```

Indirect filehandles make namespace management easier. Since filehandles are global to the current package, two subroutines trying to open `INFILE` will clash. With two functions opening indirect filehandles like `my $infile`, there's no clash and no need to worry about future conflicts.

Another convenient behavior is that an indirect filehandle automatically closes when it goes out of scope or when you undefine it:

```
    sub firstline {
        open( my $in, shift ) && return scalar <$in>;
        # no close() required
    }
```

31.2.3 Pipe Opens

In C, when you want to open a file using the standard I/O library, you use the `fopen` function, but when opening a pipe, you use the `popen` function. But in the shell, you just use a different redirection character. That's also the case for Perl. The `open` call remains the same–just its argument differs.

If the leading character is a pipe symbol, `open` starts up a new command and opens a write-only filehandle leading into that command. This lets you write into that handle and have what you write show up on that command's standard input. For example:

```
    open(PRINTER, "| lpr -Plp1")    || die "can't run lpr: $!";
    print PRINTER "stuff\n";
    close(PRINTER)                  || die "can't close lpr: $!";
```

If the trailing character is a pipe, you start up a new command and open a read-only filehandle leading out of that command. This lets whatever that command writes to its standard output show up on your handle for reading. For example:

```
    open(NET, "netstat -i -n |")    || die "can't fork netstat: $!";
    while (<NET>) { }               # do something with input
    close(NET)                      || die "can't close netstat: $!";
```

What happens if you try to open a pipe to or from a non-existent command? If possible, Perl will detect the failure and set `$!` as usual. But if the command contains special shell characters, such as > or *, called 'metacharacters', Perl does not execute the command directly. Instead, Perl runs the shell, which then tries to run the command. This means that it's the shell that gets the error indication. In such a case, the `open` call will only indicate failure if Perl can't even run the shell. See How can I capture STDERR from an external command? in *perlfaq8* to see how to cope with this. There's also an explanation in *perlipc*.

If you would like to open a bidirectional pipe, the IPC::Open2 library will handle this for you. Check out Bidirectional Communication with Another Process in *perlipc*

31.2.4 The Minus File

Again following the lead of the standard shell utilities, Perl's `open` function treats a file whose name is a single minus, "-", in a special way. If you open minus for reading, it really means to access the standard input. If you open minus for writing, it really means to access the standard output.

If minus can be used as the default input or default output, what happens if you open a pipe into or out of minus? What's the default command it would run? The same script as you're currently running! This is actually a stealth `fork` hidden inside an `open` call. See Safe Pipe Opens in *perlipc* for details.

31.2.5 Mixing Reads and Writes

It is possible to specify both read and write access. All you do is add a "+" symbol in front of the redirection. But as in the shell, using a less-than on a file never creates a new file; it only opens an existing one. On the other hand, using a greater-than always clobbers (truncates to zero length) an existing file, or creates a brand-new one if there isn't an old one. Adding a "+" for read-write doesn't affect whether it only works on existing files or always clobbers existing ones.

```
open(WTMP, "+< /usr/adm/wtmp")
    || die "can't open /usr/adm/wtmp: $!";

open(SCREEN, "+> lkscreen")
    || die "can't open lkscreen: $!";

open(LOGFILE, "+>> /var/log/applog"
    || die "can't open /var/log/applog: $!";
```

The first one won't create a new file, and the second one will always clobber an old one. The third one will create a new file if necessary and not clobber an old one, and it will allow you to read at any point in the file, but all writes will always go to the end. In short, the first case is substantially more common than the second and third cases, which are almost always wrong. (If you know C, the plus in Perl's `open` is historically derived from the one in C's fopen(3S), which it ultimately calls.)

In fact, when it comes to updating a file, unless you're working on a binary file as in the WTMP case above, you probably don't want to use this approach for updating. Instead, Perl's **-i** flag comes to the rescue. The following command takes all the C, C++, or yacc source or header files and changes all their foo's to bar's, leaving the old version in the original filename with a ".orig" tacked on the end:

```
$ perl -i.orig -pe 's/\bfoo\b/bar/g' *.[Cchy]
```

This is a short cut for some renaming games that are really the best way to update textfiles. See the second question in *perlfaq5* for more details.

31.2.6 Filters

One of the most common uses for `open` is one you never even notice. When you process the ARGV filehandle using `<ARGV>`, Perl actually does an implicit open on each file in @ARGV. Thus a program called like this:

```
$ myprogram file1 file2 file3
```

Can have all its files opened and processed one at a time using a construct no more complex than:

```
while (<>) {
    # do something with $_
}
```

If @ARGV is empty when the loop first begins, Perl pretends you've opened up minus, that is, the standard input. In fact, $ARGV, the currently open file during `<ARGV>` processing, is even set to "-" in these circumstances.

You are welcome to pre-process your @ARGV before starting the loop to make sure it's to your liking. One reason to do this might be to remove command options beginning with a minus. While you can always roll the simple ones by hand, the Getopts modules are good for this:

```
use Getopt::Std;

# -v, -D, -o ARG, sets $opt_v, $opt_D, $opt_o
getopts("vDo:");
```

```
    # -v, -D, -o ARG, sets $args{v}, $args{D}, $args{o}
    getopts("vDo:", \%args);
```

Or the standard Getopt::Long module to permit named arguments:

```
    use Getopt::Long;
    GetOptions( "verbose"  => \$verbose,        # --verbose
                "Debug"    => \$debug,          # --Debug
                "output=s" => \$output );
            # --output=somestring or --output somestring
```

Another reason for preprocessing arguments is to make an empty argument list default to all files:

```
    @ARGV = glob("*") unless @ARGV;
```

You could even filter out all but plain, text files. This is a bit silent, of course, and you might prefer to mention them on the way.

```
    @ARGV = grep { -f && -T } @ARGV;
```

If you're using the **-n** or **-p** command-line options, you should put changes to @ARGV in a `BEGIN{}` block.

Remember that a normal `open` has special properties, in that it might call fopen(3S) or it might called popen(3S), depending on what its argument looks like; that's why it's sometimes called "magic open". Here's an example:

```
    $pwdinfo = `domainname` =~ /^(\(none\))?$/
                    ? '< /etc/passwd'
                    : 'ypcat passwd |';

    open(PWD, $pwdinfo)
                or die "can't open $pwdinfo: $!";
```

This sort of thing also comes into play in filter processing. Because `<ARGV>` processing employs the normal, shell-style Perl `open`, it respects all the special things we've already seen:

```
    $ myprogram f1 "cmd1|" - f2 "cmd2|" f3 < tmpfile
```

That program will read from the file *f1*, the process *cmd1*, standard input (*tmpfile* in this case), the *f2* file, the *cmd2* command, and finally the *f3* file.

Yes, this also means that if you have files named "-" (and so on) in your directory, they won't be processed as literal files by `open`. You'll need to pass them as "./-", much as you would for the *rm* program, or you could use `sysopen` as described below.

One of the more interesting applications is to change files of a certain name into pipes. For example, to autoprocess gzipped or compressed files by decompressing them with *gzip*:

```
    @ARGV = map { /^\.(gz|Z)$/ ? "gzip -dc $_ |" : $_  } @ARGV;
```

Or, if you have the *GET* program installed from LWP, you can fetch URLs before processing them:

```
    @ARGV = map { m#^\w+://# ? "GET $_ |" : $_ } @ARGV;
```

It's not for nothing that this is called magic `<ARGV>`. Pretty nifty, eh?

31.3 Open à la C

If you want the convenience of the shell, then Perl's `open` is definitely the way to go. On the other hand, if you want finer precision than C's simplistic fopen(3S) provides you should look to Perl's `sysopen`, which is a direct hook into the open(2) system call. That does mean it's a bit more involved, but that's the price of precision.

`sysopen` takes 3 (or 4) arguments.

```
    sysopen HANDLE, PATH, FLAGS, [MASK]
```

The HANDLE argument is a filehandle just as with `open`. The PATH is a literal path, one that doesn't pay attention to any greater-thans or less-thans or pipes or minuses, nor ignore white space. If it's there, it's part of the path. The FLAGS argument contains one or more values derived from the Fcntl module that have been or'd together using the bitwise "|" operator. The final argument, the MASK, is optional; if present, it is combined with the user's current umask for the creation mode of the file. You should usually omit this.

Although the traditional values of read-only, write-only, and read-write are 0, 1, and 2 respectively, this is known not to hold true on some systems. Instead, it's best to load in the appropriate constants first from the Fcntl module, which supplies the following standard flags:

```
    O_RDONLY            Read only
    O_WRONLY            Write only
    O_RDWR              Read and write
    O_CREAT             Create the file if it doesn't exist
    O_EXCL              Fail if the file already exists
    O_APPEND            Append to the file
    O_TRUNC             Truncate the file
    O_NONBLOCK          Non-blocking access
```

Less common flags that are sometimes available on some operating systems include `O_BINARY`, `O_TEXT`, `O_SHLOCK`, `O_EXLOCK`, `O_DEFER`, `O_SYNC`, `O_ASYNC`, `O_DSYNC`, `O_RSYNC`, `O_NOCTTY`, `O_NDELAY` and `O_LARGEFILE`. Consult your open(2) manpage or its local equivalent for details. (Note: starting from Perl release 5.6 the `O_LARGEFILE` flag, if available, is automatically added to the sysopen() flags because large files are the default.)

Here's how to use `sysopen` to emulate the simple `open` calls we had before. We'll omit the || `die $!` checks for clarity, but make sure you always check the return values in real code. These aren't quite the same, since `open` will trim leading and trailing white space, but you'll get the idea.

To open a file for reading:

```
    open(FH, "< $path");
    sysopen(FH, $path, O_RDONLY);
```

To open a file for writing, creating a new file if needed or else truncating an old file:

```
    open(FH, "> $path");
    sysopen(FH, $path, O_WRONLY | O_TRUNC | O_CREAT);
```

To open a file for appending, creating one if necessary:

```
    open(FH, ">> $path");
    sysopen(FH, $path, O_WRONLY | O_APPEND | O_CREAT);
```

To open a file for update, where the file must already exist:

```
    open(FH, "+< $path");
    sysopen(FH, $path, O_RDWR);
```

And here are things you can do with sysopen that you cannot do with a regular open. As you'll see, it's just a matter of controlling the flags in the third argument.

To open a file for writing, creating a new file which must not previously exist:

```
    sysopen(FH, $path, O_WRONLY | O_EXCL | O_CREAT);
```

To open a file for appending, where that file must already exist:

```
    sysopen(FH, $path, O_WRONLY | O_APPEND);
```

To open a file for update, creating a new file if necessary:

```
    sysopen(FH, $path, O_RDWR | O_CREAT);
```

To open a file for update, where that file must not already exist:

```
    sysopen(FH, $path, O_RDWR | O_EXCL | O_CREAT);
```

To open a file without blocking, creating one if necessary:

```
    sysopen(FH, $path, O_WRONLY | O_NONBLOCK | O_CREAT);
```

31.3.1 Permissions à la mode

If you omit the MASK argument to sysopen, Perl uses the octal value 0666. The normal MASK to use for executables and directories should be 0777, and for anything else, 0666.

Why so permissive? Well, it isn't really. The MASK will be modified by your process's current umask. A umask is a number representing *disabled* permissions bits; that is, bits that will not be turned on in the created files' permissions field.

For example, if your umask were 027, then the 020 part would disable the group from writing, and the 007 part would disable others from reading, writing, or executing. Under these conditions, passing sysopen 0666 would create a file with mode 0640, since 0666 & ~027 is 0640.

You should seldom use the MASK argument to sysopen(). That takes away the user's freedom to choose what permission new files will have. Denying choice is almost always a bad thing. One exception would be for cases where sensitive or private data is being stored, such as with mail folders, cookie files, and internal temporary files.

31.4 Obscure Open Tricks

31.4.1 Re-Opening Files (dups)

Sometimes you already have a filehandle open, and want to make another handle that's a duplicate of the first one. In the shell, we place an ampersand in front of a file descriptor number when doing redirections. For example, 2>&1 makes descriptor 2 (that's STDERR in Perl) be redirected into descriptor 1 (which is usually Perl's STDOUT). The same is essentially true in Perl: a filename that begins with an ampersand is treated instead as a file descriptor if a number, or as a filehandle if a string.

```
    open(SAVEOUT, ">&SAVEERR") || die "couldn't dup SAVEERR: $!";
    open(MHCONTEXT, "<&4")     || die "couldn't dup fd4: $!";
```

That means that if a function is expecting a filename, but you don't want to give it a filename because you already have the file open, you can just pass the filehandle with a leading ampersand. It's best to use a fully qualified handle though, just in case the function happens to be in a different package:

```
    somefunction("&main::LOGFILE");
```

This way if somefunction() is planning on opening its argument, it can just use the already opened handle. This differs from passing a handle, because with a handle, you don't open the file. Here you have something you can pass to open.

If you have one of those tricky, newfangled I/O objects that the C++ folks are raving about, then this doesn't work because those aren't a proper filehandle in the native Perl sense. You'll have to use fileno() to pull out the proper descriptor number, assuming you can:

```
    use IO::Socket;
    $handle = IO::Socket::INET->new("www.perl.com:80");
    $fd = $handle->fileno;
    somefunction("&$fd");  # not an indirect function call
```

It can be easier (and certainly will be faster) just to use real filehandles though:

```
    use IO::Socket;
    local *REMOTE = IO::Socket::INET->new("www.perl.com:80");
    die "can't connect" unless defined(fileno(REMOTE));
    somefunction("&main::REMOTE");
```

If the filehandle or descriptor number is preceded not just with a simple "&" but rather with a "&=" combination, then Perl will not create a completely new descriptor opened to the same place using the dup(2) system call. Instead, it will just make something of an alias to the existing one using the fdopen(3S) library call This is slightly more parsimonious of systems resources, although this is less a concern these days. Here's an example of that:

```
    $fd = $ENV{"MHCONTEXTFD"};
    open(MHCONTEXT, "<&=$fd")   or die "couldn't fdopen $fd: $!";
```

If you're using magic `<ARGV>`, you could even pass in as a command line argument in @ARGV something like `"<&=$MHCONTEXTFD"`, but we've never seen anyone actually do this.

31.4.2 Dispelling the Dweomer

Perl is more of a DWIMmer language than something like Java–where DWIM is an acronym for "do what I mean". But this principle sometimes leads to more hidden magic than one knows what to do with. In this way, Perl is also filled with *dweomer*, an obscure word meaning an enchantment. Sometimes, Perl's DWIMmer is just too much like dweomer for comfort.

If magic `open` is a bit too magical for you, you don't have to turn to `sysopen`. To open a file with arbitrary weird characters in it, it's necessary to protect any leading and trailing whitespace. Leading whitespace is protected by inserting a `"./"` in front of a filename that starts with whitespace. Trailing whitespace is protected by appending an ASCII NUL byte (`"\0"`) at the end of the string.

```
    $file =~ s#^(\s)#./$1#;
    open(FH, "< $file\0")   || die "can't open $file: $!";
```

This assumes, of course, that your system considers dot the current working directory, slash the directory separator, and disallows ASCII NULs within a valid filename. Most systems follow these conventions, including all POSIX systems as well as proprietary Microsoft systems. The only vaguely popular system that doesn't work this way is the proprietary Macintosh system, which uses a colon where the rest of us use a slash. Maybe `sysopen` isn't such a bad idea after all.

If you want to use `<ARGV>` processing in a totally boring and non-magical way, you could do this first:

```
#   "Sam sat on the ground and put his head in his hands.
#   'I wish I had never come here, and I don't want to see
#   no more magic,' he said, and fell silent."
for (@ARGV) {
    s#^([^./])#./$1#;
    $_ .= "\0";
}
while (<>) {
    # now process $_
}
```

But be warned that users will not appreciate being unable to use "-" to mean standard input, per the standard convention.

31.4.3 Paths as Opens

You've probably noticed how Perl's `warn` and `die` functions can produce messages like:

```
Some warning at scriptname line 29, <FH> line 7.
```

That's because you opened a filehandle FH, and had read in seven records from it. But what was the name of the file, rather than the handle?

If you aren't running with `strict refs`, or if you've turned them off temporarily, then all you have to do is this:

```
open($path, "< $path") || die "can't open $path: $!";
while (<$path>) {
    # whatever
}
```

Since you're using the pathname of the file as its handle, you'll get warnings more like

```
Some warning at scriptname line 29, </etc/motd> line 7.
```

31.4.4 Single Argument Open

Remember how we said that Perl's open took two arguments? That was a passive prevarication. You see, it can also take just one argument. If and only if the variable is a global variable, not a lexical, you can pass `open` just one argument, the filehandle, and it will get the path from the global scalar variable of the same name.

```
$FILE = "/etc/motd";
open FILE or die "can't open $FILE: $!";
while (<FILE>) {
    # whatever
}
```

Why is this here? Someone has to cater to the hysterical porpoises. It's something that's been in Perl since the very beginning, if not before.

31.4.5 Playing with STDIN and STDOUT

One clever move with STDOUT is to explicitly close it when you're done with the program.

```
END { close(STDOUT) || die "can't close stdout: $!" }
```

If you don't do this, and your program fills up the disk partition due to a command line redirection, it won't report the error exit with a failure status.

You don't have to accept the STDIN and STDOUT you were given. You are welcome to reopen them if you'd like.

```
open(STDIN, "< datafile")
    || die "can't open datafile: $!";

open(STDOUT, "> output")
    || die "can't open output: $!";
```

And then these can be accessed directly or passed on to subprocesses. This makes it look as though the program were initially invoked with those redirections from the command line.

It's probably more interesting to connect these to pipes. For example:

```
$pager = $ENV{PAGER} || "(less || more)";
open(STDOUT, "| $pager")
    || die "can't fork a pager: $!";
```

This makes it appear as though your program were called with its stdout already piped into your pager. You can also use this kind of thing in conjunction with an implicit fork to yourself. You might do this if you would rather handle the post processing in your own program, just in a different process:

```
head(100);
while (<>) {
    print;
}

sub head {
    my $lines = shift || 20;
    return if $pid = open(STDOUT, "|-");       # return if parent
    die "cannot fork: $!" unless defined $pid;
    while (<STDIN>) {
        last if --$lines < 0;
        print;
    }
    exit;
}
```

This technique can be applied to repeatedly push as many filters on your output stream as you wish.

31.5 Other I/O Issues

These topics aren't really arguments related to `open` or `sysopen`, but they do affect what you do with your open files.

31.5.1 Opening Non-File Files

When is a file not a file? Well, you could say when it exists but isn't a plain file. We'll check whether it's a symbolic link first, just in case.

```
    if (-l $file || ! -f _) {
        print "$file is not a plain file\n";
    }
```

What other kinds of files are there than, well, files? Directories, symbolic links, named pipes, Unix-domain sockets, and block and character devices. Those are all files, too–just not *plain* files. This isn't the same issue as being a text file. Not all text files are plain files. Not all plain files are text files. That's why there are separate `-f` and `-T` file tests.

To open a directory, you should use the `opendir` function, then process it with `readdir`, carefully restoring the directory name if necessary:

```
    opendir(DIR, $dirname) or die "can't opendir $dirname: $!";
    while (defined($file = readdir(DIR))) {
        # do something with "$dirname/$file"
    }
    closedir(DIR);
```

If you want to process directories recursively, it's better to use the File::Find module. For example, this prints out all files recursively and adds a slash to their names if the file is a directory.

```
    @ARGV = qw(.) unless @ARGV;
    use File::Find;
    find sub { print $File::Find::name, -d && '/', "\n" }, @ARGV;
```

This finds all bogus symbolic links beneath a particular directory:

```
    find sub { print "$File::Find::name\n" if -l && !-e }, $dir;
```

As you see, with symbolic links, you can just pretend that it is what it points to. Or, if you want to know *what* it points to, then `readlink` is called for:

```
    if (-l $file) {
        if (defined($whither = readlink($file))) {
            print "$file points to $whither\n";
        } else {
            print "$file points nowhere: $!\n";
        }
    }
```

31.5.2 Opening Named Pipes

Named pipes are a different matter. You pretend they're regular files, but their opens will normally block until there is both a reader and a writer. You can read more about them in Named Pipes in *perlipc*. Unix-domain sockets are rather different beasts as well; they're described in Unix-Domain TCP Clients and Servers in *perlipc*.

When it comes to opening devices, it can be easy and it can be tricky. We'll assume that if you're opening up a block device, you know what you're doing. The character devices are more interesting. These are typically used for modems, mice, and some kinds of printers. This is described in How do I read and write the serial port? in *perlfaq8* It's often enough to open them carefully:

```
    sysopen(TTYIN, "/dev/ttyS1", O_RDWR | O_NDELAY | O_NOCTTY)
                # (O_NOCTTY no longer needed on POSIX systems)
        or die "can't open /dev/ttyS1: $!";
    open(TTYOUT, "+>&TTYIN")
        or die "can't dup TTYIN: $!";

    $ofh = select(TTYOUT); $| = 1; select($ofh);

    print TTYOUT "+++at\015";
    $answer = <TTYIN>;
```

With descriptors that you haven't opened using `sysopen`, such as sockets, you can set them to be non-blocking using `fcntl`:

```
    use Fcntl;
    my $old_flags = fcntl($handle, F_GETFL, 0)
        or die "can't get flags: $!";
    fcntl($handle, F_SETFL, $old_flags | O_NONBLOCK)
        or die "can't set non blocking: $!";
```

Rather than losing yourself in a morass of twisting, turning `ioctl`s, all dissimilar, if you're going to manipulate ttys, it's best to make calls out to the stty(1) program if you have it, or else use the portable POSIX interface. To figure this all out, you'll need to read the termios(3) manpage, which describes the POSIX interface to tty devices, and then *POSIX*, which describes Perl's interface to POSIX. There are also some high-level modules on CPAN that can help you with these games. Check out Term::ReadKey and Term::ReadLine.

31.5.3 Opening Sockets

What else can you open? To open a connection using sockets, you won't use one of Perl's two open functions. See Sockets: Client/Server Communication in *perlipc* for that. Here's an example. Once you have it, you can use FH as a bidirectional filehandle.

```
    use IO::Socket;
    local *FH = IO::Socket::INET->new("www.perl.com:80");
```

For opening up a URL, the LWP modules from CPAN are just what the doctor ordered. There's no filehandle interface, but it's still easy to get the contents of a document:

```
    use LWP::Simple;
    $doc = get('http://www.linpro.no/lwp/');
```

31.5.4 Binary Files

On certain legacy systems with what could charitably be called terminally convoluted (some would say broken) I/O models, a file isn't a file–at least, not with respect to the C standard I/O library. On these old systems whose libraries (but not kernels) distinguish between text and binary streams, to get files to behave properly you'll have to bend over backwards to avoid nasty problems. On such infelicitous systems, sockets and pipes are already opened in binary mode, and there is currently no way to turn that off. With files, you have more options.

Another option is to use the `binmode` function on the appropriate handles before doing regular I/O on them:

```
    binmode(STDIN);
    binmode(STDOUT);
    while (<STDIN>) { print }
```

Passing sysopen a non-standard flag option will also open the file in binary mode on those systems that support it. This is the equivalent of opening the file normally, then calling binmode on the handle.

```
    sysopen(BINDAT, "records.data", O_RDWR | O_BINARY)
        || die "can't open records.data: $!";
```

Now you can use read and print on that handle without worrying about the non-standard system I/O library breaking your data. It's not a pretty picture, but then, legacy systems seldom are. CP/M will be with us until the end of days, and after.

On systems with exotic I/O systems, it turns out that, astonishingly enough, even unbuffered I/O using sysread and syswrite might do sneaky data mutilation behind your back.

```
    while (sysread(WHENCE, $buf, 1024)) {
        syswrite(WHITHER, $buf, length($buf));
    }
```

Depending on the vicissitudes of your runtime system, even these calls may need binmode or O_BINARY first. Systems known to be free of such difficulties include Unix, the Mac OS, Plan 9, and Inferno.

31.5.5 File Locking

In a multitasking environment, you may need to be careful not to collide with other processes who want to do I/O on the same files as you are working on. You'll often need shared or exclusive locks on files for reading and writing respectively. You might just pretend that only exclusive locks exist.

Never use the existence of a file -e $file as a locking indication, because there is a race condition between the test for the existence of the file and its creation. It's possible for another process to create a file in the slice of time between your existence check and your attempt to create the file. Atomicity is critical.

Perl's most portable locking interface is via the flock function, whose simplicity is emulated on systems that don't directly support it such as SysV or Windows. The underlying semantics may affect how it all works, so you should learn how flock is implemented on your system's port of Perl.

File locking *does not* lock out another process that would like to do I/O. A file lock only locks out others trying to get a lock, not processes trying to do I/O. Because locks are advisory, if one process uses locking and another doesn't, all bets are off.

By default, the flock call will block until a lock is granted. A request for a shared lock will be granted as soon as there is no exclusive locker. A request for an exclusive lock will be granted as soon as there is no locker of any kind. Locks are on file descriptors, not file names. You can't lock a file until you open it, and you can't hold on to a lock once the file has been closed.

Here's how to get a blocking shared lock on a file, typically used for reading:

```
    use 5.004;
    use Fcntl qw(:DEFAULT :flock);
    open(FH, "< filename")  or die "can't open filename: $!";
    flock(FH, LOCK_SH)      or die "can't lock filename: $!";
    # now read from FH
```

You can get a non-blocking lock by using LOCK_NB.

```
    flock(FH, LOCK_SH | LOCK_NB)
        or die "can't lock filename: $!";
```

This can be useful for producing more user-friendly behaviour by warning if you're going to be blocking:

```
use 5.004;
use Fcntl qw(:DEFAULT :flock);
open(FH, "< filename")  or die "can't open filename: $!";
unless (flock(FH, LOCK_SH | LOCK_NB)) {
    $| = 1;
    print "Waiting for lock...";
    flock(FH, LOCK_SH)  or die "can't lock filename: $!";
    print "got it.\n"
}
# now read from FH
```

To get an exclusive lock, typically used for writing, you have to be careful. We `sysopen` the file so it can be locked before it gets emptied. You can get a nonblocking version using `LOCK_EX | LOCK_NB`.

```
use 5.004;
use Fcntl qw(:DEFAULT :flock);
sysopen(FH, "filename", O_WRONLY | O_CREAT)
    or die "can't open filename: $!";
flock(FH, LOCK_EX)
    or die "can't lock filename: $!";
truncate(FH, 0)
    or die "can't truncate filename: $!";
# now write to FH
```

Finally, due to the uncounted millions who cannot be dissuaded from wasting cycles on useless vanity devices called hit counters, here's how to increment a number in a file safely:

```
use Fcntl qw(:DEFAULT :flock);

sysopen(FH, "numfile", O_RDWR | O_CREAT)
    or die "can't open numfile: $!";
# autoflush FH
$ofh = select(FH); $| = 1; select ($ofh);
flock(FH, LOCK_EX)
    or die "can't write-lock numfile: $!";

$num = <FH> || 0;
seek(FH, 0, 0)
    or die "can't rewind numfile : $!";
print FH $num+1, "\n"
    or die "can't write numfile: $!";

truncate(FH, tell(FH))
    or die "can't truncate numfile: $!";
close(FH)
    or die "can't close numfile: $!";
```

31.5.6 IO Layers

In Perl 5.8.0 a new I/O framework called "PerlIO" was introduced. This is a new "plumbing" for all the I/O happening in Perl; for the most part everything will work just as it did, but PerlIO also brought in some new features such as the ability to think of I/O as "layers". One I/O layer may in addition to just moving the data also do transformations on the data. Such transformations may include compression and decompression, encryption and decryption, and transforming between various character encodings.

Full discussion about the features of PerlIO is out of scope for this tutorial, but here is how to recognize the layers being used:

- The three-(or more)-argument form of `open` is being used and the second argument contains something else in addition to the usual `'<'`, `'>'`, `'>>'`, `'|'` and their variants, for example:

```
    open(my $fh, "<:utf8", $fn);
```

- The two-argument form of `binmode` is being used, for example

```
    binmode($fh, ":encoding(utf16)");
```

For more detailed discussion about PerlIO see *PerlIO*; for more detailed discussion about Unicode and I/O see *perluniintro*.

perlpacktut

Tutorial on `pack` and `unpack`

32.1 DESCRIPTION

`pack` and `unpack` are two functions for transforming data according to a user-defined template, between the guarded way Perl stores values and some well-defined representation as might be required in the environment of a Perl program. Unfortunately, they're also two of the most misunderstood and most often overlooked functions that Perl provides. This tutorial will demystify them for you.

32.2 The Basic Principle

Most programming languages don't shelter the memory where variables are stored. In C, for instance, you can take the address of some variable, and the `sizeof` operator tells you how many bytes are allocated to the variable. Using the address and the size, you may access the storage to your heart's content.

In Perl, you just can't access memory at random, but the structural and representational conversion provided by `pack` and `unpack` is an excellent alternative. The `pack` function converts values to a byte sequence containing representations according to a given specification, the so-called "template" argument. `unpack` is the reverse process, deriving some values from the contents of a string of bytes. (Be cautioned, however, that not all that has been packed together can be neatly unpacked - a very common experience as seasoned travellers are likely to confirm.)

Why, you may ask, would you need a chunk of memory containing some values in binary representation? One good reason is input and output accessing some file, a device, or a network connection, whereby this binary representation is either forced on you or will give you some benefit in processing. Another cause is passing data to some system call that is not available as a Perl function: `syscall` requires you to provide parameters stored in the way it happens in a C program. Even text processing (as shown in the next section) may be simplified with judicious usage of these two functions.

To see how (un)packing works, we'll start with a simple template code where the conversion is in low gear: between the contents of a byte sequence and a string of hexadecimal digits. Let's use `unpack`, since this is likely to remind you of a dump program, or some desperate last message unfortunate programs are wont to throw at you before they expire into the wild blue yonder. Assuming that the variable `$mem` holds a sequence of bytes that we'd like to inspect without assuming anything about its meaning, we can write

```
   my( $hex ) = unpack( 'H*', $mem );
   print "$hex\n";
```

whereupon we might see something like this, with each pair of hex digits corresponding to a byte:

```
   41204d414e204120504c414e20412043414e414c2050414e414d41
```

What was in this chunk of memory? Numbers, characters, or a mixture of both? Assuming that we're on a computer where ASCII (or some similar) encoding is used: hexadecimal values in the range `0x40` - `0x5A` indicate an uppercase letter, and `0x20` encodes a space. So we might assume it is a piece of text, which some are able to read like a tabloid; but others will have to get hold of an ASCII table and relive that firstgrader feeling. Not caring too much about which way to read this, we note that `unpack` with the template code `H` converts the contents of a sequence of bytes into the customary hexadecimal notation. Since "a sequence of" is a pretty vague indication of quantity, `H` has been defined to convert just a single hexadecimal digit unless it is followed by a repeat count. An asterisk for the repeat count means to use whatever remains.

The inverse operation - packing byte contents from a string of hexadecimal digits - is just as easily written. For instance:

```
my $s = pack( 'H2' x 10, map { "3$_" } ( 0..9 ) );
print "$s\n";
```

Since we feed a list of ten 2-digit hexadecimal strings to `pack`, the pack template should contain ten pack codes. If this is run on a computer with ASCII character coding, it will print `0123456789`.

32.3 Packing Text

Let's suppose you've got to read in a data file like this:

```
Date      |Description                | Income|Expenditure
01/24/2001 Ahmed's Camel Emporium                  1147.99
01/28/2001 Flea spray                                24.99
01/29/2001 Camel rides to tourists      235.00
```

How do we do it? You might think first to use `split`; however, since `split` collapses blank fields, you'll never know whether a record was income or expenditure. Oops. Well, you could always use `substr`:

```
while (<>) {
    my $date   = substr($_,  0, 11);
    my $desc   = substr($_, 12, 27);
    my $income = substr($_, 40,  7);
    my $expend = substr($_, 52,  7);
    ...
}
```

It's not really a barrel of laughs, is it? In fact, it's worse than it may seem; the eagle-eyed may notice that the first field should only be 10 characters wide, and the error has propagated right through the other numbers - which we've had to count by hand. So it's error-prone as well as horribly unfriendly.

Or maybe we could use regular expressions:

```
while (<>) {
    my($date, $desc, $income, $expend) =
        m|(\d\d/\d\d/\d{4}) (.{27}) (.{7})(.*)|;
    ...
}
```

Urgh. Well, it's a bit better, but - well, would you want to maintain that?

Hey, isn't Perl supposed to make this sort of thing easy? Well, it does, if you use the right tools. `pack` and `unpack` are designed to help you out when dealing with fixed-width data like the above. Let's have a look at a solution with `unpack`:

```
while (<>) {
    my($date, $desc, $income, $expend) = unpack("A10xA27xA7A*", $_);
    ...
}
```

That looks a bit nicer; but we've got to take apart that weird template. Where did I pull that out of?

OK, let's have a look at some of our data again; in fact, we'll include the headers, and a handy ruler so we can keep track of where we are.

```
         1         2         3         4         5
1234567890123456789012345678901234567890123456789012345678
Date      |Description                | Income|Expenditure
01/28/2001 Flea spray                               24.99
01/29/2001 Camel rides to tourists      235.00
```

From this, we can see that the date column stretches from column 1 to column 10 - ten characters wide. The `pack`-ese for "character" is `A`, and ten of them are `A10`. So if we just wanted to extract the dates, we could say this:

```
my($date) = unpack("A10", $_);
```

OK, what's next? Between the date and the description is a blank column; we want to skip over that. The `x` template means "skip forward", so we want one of those. Next, we have another batch of characters, from 12 to 38. That's 27 more characters, hence `A27`. (Don't make the fencepost error - there are 27 characters between 12 and 38, not 26. Count 'em!)

Now we skip another character and pick up the next 7 characters:

```
my($date,$description,$income) = unpack("A10xA27xA7", $_);
```

Now comes the clever bit. Lines in our ledger which are just income and not expenditure might end at column 46. Hence, we don't want to tell our `unpack` pattern that we **need** to find another 12 characters; we'll just say "if there's anything left, take it". As you might guess from regular expressions, that's what the * means: "use everything remaining".

- Be warned, though, that unlike regular expressions, if the `unpack` template doesn't match the incoming data, Perl will scream and die.

Hence, putting it all together:

```
my($date,$description,$income,$expend) = unpack("A10xA27xA7xA*", $_);
```

Now, that's our data parsed. I suppose what we might want to do now is total up our income and expenditure, and add another line to the end of our ledger - in the same format - saying how much we've brought in and how much we've spent:

```
while (<>) {
    my($date, $desc, $income, $expend) = unpack("A10xA27xA7xA*", $_);
    $tot_income += $income;
    $tot_expend += $expend;
}

$tot_income = sprintf("%.2f", $tot_income); # Get them into
$tot_expend = sprintf("%.2f", $tot_expend); # "financial" format

$date = POSIX::strftime("%m/%d/%Y", localtime);

# OK, let's go:

print pack("A10xA27xA7xA*", $date, "Totals", $tot_income, $tot_expend);
```

Oh, hmm. That didn't quite work. Let's see what happened:

```
01/24/2001 Ahmed's Camel Emporium                   1147.99
01/28/2001 Flea spray                                 24.99
01/29/2001 Camel rides to tourists     1235.00
03/23/2001Totals                    1235.001172.98
```

OK, it's a start, but what happened to the spaces? We put `x`, didn't we? Shouldn't it skip forward? Let's look at what `pack` in *perlfunc* says:

```
x   A null byte.
```

Urgh. No wonder. There's a big difference between "a null byte", character zero, and "a space", character 32. Perl's put something between the date and the description - but unfortunately, we can't see it!

What we actually need to do is expand the width of the fields. The `A` format pads any non-existent characters with spaces, so we can use the additional spaces to line up our fields, like this:

```
print pack("A11 A28 A8 A*", $date, "Totals", $tot_income, $tot_expend);
```

(Note that you can put spaces in the template to make it more readable, but they don't translate to spaces in the output.) Here's what we got this time:

```
01/24/2001 Ahmed's Camel Emporium                   1147.99
01/28/2001 Flea spray                                 24.99
01/29/2001 Camel rides to tourists     1235.00
03/23/2001 Totals                      1235.00 1172.98
```

That's a bit better, but we still have that last column which needs to be moved further over. There's an easy way to fix this up: unfortunately, we can't get `pack` to right-justify our fields, but we can get `sprintf` to do it:

```
$tot_income = sprintf("%.2f", $tot_income);
$tot_expend = sprintf("%12.2f", $tot_expend);
$date = POSIX::strftime("%m/%d/%Y", localtime);
print pack("A11 A28 A8 A*", $date, "Totals", $tot_income, $tot_expend);
```

This time we get the right answer:

```
01/28/2001 Flea spray                                 24.99
01/29/2001 Camel rides to tourists     1235.00
03/23/2001 Totals                      1235.00      1172.98
```

So that's how we consume and produce fixed-width data. Let's recap what we've seen of `pack` and `unpack` so far:

- Use `pack` to go from several pieces of data to one fixed-width version; use `unpack` to turn a fixed-width-format string into several pieces of data.
- The pack format `A` means "any character"; if you're `pack`ing and you've run out of things to pack, `pack` will fill the rest up with spaces.
- `x` means "skip a byte" when `unpack`ing; when `pack`ing, it means "introduce a null byte" - that's probably not what you mean if you're dealing with plain text.
- You can follow the formats with numbers to say how many characters should be affected by that format: `A12` means "take 12 characters"; `x6` means "skip 6 bytes" or "character 0, 6 times".
- Instead of a number, you can use `*` to mean "consume everything else left".

  Warning: when packing multiple pieces of data, `*` only means "consume all of the current piece of data". That's to say

  ```
  pack("A*A*", $one, $two)
  ```

  packs all of `$one` into the first `A*` and then all of `$two` into the second. This is a general principle: each format character corresponds to one piece of data to be `pack`ed.

32.4 Packing Numbers

So much for textual data. Let's get onto the meaty stuff that pack and unpack are best at: handling binary formats for numbers. There is, of course, not just one binary format - life would be too simple - but Perl will do all the finicky labor for you.

32.4.1 Integers

Packing and unpacking numbers implies conversion to and from some *specific* binary representation. Leaving floating point numbers aside for the moment, the salient properties of any such representation are:

- the number of bytes used for storing the integer,
- whether the contents are interpreted as a signed or unsigned number,
- the byte ordering: whether the first byte is the least or most significant byte (or: little-endian or big-endian, respectively).

So, for instance, to pack 20302 to a signed 16 bit integer in your computer's representation you write

```
my $ps = pack( 's', 20302 );
```

Again, the result is a string, now containing 2 bytes. If you print this string (which is, generally, not recommended) you might see ON or NO (depending on your system's byte ordering) - or something entirely different if your computer doesn't use ASCII character encoding. Unpacking $ps with the same template returns the original integer value:

```
my( $s ) = unpack( 's', $ps );
```

This is true for all numeric template codes. But don't expect miracles: if the packed value exceeds the allotted byte capacity, high order bits are silently discarded, and unpack certainly won't be able to pull them back out of some magic hat. And, when you pack using a signed template code such as s, an excess value may result in the sign bit getting set, and unpacking this will smartly return a negative value.

16 bits won't get you too far with integers, but there is l and L for signed and unsigned 32-bit integers. And if this is not enough and your system supports 64 bit integers you can push the limits much closer to infinity with pack codes q and Q. A notable exception is provided by pack codes i and I for signed and unsigned integers of the "local custom" variety: Such an integer will take up as many bytes as a local C compiler returns for sizeof(int), but it'll use *at least* 32 bits.

Each of the integer pack codes sSlLqQ results in a fixed number of bytes, no matter where you execute your program. This may be useful for some applications, but it does not provide for a portable way to pass data structures between Perl and C programs (bound to happen when you call XS extensions or the Perl function syscall), or when you read or write binary files. What you'll need in this case are template codes that depend on what your local C compiler compiles when you code short or unsigned long, for instance. These codes and their corresponding byte lengths are shown in the table below. Since the C standard leaves much leeway with respect to the relative sizes of these data types, actual values may vary, and that's why the values are given as expressions in C and Perl. (If you'd like to use values from %Config in your program you have to import it with use Config.)

```
signed unsigned  byte length in C   byte length in Perl
  s!     S!      sizeof(short)      $Config{shortsize}
  i!     I!      sizeof(int)        $Config{intsize}
  l!     L!      sizeof(long)       $Config{longsize}
  q!     Q!      sizeof(long long)  $Config{longlongsize}
```

The i! and I! codes aren't different from i and I; they are tolerated for completeness' sake.

32.4.2 Unpacking a Stack Frame

Requesting a particular byte ordering may be necessary when you work with binary data coming from some specific architecture whereas your program could run on a totally different system. As an example, assume you have 24 bytes containing a stack frame as it happens on an Intel 8086:

```
     +---------+        +----+----+               +---------+
TOS: |   IP    |  TOS+4:| FL | FH | FLAGS  TOS+14:|   SI    |
     +---------+        +----+----+               +---------+
     |   CS    |        | AL | AH | AX            |   DI    |
     +---------+        +----+----+               +---------+
                        | BL | BH | BX            |   BP    |
                        +----+----+               +---------+
                        | CL | CH | CX            |   DS    |
                        +----+----+               +---------+
                        | DL | DH | DX            |   ES    |
                        +----+----+               +---------+
```

First, we note that this time-honored 16-bit CPU uses little-endian order, and that's why the low order byte is stored at the lower address. To unpack such a (signed) short we'll have to use code `v`. A repeat count unpacks all 12 shorts:

```
my( $ip, $cs, $flags, $ax, $bx, $cd, $dx, $si, $di, $bp, $ds, $es ) =
  unpack( 'v12', $frame );
```

Alternatively, we could have used `C` to unpack the individually accessible byte registers FL, FH, AL, AH, etc.:

```
my( $fl, $fh, $al, $ah, $bl, $bh, $cl, $ch, $dl, $dh ) =
  unpack( 'C10', substr( $frame, 4, 10 ) );
```

It would be nice if we could do this in one fell swoop: unpack a short, back up a little, and then unpack 2 bytes. Since Perl *is* nice, it proffers the template code `X` to back up one byte. Putting this all together, we may now write:

```
my( $ip, $cs,
    $flags,$fl,$fh,
    $ax,$al,$ah, $bx,$bl,$bh, $cx,$cl,$ch, $dx,$dl,$dh,
    $si, $di, $bp, $ds, $es ) =
unpack( 'v2' . ('vXXCC' x 5) . 'v5', $frame );
```

(The clumsy construction of the template can be avoided - just read on!)
We've taken some pains to construct the template so that it matches the contents of our frame buffer. Otherwise we'd either get undefined values, or `unpack` could not unpack all. If `pack` runs out of items, it will supply null strings (which are coerced into zeroes whenever the pack code says so).

32.4.3 How to Eat an Egg on a Net

The pack code for big-endian (high order byte at the lowest address) is `n` for 16 bit and `N` for 32 bit integers. You use these codes if you know that your data comes from a compliant architecture, but, surprisingly enough, you should also use these pack codes if you exchange binary data, across the network, with some system that you know next to nothing about. The simple reason is that this order has been chosen as the *network order*, and all standard-fearing programs ought to follow this convention. (This is, of course, a stern backing for one of the Lilliputian parties and may well influence the political development there.) So, if the protocol expects you to send a message by sending the length first, followed by just so many bytes, you could write:

```
my $buf = pack( 'N', length( $msg ) ) . $msg;
```

or even:

```
my $buf = pack( 'NA*', length( $msg ), $msg );
```

and pass `$buf` to your send routine. Some protocols demand that the count should include the length of the count itself: then just add 4 to the data length. (But make sure to read §32.7 before you really code this!)

32.4.4 Floating point Numbers

For packing floating point numbers you have the choice between the pack codes `f` and `d` which pack into (or unpack from) single-precision or double-precision representation as it is provided by your system. (There is no such thing as a network representation for reals, so if you want to send your real numbers across computer boundaries, you'd better stick to ASCII representation, unless you're absolutely sure what's on the other end of the line.)

32.5 Exotic Templates

32.5.1 Bit Strings

Bits are the atoms in the memory world. Access to individual bits may have to be used either as a last resort or because it is the most convenient way to handle your data. Bit string (un)packing converts between strings containing a series of `0` and 1 characters and a sequence of bytes each containing a group of 8 bits. This is almost as simple as it sounds, except that there are two ways the contents of a byte may be written as a bit string. Let's have a look at an annotated byte:

```
  7 6 5 4 3 2 1 0
+-----------------+
| 1 0 0 0 1 1 0 0 |
+-----------------+
 MSB           LSB
```

It's egg-eating all over again: Some think that as a bit string this should be written "10001100" i.e. beginning with the most significant bit, others insist on "00110001". Well, Perl isn't biased, so that's why we have two bit string codes:

```
$byte = pack( 'B8', '10001100' ); # start with MSB
$byte = pack( 'b8', '00110001' ); # start with LSB
```

It is not possible to pack or unpack bit fields - just integral bytes. `pack` always starts at the next byte boundary and "rounds up" to the next multiple of 8 by adding zero bits as required. (If you do want bit fields, there is `vec` in *perlfunc*. Or you could implement bit field handling at the character string level, using split, substr, and concatenation on unpacked bit strings.)

To illustrate unpacking for bit strings, we'll decompose a simple status register (a "-" stands for a "reserved" bit):

```
+-----------------+-----------------+
| S Z - A - P - C | - - - - O D I T |
+-----------------+-----------------+
 MSB           LSB MSB           LSB
```

Converting these two bytes to a string can be done with the unpack template `'b16'`. To obtain the individual bit values from the bit string we use `split` with the "empty" separator pattern which dissects into individual characters. Bit values from the "reserved" positions are simply assigned to `undef`, a convenient notation for "I don't care where this goes".

```
($carry, undef, $parity, undef, $auxcarry, undef, $zero, $sign,
 $trace, $interrupt, $direction, $overflow) =
   split( //, unpack( 'b16', $status ) );
```

We could have used an unpack template `'b12'` just as well, since the last 4 bits can be ignored anyway.

32.5.2 Uuencoding

Another odd-man-out in the template alphabet is u, which packs an "uuencoded string". ("uu" is short for Unix-to-Unix.) Chances are that you won't ever need this encoding technique which was invented to overcome the shortcomings of old-fashioned transmission mediums that do not support other than simple ASCII data. The essential recipe is simple: Take three bytes, or 24 bits. Split them into 4 six-packs, adding a space (0x20) to each. Repeat until all of the data is blended. Fold groups of 4 bytes into lines no longer than 60 and garnish them in front with the original byte count (incremented by 0x20) and a "\n" at the end. - The pack chef will prepare this for you, a la minute, when you select pack code u on the menu:

```
my $uubuf = pack( 'u', $bindat );
```

A repeat count after u sets the number of bytes to put into an uuencoded line, which is the maximum of 45 by default, but could be set to some (smaller) integer multiple of three. unpack simply ignores the repeat count.

32.5.3 Doing Sums

An even stranger template code is %<*number*>. First, because it's used as a prefix to some other template code. Second, because it cannot be used in pack at all, and third, in unpack, doesn't return the data as defined by the template code it precedes. Instead it'll give you an integer of *number* bits that is computed from the data value by doing sums. For numeric unpack codes, no big feat is achieved:

```
my $buf = pack( 'iii', 100, 20, 3 );
print unpack( '%32i3', $buf ), "\n";  # prints 123
```

For string values, % returns the sum of the byte values saving you the trouble of a sum loop with substr and ord:

```
print unpack( '%32A*', "\x01\x10" ), "\n";  # prints 17
```

Although the % code is documented as returning a "checksum": don't put your trust in such values! Even when applied to a small number of bytes, they won't guarantee a noticeable Hamming distance.

In connection with b or B, % simply adds bits, and this can be put to good use to count set bits efficiently:

```
my $bitcount = unpack( '%32b*', $mask );
```

And an even parity bit can be determined like this:

```
my $evenparity = unpack( '%1b*', $mask );
```

32.5.4 Unicode

Unicode is a character set that can represent most characters in most of the world's languages, providing room for over one million different characters. Unicode 3.1 specifies 94,140 characters: The Basic Latin characters are assigned to the numbers 0 - 127. The Latin-1 Supplement with characters that are used in several European languages is in the next range, up to 255. After some more Latin extensions we find the character sets from languages using non-Roman alphabets, interspersed with a variety of symbol sets such as currency symbols, Zapf Dingbats or Braille. (You might want to visit *www.unicode.org* for a look at some of them - my personal favourites are Telugu and Kannada.)

The Unicode character sets associates characters with integers. Encoding these numbers in an equal number of bytes would more than double the requirements for storing texts written in Latin alphabets. The UTF-8 encoding avoids this by storing the most common (from a western point of view) characters in a single byte while encoding the rarer ones in three or more bytes.

So what has this got to do with pack? Well, if you want to convert between a Unicode number and its UTF-8 representation you can do so by using template code U. As an example, let's produce the UTF-8 representation of the Euro currency symbol (code number 0x20AC):

```
$UTF8{Euro} = pack( 'U', 0x20AC );
```

Inspecting `$UTF8{Euro}` shows that it contains 3 bytes: "\xe2\x82\xac". The round trip can be completed with `unpack`:

```
$Unicode{Euro} = unpack( 'U', $UTF8{Euro} );
```

Usually you'll want to pack or unpack UTF-8 strings:

```
# pack and unpack the Hebrew alphabet
my $alefbet = pack( 'U*', 0x05d0..0x05ea );
my @hebrew = unpack( 'U*', $utf );
```

32.5.5 Another Portable Binary Encoding

The pack code `w` has been added to support a portable binary data encoding scheme that goes way beyond simple integers. (Details can be found at *Casbah.org*, the Scarab project.) A BER (Binary Encoded Representation) compressed unsigned integer stores base 128 digits, most significant digit first, with as few digits as possible. Bit eight (the high bit) is set on each byte except the last. There is no size limit to BER encoding, but Perl won't go to extremes.

```
my $berbuf = pack( 'w*', 1, 128, 128+1, 128*128+127 );
```

A hex dump of `$berbuf`, with spaces inserted at the right places, shows 01 8100 8101 81807F. Since the last byte is always less than 128, `unpack` knows where to stop.

32.6 Template Grouping

Prior to Perl 5.8, repetitions of templates had to be made by `x`-multiplication of template strings. Now there is a better way as we may use the pack codes `(` and `)` combined with a repeat count. The `unpack` template from the Stack Frame example can simply be written like this:

```
unpack( 'v2 (vXXCC)5 v5', $frame )
```

Let's explore this feature a little more. We'll begin with the equivalent of

```
join( '', map( substr( $_, 0, 1 ), @str ) )
```

which returns a string consisting of the first character from each string. Using pack, we can write

```
pack( '(A)'.@str, @str )
```

or, because a repeat count * means "repeat as often as required", simply

```
pack( '(A)*', @str )
```

(Note that the template `A*` would only have packed `$str[0]` in full length.)
To pack dates stored as triplets (day, month, year) in an array `@dates` into a sequence of byte, byte, short integer we can write

```
$pd = pack( '(CCS)*', map( @$_, @dates ) );
```

To swap pairs of characters in a string (with even length) one could use several techniques. First, let's use `x` and `X` to skip forward and back:

```
$s = pack( '(A)*', unpack( '(xAXXAx)*', $s ) );
```

We can also use `@` to jump to an offset, with 0 being the position where we were when the last `(` was encountered:

```
$s = pack( '(A)*', unpack( '(@1A @0A @2)*', $s ) );
```

Finally, there is also an entirely different approach by unpacking big endian shorts and packing them in the reverse byte order:

```
$s = pack( '(v)*', unpack( '(n)*', $s );
```

32.7 Lengths and Widths

32.7.1 String Lengths

In the previous section we've seen a network message that was constructed by prefixing the binary message length to the actual message. You'll find that packing a length followed by so many bytes of data is a frequently used recipe since appending a null byte won't work if a null byte may be part of the data. Here is an example where both techniques are used: after two null terminated strings with source and destination address, a Short Message (to a mobile phone) is sent after a length byte:

```
   my $msg = pack( 'Z*Z*CA*', $src, $dst, length( $sm ), $sm );
```

Unpacking this message can be done with the same template:

```
   ( $src, $dst, $len, $sm ) = unpack( 'Z*Z*CA*', $msg );
```

There's a subtle trap lurking in the offing: Adding another field after the Short Message (in variable `$sm`) is all right when packing, but this cannot be unpacked naively:

```
   # pack a message
   my $msg = pack( 'Z*Z*CA*C', $src, $dst, length( $sm ), $sm, $prio );

   # unpack fails - $prio remains undefined!
   ( $src, $dst, $len, $sm, $prio ) = unpack( 'Z*Z*CA*C', $msg );
```

The pack code `A*` gobbles up all remaining bytes, and `$prio` remains undefined! Before we let disappointment dampen the morale: Perl's got the trump card to make this trick too, just a little further up the sleeve. Watch this:

```
   # pack a message: ASCIIZ, ASCIIZ, length/string, byte
   my $msg = pack( 'Z* Z* C/A* C', $src, $dst, $sm, $prio );

   # unpack
   ( $src, $dst, $sm, $prio ) = unpack( 'Z* Z* C/A* C', $msg );
```

Combining two pack codes with a slash (`/`) associates them with a single value from the argument list. In `pack`, the length of the argument is taken and packed according to the first code while the argument itself is added after being converted with the template code after the slash. This saves us the trouble of inserting the `length` call, but it is in `unpack` where we really score: The value of the length byte marks the end of the string to be taken from the buffer. Since this combination doesn't make sense except when the second pack code isn't `a*`, `A*` or `Z*`, Perl won't let you.

The pack code preceding `/` may be anything that's fit to represent a number: All the numeric binary pack codes, and even text codes such as `A4` or `Z*`:

```
   # pack/unpack a string preceded by its length in ASCII
   my $buf = pack( 'A4/A*', "Humpty-Dumpty" );
   # unpack $buf: '13  Humpty-Dumpty'
   my $txt = unpack( 'A4/A*', $buf );
```

`/` is not implemented in Perls before 5.6, so if your code is required to work on older Perls you'll need to `unpack( 'Z* Z* C')` to get the length, then use it to make a new unpack string. For example

```
   # pack a message: ASCIIZ, ASCIIZ, length, string, byte (5.005 compatible)
   my $msg = pack( 'Z* Z* C A* C', $src, $dst, length $sm, $sm, $prio );

   # unpack
   ( undef, undef, $len) = unpack( 'Z* Z* C', $msg );
   ($src, $dst, $sm, $prio) = unpack ( "Z* Z* x A$len C", $msg );
```

But that second `unpack` is rushing ahead. It isn't using a simple literal string for the template. So maybe we should introduce...

32.7.2 Dynamic Templates

So far, we've seen literals used as templates. If the list of pack items doesn't have fixed length, an expression constructing the template is required (whenever, for some reason, `()*` cannot be used). Here's an example: To store named string values in a way that can be conveniently parsed by a C program, we create a sequence of names and null terminated ASCII strings, with = between the name and the value, followed by an additional delimiting null byte. Here's how:

```
   my $env = pack( '(A*A*Z*)' . keys( %Env ) . 'C',
                   map( { ( $_, '=', $Env{$_} ) } keys( %Env ) ), 0 );
```

Let's examine the cogs of this byte mill, one by one. There's the `map` call, creating the items we intend to stuff into the `$env` buffer: to each key (in `$_`) it adds the = separator and the hash entry value. Each triplet is packed with the template code sequence `A*A*Z*` that is repeated according to the number of keys. (Yes, that's what the `keys` function returns in scalar context.) To get the very last null byte, we add a `0` at the end of the `pack` list, to be packed with `C`. (Attentive readers may have noticed that we could have omitted the 0.)

For the reverse operation, we'll have to determine the number of items in the buffer before we can let `unpack` rip it apart:

```
   my $n = $env =~ tr/\0// - 1;
   my %env = map( split( /=/, $_ ), unpack( "(Z*)$n", $env ) );
```

The `tr` counts the null bytes. The `unpack` call returns a list of name-value pairs each of which is taken apart in the `map` block.

32.7.3 Counting Repetitions

Rather than storing a sentinel at the end of a data item (or a list of items), we could precede the data with a count. Again, we pack keys and values of a hash, preceding each with an unsigned short length count, and up front we store the number of pairs:

```
   my $env = pack( 'S(S/A* S/A*)*', scalar keys( %Env ), %Env );
```

This simplifies the reverse operation as the number of repetitions can be unpacked with the `/` code:

```
   my %env = unpack( 'S/(S/A* S/A*)', $env );
```

Note that this is one of the rare cases where you cannot use the same template for `pack` and `unpack` because `pack` can't determine a repeat count for a `()`-group.

32.8 Packing and Unpacking C Structures

In previous sections we have seen how to pack numbers and character strings. If it were not for a couple of snags we could conclude this section right away with the terse remark that C structures don't contain anything else, and therefore you already know all there is to it. Sorry, no: read on, please.

32.8.1 The Alignment Pit

In the consideration of speed against memory requirements the balance has been tilted in favor of faster execution. This has influenced the way C compilers allocate memory for structures: On architectures where a 16-bit or 32-bit operand can be moved faster between places in memory, or to or from a CPU register, if it is aligned at an even or multiple-of-four or even at a multiple-of eight address, a C compiler will give you this speed benefit by stuffing extra bytes into structures. If you don't cross the C shoreline this is not likely to cause you any grief (although you should care when you design large data structures, or you want your code to be portable between architectures (you do want that, don't you?)).

To see how this affects `pack` and `unpack`, we'll compare these two C structures:

```
   typedef struct {
     char     c1;
     short    s;
     char     c2;
     long     l;
   } gappy_t;

   typedef struct {
     long     l;
     short    s;
     char     c1;
     char     c2;
   } dense_t;
```

Typically, a C compiler allocates 12 bytes to a `gappy_t` variable, but requires only 8 bytes for a `dense_t`. After investigating this further, we can draw memory maps, showing where the extra 4 bytes are hidden:

```
   0           +4          +8          +12
   +--+--+--+--+--+--+--+--+--+--+--+--+
   |c1|xx|  s  |c2|xx|xx|xx|     l     |    xx = fill byte
   +--+--+--+--+--+--+--+--+--+--+--+--+
   gappy_t

   0           +4          +8
   +--+--+--+--+--+--+--+--+
   |     l     |  h  |c1|c2|
   +--+--+--+--+--+--+--+--+
   dense_t
```

And that’s where the first quirk strikes: `pack` and `unpack` templates have to be stuffed with `x` codes to get those extra fill bytes.

The natural question: "Why can’t Perl compensate for the gaps?" warrants an answer. One good reason is that C compilers might provide (non-ANSI) extensions permitting all sorts of fancy control over the way structures are aligned, even at the level of an individual structure field. And, if this were not enough, there is an insidious thing called `union` where the amount of fill bytes cannot be derived from the alignment of the next item alone.

OK, so let’s bite the bullet. Here’s one way to get the alignment right by inserting template codes `x`, which don’t take a corresponding item from the list:

```
  my $gappy = pack( 'cxs cxxx l!', $c1, $s, $c2, $l );
```

Note the `!` after `l`: We want to make sure that we pack a long integer as it is compiled by our C compiler. And even now, it will only work for the platforms where the compiler aligns things as above. And somebody somewhere has a platform where it doesn’t. [Probably a Cray, where `short`s, `int`s and `long`s are all 8 bytes. :-)]

Counting bytes and watching alignments in lengthy structures is bound to be a drag. Isn’t there a way we can create the template with a simple program? Here’s a C program that does the trick:

```
   #include <stdio.h>
   #include <stddef.h>

   typedef struct {
     char     fc1;
     short    fs;
     char     fc2;
     long     fl;
   } gappy_t;
```

```
#define Pt(struct,field,tchar) \
  printf( "@%d%s ", offsetof(struct,field), # tchar );

int main() {
  Pt( gappy_t, fc1, c  );
  Pt( gappy_t, fs,  s! );
  Pt( gappy_t, fc2, c  );
  Pt( gappy_t, fl,  l! );
  printf( "\n" );
}
```

The output line can be used as a template in a `pack` or `unpack` call:

```
my $gappy = pack( '@0c @2s! @4c @8l!', $c1, $s, $c2, $l );
```

Gee, yet another template code - as if we hadn't plenty. But `@` saves our day by enabling us to specify the offset from the beginning of the pack buffer to the next item: This is just the value the `offsetof` macro (defined in `<stddef.h>`) returns when given a `struct` type and one of its field names ("member-designator" in C standardese).

Neither using offsets nor adding `x`'s to bridge the gaps is satisfactory. (Just imagine what happens if the structure changes.) What we really need is a way of saying "skip as many bytes as required to the next multiple of N". In fluent Templatese, you say this with `x!N` where N is replaced by the appropriate value. Here's the next version of our struct packaging:

```
my $gappy = pack( 'c x!2 s c x!4 l!', $c1, $s, $c2, $l );
```

That's certainly better, but we still have to know how long all the integers are, and portability is far away. Rather than `2`, for instance, we want to say "however long a short is". But this can be done by enclosing the appropriate pack code in brackets: `[s]`. So, here's the very best we can do:

```
my $gappy = pack( 'c x![s] s c x![l!] l!', $c1, $s, $c2, $l );
```

32.8.2 Alignment, Take 2

I'm afraid that we're not quite through with the alignment catch yet. The hydra raises another ugly head when you pack arrays of structures:

```
typedef struct {
  short   count;
  char    glyph;
} cell_t;

typedef cell_t buffer_t[BUFLEN];
```

Where's the catch? Padding is neither required before the first field `count`, nor between this and the next field `glyph`, so why can't we simply pack like this:

```
# something goes wrong here:
pack( 's!a' x @buffer,
      map{ ( $_->{count}, $_->{glyph} ) } @buffer );
```

This packs `3*@buffer` bytes, but it turns out that the size of `buffer_t` is four times `BUFLEN`! The moral of the story is that the required alignment of a structure or array is propagated to the next higher level where we have to consider padding *at the end* of each component as well. Thus the correct template is:

```
pack( 's!ax' x @buffer,
      map{ ( $_->{count}, $_->{glyph} ) } @buffer );
```

32.8.3 Alignment, Take 3

And even if you take all the above into account, ANSI still lets this:

```
typedef struct {
  char     foo[2];
} foo_t;
```

vary in size. The alignment constraint of the structure can be greater than any of its elements. [And if you think that this doesn't affect anything common, dismember the next cellphone that you see. Many have ARM cores, and the ARM structure rules make `sizeof (foo_t)` == 4]

32.8.4 Pointers for How to Use Them

The title of this section indicates the second problem you may run into sooner or later when you pack C structures. If the function you intend to call expects a, say, `void *` value, you *cannot* simply take a reference to a Perl variable. (Although that value certainly is a memory address, it's not the address where the variable's contents are stored.)

Template code `P` promises to pack a "pointer to a fixed length string". Isn't this what we want? Let's try:

```
# allocate some storage and pack a pointer to it
my $memory = "\x00" x $size;
my $memptr = pack( 'P', $memory );
```

But wait: doesn't `pack` just return a sequence of bytes? How can we pass this string of bytes to some C code expecting a pointer which is, after all, nothing but a number? The answer is simple: We have to obtain the numeric address from the bytes returned by `pack`.

```
my $ptr = unpack( 'L!', $memptr );
```

Obviously this assumes that it is possible to typecast a pointer to an unsigned long and vice versa, which frequently works but should not be taken as a universal law. - Now that we have this pointer the next question is: How can we put it to good use? We need a call to some C function where a pointer is expected. The read(2) system call comes to mind:

```
ssize_t read(int fd, void *buf, size_t count);
```

After reading *perlfunc* explaining how to use `syscall` we can write this Perl function copying a file to standard output:

```
require 'syscall.ph';
sub cat($){
    my $path = shift();
    my $size = -s $path;
    my $memory = "\x00" x $size;  # allocate some memory
    my $ptr = unpack( 'L', pack( 'P', $memory ) );
    open( F, $path ) || die( "$path: cannot open ($!)\n" );
    my $fd = fileno(F);
    my $res = syscall( &SYS_read, fileno(F), $ptr, $size );
    print $memory;
    close( F );
}
```

This is neither a specimen of simplicity nor a paragon of portability but it illustrates the point: We are able to sneak behind the scenes and access Perl's otherwise well-guarded memory! (Important note: Perl's `syscall` does *not* require you to construct pointers in this roundabout way. You simply pass a string variable, and Perl forwards the address.)

How does `unpack` with `P` work? Imagine some pointer in the buffer about to be unpacked: If it isn't the null pointer (which will smartly produce the `undef` value) we have a start address - but then what? Perl has no way of knowing how long this "fixed length string" is, so it's up to you to specify the actual size as an explicit length after `P`.

```
my $mem = "abcdefghijklmn";
print unpack( 'P5', pack( 'P', $mem ) ); # prints "abcde"
```

As a consequence, pack ignores any number or * after P.

Now that we have seen P at work, we might as well give p a whirl. Why do we need a second template code for packing pointers at all? The answer lies behind the simple fact that an unpack with p promises a null-terminated string starting at the address taken from the buffer, and that implies a length for the data item to be returned:

```
my $buf = pack( 'p', "abc\x00efhijklmn" );
print unpack( 'p', $buf );    # prints "abc"
```

Albeit this is apt to be confusing: As a consequence of the length being implied by the string's length, a number after pack code p is a repeat count, not a length as after P.

Using pack(..., $x) with P or p to get the address where $x is actually stored must be used with circumspection. Perl's internal machinery considers the relation between a variable and that address as its very own private matter and doesn't really care that we have obtained a copy. Therefore:

- Do not use pack with p or P to obtain the address of variable that's bound to go out of scope (and thereby freeing its memory) before you are done with using the memory at that address.
- Be very careful with Perl operations that change the value of the variable. Appending something to the variable, for instance, might require reallocation of its storage, leaving you with a pointer into no-man's land.
- Don't think that you can get the address of a Perl variable when it is stored as an integer or double number! pack('P', $x) will force the variable's internal representation to string, just as if you had written something like $x .= ".

It's safe, however, to P- or p-pack a string literal, because Perl simply allocates an anonymous variable.

32.9 Pack Recipes

Here are a collection of (possibly) useful canned recipes for pack and unpack:

```
# Convert IP address for socket functions
pack( "C4", split /\./, "123.4.5.6" );

# Count the bits in a chunk of memory (e.g. a select vector)
unpack( '%32b*', $mask );

# Determine the endianness of your system
$is_little_endian = unpack( 'c', pack( 's', 1 ) );
$is_big_endian = unpack( 'xc', pack( 's', 1 ) );

# Determine the number of bits in a native integer
$bits = unpack( '%32I!', ~0 );

# Prepare argument for the nanosleep system call
my $timespec = pack( 'L!L!', $secs, $nanosecs );
```

For a simple memory dump we unpack some bytes into just as many pairs of hex digits, and use map to handle the traditional spacing - 16 bytes to a line:

```
my $i;
print map( ++$i % 16 ? "$_ " : "$_\n",
           unpack( 'H2' x length( $mem ), $mem ) ),
      length( $mem ) % 16 ? "\n" : '';
```

32.10 Funnies Section

```
# Pulling digits out of nowhere...
print unpack( 'C', pack( 'x' ) ),
      unpack( '%B*', pack( 'A' ) ),
      unpack( 'H', pack( 'A' ) ),
      unpack( 'A', unpack( 'C', pack( 'A' ) ) ), "\n";

# One for the road ;-)
my $advice = pack( 'all u can in a van' );
```

Chapter 33

perlpod

The Plain Old Documentation format

33.1 DESCRIPTION

Pod is a simple-to-use markup language used for writing documentation for Perl, Perl programs, and Perl modules.

Translators are available for converting Pod to various formats like plain text, HTML, man pages, and more.

Pod markup consists of three basic kinds of paragraphs: §33.1.1, §33.1.2, and §33.1.3.

33.1.1 Ordinary Paragraph

Most paragraphs in your documentation will be ordinary blocks of text, like this one. You can simply type in your text without any markup whatsoever, and with just a blank line before and after. When it gets formatted, it will undergo minimal formatting, like being rewrapped, probably put into a proportionally spaced font, and maybe even justified.

You can use formatting codes in ordinary paragraphs, for **bold**, *italic*, `code-style`, hyperlinks, and more. Such codes are explained in the "§33.1.4" section, below.

33.1.2 Verbatim Paragraph

Verbatim paragraphs are usually used for presenting a codeblock or other text which does not require any special parsing or formatting, and which shouldn't be wrapped.

A verbatim paragraph is distinguished by having its first character be a space or a tab. (And commonly, all its lines begin with spaces and/or tabs.) It should be reproduced exactly, with tabs assumed to be on 8-column boundaries. There are no special formatting codes, so you can't italicize or anything like that. A \ means \, and nothing else.

33.1.3 Command Paragraph

A command paragraph is used for special treatment of whole chunks of text, usually as headings or parts of lists.

All command paragraphs (which are typically only one line long) start with "=", followed by an identifier, followed by arbitrary text that the command can use however it pleases. Currently recognized commands are

```
=head1 Heading Text
=head2 Heading Text
=head3 Heading Text
=head4 Heading Text
=over indentlevel
=item stuff
```

```
    =back
    =cut
    =pod
    =begin format
    =end format
    =for format text...
```

To explain them each in detail:

=head1 *Heading Text*

=head2 *Heading Text*

=head3 *Heading Text*

=head4 *Heading Text*

Head1 through head4 produce headings, head1 being the highest level. The text in the rest of this paragraph is the content of the heading. For example:

```
  =head2 Object Attributes
```

The text "Object Attributes" comprises the heading there. (Note that head3 and head4 are recent additions, not supported in older Pod translators.) The text in these heading commands can use formatting codes, as seen here:

```
  =head2 Possible Values for C<$/>
```

Such commands are explained in the "§33.1.4" section, below.

=over *indentlevel*

=item *stuff...*

=back

Item, over, and back require a little more explanation: "=over" starts a region specifically for the generation of a list using "=item" commands, or for indenting (groups of) normal paragraphs. At the end of your list, use "=back" to end it. The *indentlevel* option to "=over" indicates how far over to indent, generally in ems (where one em is the width of an "M" in the document's base font) or roughly comparable units; if there is no *indentlevel* option, it defaults to four. (And some formatters may just ignore whatever *indentlevel* you provide.) In the *stuff* in `=item` *`stuff...`*, you may use formatting codes, as seen here:

```
  =item Using C<$|> to Control Buffering
```

Such commands are explained in the "§33.1.4" section, below.

Note also that there are some basic rules to using "=over" ... "=back" regions:

- Don't use "=item"s outside of an "=over" ... "=back" region.
- The first thing after the "=over" command should be an "=item", unless there aren't going to be any items at all in this "=over" ... "=back" region.
- Don't put "=head*n*" commands inside an "=over" ... "=back" region.
- And perhaps most importantly, keep the items consistent: either use "=item *" for all of them, to produce bullets; or use "=item 1.", "=item 2.", etc., to produce numbered lists; or use "=item foo", "=item bar", etc. – namely, things that look nothing like bullets or numbers.

  If you start with bullets or numbers, stick with them, as formatters use the first "=item" type to decide how to format the list.

=cut

To end a Pod block, use a blank line, then a line beginning with "=cut", and a blank line after it. This lets Perl (and the Pod formatter) know that this is where Perl code is resuming. (The blank line before the "=cut" is not technically necessary, but many older Pod processors require it.)

=pod

The "=pod" command by itself doesn't do much of anything, but it signals to Perl (and Pod formatters) that a Pod block starts here. A Pod block starts with *any* command paragraph, so a "=pod" command is usually used just when you want to start a Pod block with an ordinary paragraph or a verbatim paragraph. For example:

```
=item stuff()

This function does stuff.

=cut

sub stuff {
  ...
}

=pod

Remember to check its return value, as in:

  stuff() || die "Couldn't do stuff!";

=cut
```

=begin *formatname*

=end *formatname*

=for *formatname text...*

For, begin, and end will let you have regions of text/code/data that are not generally interpreted as normal Pod text, but are passed directly to particular formatters, or are otherwise special. A formatter that can use that format will use the region, otherwise it will be completely ignored.

A command "=begin *formatname*", some paragraphs, and a command "=end *formatname*", mean that the text/data inbetween is meant for formatters that understand the special format called *formatname*. For example,

```
=begin html

<hr> <img src="thang.png">
<p> This is a raw HTML paragraph </p>

=end html
```

The command "=for *formatname text...*" specifies that the remainder of just this paragraph (starting right after *formatname*) is in that special format.

```
=for html <hr> <img src="thang.png">
<p> This is a raw HTML paragraph </p>
```

This means the same thing as the above "=begin html" ... "=end html" region.

That is, with "=for", you can have only one paragraph's worth of text (i.e., the text in "=foo targetname text..."), but with "=begin targetname" ... "=end targetname", you can have any amount of stuff inbetween. (Note that there still must be a blank line after the "=begin" command and a blank line before the "=end" command.

Here are some examples of how to use these:

```
=begin html

<br>Figure 1.<br><IMG SRC="figure1.png"><br>

=end html

=begin text

  ---------------
  |  foo        |
  |        bar  |
  ---------------

^^^^ Figure 1. ^^^^

=end text
```

Some format names that formatters currently are known to accept include "roff", "man", "latex", "tex", "text", and "html". (Some formatters will treat some of these as synonyms.)

A format name of "comment" is common for just making notes (presumably to yourself) that won't appear in any formatted version of the Pod document:

```
=for comment
Make sure that all the available options are documented!
```

Some *formatnames* will require a leading colon (as in `"=for :formatname"`, or `"=begin :formatname" ... "=end :formatname"`), to signal that the text is not raw data, but instead *is* Pod text (i.e., possibly containing formatting codes) that's just not for normal formatting (e.g., may not be a normal-use paragraph, but might be for formatting as a footnote).

`=encoding` *`encodingname`*

This command is used for declaring the encoding of a document. Most users won't need this; but if your encoding isn't US-ASCII or Latin-1, then put a `=encoding` *`encodingname`* command early in the document so that pod formatters will know how to decode the document. For *encodingname*, use a name recognized by the *Encode::Supported* module. Examples:

```
=encoding utf8

=encoding koi8-r

=encoding ShiftJIS

=encoding big5
```

And don't forget, when using any command, that the command lasts up until the end of its *paragraph*, not its line. So in the examples below, you can see that every command needs the blank line after it, to end its paragraph.

Some examples of lists include:

```
=over

=item *

First item

=item *

Second item

=back

=over

=item Foo()

Description of Foo function

=item Bar()

Description of Bar function

=back
```

33.1.4 Formatting Codes

In ordinary paragraphs and in some command paragraphs, various formatting codes (a.k.a. "interior sequences") can be used:

`I<text>` – italic text

Used for emphasis ("`be I<careful!>`") and parameters ("`redo I<LABEL>`")

`B<text>` – bold text

Used for switches ("`perl's B<-n> switch`"), programs ("`some systems provide a B<chfn> for that`"), emphasis ("`be B<careful!>`"), and so on ("`and that feature is known as B<autovivification>`").

`C<code>` – code text

Renders code in a typewriter font, or gives some other indication that this represents program text ("`C<gmtime($^T)>`") or some other form of computerese ("`C<drwxr-xr-x>`").

`L<name>` – a hyperlink

There are various syntaxes, listed below. In the syntaxes given, `text`, `name`, and `section` cannot contain the characters '/' and '|'; and any '<' or '>' should be matched.

- `L<name>`
  Link to a Perl manual page (e.g., `L<Net::Ping>`). Note that `name` should not contain spaces. This syntax is also occasionally used for references to UNIX man pages, as in `L<crontab(5)>`.
- `L<name/"sec">` or `L<name/sec>`
  Link to a section in other manual page. E.g., `L<perlsyn/"For Loops">`
- `L</"sec">` or `L</sec>` or `L<"sec">`
  Link to a section in this manual page. E.g., `L</"Object Methods">`

A section is started by the named heading or item. For example, `L<perlvar/$.>` or `L<perlvar/"$.">` both link to the section started by "`=item $.`" in perlvar. And `L<perlsyn/For Loops>` or `L<perlsyn/"For Loops">` both link to the section started by "`=head2 For Loops`" in perlsyn.

To control what text is used for display, you use "`L<text|...>`", as in:

- `L<text|name>`
  Link this text to that manual page. E.g., `L<Perl Error Messages|perldiag>`
- `L<text|name/"sec">` or `L<text|name/sec>`
  Link this text to that section in that manual page. E.g., `L<SWITCH statements|perlsyn/"Basic BLOCKs and Switch Statements">`
- `L<text|/"sec">` or `L<text|/sec>` or `L<text|"sec">`
  Link this text to that section in this manual page. E.g., `L<the various attributes|/"Member Data">`

Or you can link to a web page:

- `L<scheme:...>`
  Links to an absolute URL. For example, `L<http://www.perl.org/>`. But note that there is no corresponding `L<text|scheme:...>` syntax, for various reasons.

`E<escape>` – a character escape

Very similar to HTML/XML `&foo;` "entity references":

- `E<lt>` – a literal < (less than)
- `E<gt>` – a literal > (greater than)
- `E<verbar>` – a literal | (*ver*tical *bar*)
- `E<sol>` = a literal / (*sol*idus)
  The above four are optional except in other formatting codes, notably `L<...>`, and when preceded by a capital letter.
- `E<htmlname>`
  Some non-numeric HTML entity name, such as `E<eacute>`, meaning the same thing as `&eacute;` in HTML – i.e., a lowercase e with an acute (/-shaped) accent.
- `E<number>`
  The ASCII/Latin-1/Unicode character with that number. A leading "0x" means that *number* is hex, as in `E<0x201E>`. A leading "0" means that *number* is octal, as in `E<075>`. Otherwise *number* is interpreted as being in decimal, as in `E<181>`.
  Note that older Pod formatters might not recognize octal or hex numeric escapes, and that many formatters cannot reliably render characters above 255. (Some formatters may even have to use compromised renderings of Latin-1 characters, like rendering `E<eacute>` as just a plain "e".)

`F<filename>` – used for filenames

Typically displayed in italics. Example: "`F<.cshrc>`"

`S<text>` – text contains non-breaking spaces

This means that the words in *text* should not be broken across lines. Example: `S<$x ? $y : $z>`.

`X<topic name>` – an index entry

This is ignored by most formatters, but some may use it for building indexes. It always renders as empty-string. Example: `X<absolutizing relative URLs>`

`Z<>` – a null (zero-effect) formatting code

This is rarely used. It's one way to get around using an E<...> code sometimes. For example, instead of "`NE<lt>3`" (for "N<3") you could write "`NZ<><3`" (the "Z<>" breaks up the "N" and the "<" so they can't be considered the part of a (fictitious) "N<...>" code.

Most of the time, you will need only a single set of angle brackets to delimit the beginning and end of formatting codes. However, sometimes you will want to put a real right angle bracket (a greater-than sign, '>') inside of a formatting code. This is particularly common when using a formatting code to provide a different font-type for a snippet of code. As with all things in Perl, there is more than one way to do it. One way is to simply escape the closing bracket using an `E` code:

```
    C<$a E<lt>=E<gt> $b>
```

This will produce: "`$a <=> $b`"

A more readable, and perhaps more "plain" way is to use an alternate set of delimiters that doesn't require a single ">" to be escaped. With the Pod formatters that are standard starting with perl5.5.660, doubled angle brackets ("<<" and ">>") may be used *if and only if there is whitespace right after the opening delimiter and whitespace right before the closing delimiter!* For example, the following will do the trick:

```
    C<< $a <=> $b >>
```

In fact, you can use as many repeated angle-brackets as you like so long as you have the same number of them in the opening and closing delimiters, and make sure that whitespace immediately follows the last '<' of the opening delimiter, and immediately precedes the first '>' of the closing delimiter. (The whitespace is ignored.) So the following will also work:

```
    C<<< $a <=> $b >>>
    C<<<<  $a <=> $b     >>>>
```

And they all mean exactly the same as this:

```
    C<$a E<lt>=E<gt> $b>
```

As a further example, this means that if you wanted to put these bits of code in `C` (code) style:

```
    open(X, ">>thing.dat") || die $!
    $foo->bar();
```

you could do it like so:

```
    C<<< open(X, ">>thing.dat") || die $! >>>
    C<< $foo->bar(); >>
```

which is presumably easier to read than the old way:

```
    C<open(X, "E<gt>E<gt>thing.dat") || die $!>
    C<$foo-E<gt>bar();>
```

This is currently supported by pod2text (Pod::Text), pod2man (Pod::Man), and any other pod2xxx or Pod::Xxxx translators that use Pod::Parser 1.093 or later, or Pod::Tree 1.02 or later.

33.1.5 The Intent

The intent is simplicity of use, not power of expression. Paragraphs look like paragraphs (block format), so that they stand out visually, and so that I could run them through `fmt` easily to reformat them (that's F7 in my version of **vi**, or Esc Q in my version of **emacs**). I wanted the translator to always leave the `'` and `‘` and " quotes alone, in verbatim mode, so I could slurp in a working program, shift it over four spaces, and have it print out, er, verbatim. And presumably in a monospace font.

The Pod format is not necessarily sufficient for writing a book. Pod is just meant to be an idiot-proof common source for nroff, HTML, TeX, and other markup languages, as used for online documentation. Translators exist for **pod2text**, **pod2html**, **pod2man** (that's for nroff(1) and troff(1)), **pod2latex**, and **pod2fm**. Various others are available in CPAN.

33.1.6 Embedding Pods in Perl Modules

You can embed Pod documentation in your Perl modules and scripts. Start your documentation with an empty line, a "=head1" command at the beginning, and end it with a "=cut" command and an empty line. Perl will ignore the Pod text. See any of the supplied library modules for examples. If you're going to put your Pod at the end of the file, and you're using an __END__ or __DATA__ cut mark, make sure to put an empty line there before the first Pod command.

```
__END__

=head1 NAME

Time::Local - efficiently compute time from local and GMT time
```

Without that empty line before the "=head1", many translators wouldn't have recognized the "=head1" as starting a Pod block.

33.1.7 Hints for Writing Pod

- The **podchecker** command is provided for checking Pod syntax for errors and warnings. For example, it checks for completely blank lines in Pod blocks and for unknown commands and formatting codes. You should still also pass your document through one or more translators and proofread the result, or print out the result and proofread that. Some of the problems found may be bugs in the translators, which you may or may not wish to work around.
- If you're more familiar with writing in HTML than with writing in Pod, you can try your hand at writing documentation in simple HTML, and converting it to Pod with the experimental Pod::HTML2Pod module, (available in CPAN), and looking at the resulting code. The experimental Pod::PXML module in CPAN might also be useful.
- Many older Pod translators require the lines before every Pod command and after every Pod command (including "=cut"!) to be a blank line. Having something like this:

  ```
  # - - - - - - - - - - - -
  =item $firecracker->boom()

  This noisily detonates the firecracker object.
  =cut
  sub boom {
  ...
  ```

  ...will make such Pod translators completely fail to see the Pod block at all.

  Instead, have it like this:

  ```
  # - - - - - - - - - - - -

  =item $firecracker->boom()

  This noisily detonates the firecracker object.

  =cut

  sub boom {
  ...
  ```

- Some older Pod translators require paragraphs (including command paragraphs like "=head2 Functions") to be separated by *completely* empty lines. If you have an apparently empty line with some spaces on it, this might not count as a separator for those translators, and that could cause odd formatting.
- Older translators might add wording around an L<> link, so that `L<Foo::Bar>` may become "the Foo::Bar manpage", for example. So you shouldn't write things like `the L<foo> documentation`, if you want the translated document to read sensibly – instead write `the L<Foo::Bar|Foo::Bar> documentation` or `L<the Foo::Bar documentation|Foo::Bar>`, to control how the link comes out.
- Going past the 70th column in a verbatim block might be ungracefully wrapped by some formatters.

Chapter 34

perlpodspec

Plain Old Documentation: format specification and notes

34.1 DESCRIPTION

This document is detailed notes on the Pod markup language. Most people will only have to read perlpod to know how to write in Pod, but this document may answer some incidental questions to do with parsing and rendering Pod.

In this document, "must" / "must not", "should" / "should not", and "may" have their conventional (cf. RFC 2119) meanings: "X must do Y" means that if X doesn't do Y, it's against this specification, and should really be fixed. "X should do Y" means that it's recommended, but X may fail to do Y, if there's a good reason. "X may do Y" is merely a note that X can do Y at will (although it is up to the reader to detect any connotation of "and I think it would be *nice* if X did Y" versus "it wouldn't really *bother* me if X did Y").

Notably, when I say "the parser should do Y", the parser may fail to do Y, if the calling application explicitly requests that the parser *not* do Y. I often phrase this as "the parser should, by default, do Y." This doesn't *require* the parser to provide an option for turning off whatever feature Y is (like expanding tabs in verbatim paragraphs), although it implicates that such an option *may* be provided.

34.2 Pod Definitions

Pod is embedded in files, typically Perl source files – although you can write a file that's nothing but Pod.

A **line** in a file consists of zero or more non-newline characters, terminated by either a newline or the end of the file.

A **newline sequence** is usually a platform-dependent concept, but Pod parsers should understand it to mean any of CR (ASCII 13), LF (ASCII 10), or a CRLF (ASCII 13 followed immediately by ASCII 10), in addition to any other system-specific meaning. The first CR/CRLF/LF sequence in the file may be used as the basis for identifying the newline sequence for parsing the rest of the file.

A **blank line** is a line consisting entirely of zero or more spaces (ASCII 32) or tabs (ASCII 9), and terminated by a newline or end-of-file. A **non-blank line** is a line containing one or more characters other than space or tab (and terminated by a newline or end-of-file).

(*Note:* Many older Pod parsers did not accept a line consisting of spaces/tabs and then a newline as a blank line – the only lines they considered blank were lines consisting of *no characters at all*, terminated by a newline.)

Whitespace is used in this document as a blanket term for spaces, tabs, and newline sequences. (By itself, this term usually refers to literal whitespace. That is, sequences of whitespace characters in Pod source, as opposed to "E<32>", which is a formatting code that *denotes* a whitespace character.)

A **Pod parser** is a module meant for parsing Pod (regardless of whether this involves calling callbacks or building a parse tree or directly formatting it). A **Pod formatter** (or **Pod translator**) is a module or program that converts Pod to some other format (HTML, plaintext, TeX, PostScript, RTF). A **Pod processor** might be a formatter or translator, or might be a program that does something else with the Pod (like wordcounting it, scanning for index points, etc.).

Pod content is contained in **Pod blocks**. A Pod block starts with a line that matches <m/\A=[a-zA-Z]/>, and continues up to the next line that matches `m/\A=cut/` – or up to the end of the file, if there is no `m/\A=cut/` line.

Within a Pod block, there are **Pod paragraphs**. A Pod paragraph consists of non-blank lines of text, separated by one or more blank lines.

For purposes of Pod processing, there are four types of paragraphs in a Pod block:

- A command paragraph (also called a "directive"). The first line of this paragraph must match `m/\A=[a-zA-Z]/`. Command paragraphs are typically one line, as in:

  ```
  =head1 NOTES

  =item *
  ```

  But they may span several (non-blank) lines:

  ```
  =for comment
  Hm, I wonder what it would look like if
  you tried to write a BNF for Pod from this.

  =head3 Dr. Strangelove, or: How I Learned to
  Stop Worrying and Love the Bomb
  ```

  Some command paragraphs allow formatting codes in their content (i.e., after the part that matches `m/\A=[a-zA-Z]\S*\s*/`), as in:

  ```
  =head1 Did You Remember to C<use strict;>?
  ```

  In other words, the Pod processing handler for "head1" will apply the same processing to "Did You Remember to C<use strict;>?" that it would to an ordinary paragraph – i.e., formatting codes (like "C<...>") are parsed and presumably formatted appropriately, and whitespace in the form of literal spaces and/or tabs is not significant.

- A **verbatim paragraph**. The first line of this paragraph must be a literal space or tab, and this paragraph must not be inside a "=begin *identifier*", ... "=end *identifier*" sequence unless "*identifier*" begins with a colon (":"). That is, if a paragraph starts with a literal space or tab, but *is* inside a "=begin *identifier*", ... "=end *identifier*" region, then it's a data paragraph, unless "*identifier*" begins with a colon.

  Whitespace *is* significant in verbatim paragraphs (although, in processing, tabs are probably expanded).

- An **ordinary paragraph**. A paragraph is an ordinary paragraph if its first line matches neither `m/\A=[a-zA-Z]/` nor `m/\A[ \t]/`, *and* if it's not inside a "=begin *identifier*", ... "=end *identifier*" sequence unless "*identifier*" begins with a colon (":").

- A **data paragraph**. This is a paragraph that *is* inside a "=begin *identifier*" ... "=end *identifier*" sequence where "*identifier*" does *not* begin with a literal colon (":"). In some sense, a data paragraph is not part of Pod at all (i.e., effectively it's "out-of-band"), since it's not subject to most kinds of Pod parsing; but it is specified here, since Pod parsers need to be able to call an event for it, or store it in some form in a parse tree, or at least just parse *around* it.

For example: consider the following paragraphs:

```
# <- that's the 0th column

=head1 Foo

Stuff

  $foo->bar

=cut
```

Here, "=head1 Foo" and "=cut" are command paragraphs because the first line of each matches `m/\A=[a-zA-Z]/`. "*[space][space]*$foo->bar" is a verbatim paragraph, because its first line starts with a literal whitespace character (and there's no "=begin"..."=end" region around).

The "=begin *identifier*" ... "=end *identifier*" commands stop paragraphs that they surround from being parsed as data or verbatim paragraphs, if *identifier* doesn't begin with a colon. This is discussed in detail in the section About Data Paragraphs and "=begin/=end" Regions.

34.3 Pod Commands

This section is intended to supplement and clarify the discussion in Command Paragraph in *perlpod*. These are the currently recognized Pod commands:

"=head1", "=head2", "=head3", "=head4"

This command indicates that the text in the remainder of the paragraph is a heading. That text may contain formatting codes. Examples:

```
=head1 Object Attributes

=head3 What B<Not> to Do!
```

"=pod"

This command indicates that this paragraph begins a Pod block. (If we are already in the middle of a Pod block, this command has no effect at all.) If there is any text in this command paragraph after "=pod", it must be ignored. Examples:

```
=pod

This is a plain Pod paragraph.

=pod This text is ignored.
```

"=cut"

This command indicates that this line is the end of this previously started Pod block. If there is any text after "=cut" on the line, it must be ignored. Examples:

```
=cut

=cut The documentation ends here.

=cut
# This is the first line of program text.
sub foo { # This is the second.
```

It is an error to try to *start* a Pod block with a "=cut" command. In that case, the Pod processor must halt parsing of the input file, and must by default emit a warning.

"=over"

This command indicates that this is the start of a list/indent region. If there is any text following the "=over", it must consist of only a nonzero positive numeral. The semantics of this numeral is explained in the §34.7 section, further below. Formatting codes are not expanded. Examples:

```
=over 3

=over 3.5

=over
```

"=item"

This command indicates that an item in a list begins here. Formatting codes are processed. The semantics of the (optional) text in the remainder of this paragraph are explained in the §34.7 section, further below. Examples:

```
=item

=item *

=item      *

=item 14

=item   3.

=item C<< $thing->stuff(I<dodad>) >>

=item For transporting us beyond seas to be tried for pretended
offenses

=item He is at this time transporting large armies of foreign
mercenaries to complete the works of death, desolation and
tyranny, already begun with circumstances of cruelty and perfidy
scarcely paralleled in the most barbarous ages, and totally
unworthy the head of a civilized nation.
```

"=back"

This command indicates that this is the end of the region begun by the most recent "=over" command. It permits no text after the "=back" command.

"=begin formatname"

This marks the following paragraphs (until the matching "=end formatname") as being for some special kind of processing. Unless "formatname" begins with a colon, the contained non-command paragraphs are data paragraphs. But if "formatname" *does* begin with a colon, then non-command paragraphs are ordinary paragraphs or data paragraphs. This is discussed in detail in the section About Data Paragraphs and "=begin/=end" Regions.

It is advised that formatnames match the regexp `m/\A:?[-a-zA-Z0-9_]+\z/`. Implementors should anticipate future expansion in the semantics and syntax of the first parameter to "=begin"/"=end"/"=for".

"=end formatname"

This marks the end of the region opened by the matching "=begin formatname" region. If "formatname" is not the formatname of the most recent open "=begin formatname" region, then this is an error, and must generate an error message. This is discussed in detail in the section About Data Paragraphs and "=begin/=end" Regions.

"=for formatname text..."

This is synonymous with:

```
=begin formatname

text...

=end formatname
```

That is, it creates a region consisting of a single paragraph; that paragraph is to be treated as a normal paragraph if "formatname" begins with a ":"; if "formatname" *doesn't* begin with a colon, then "text..." will constitute a data paragraph. There is no way to use "=for formatname text..." to express "text..." as a verbatim paragraph.

"=encoding encodingname"

This command, which should occur early in the document (at least before any non-US-ASCII data!), declares that this document is encoded in the encoding *encodingname*, which must be an encoding name that *Encoding* recognizes. (Encoding's list of supported encodings, in *Encoding::Supported*, is useful here.) If the Pod parser cannot decode the declared encoding, it should emit a warning and may abort parsing the document altogether.

A document having more than one "=encoding" line should be considered an error. Pod processors may silently tolerate this if the not-first "=encoding" lines are just duplicates of the first one (e.g., if there's a "=use utf8" line, and later on another "=use utf8" line). But Pod processors should complain if there are contradictory "=encoding" lines in the same document (e.g., if there is a "=encoding utf8" early in the document and "=encoding big5" later). Pod processors that recognize BOMs may also complain if they see an "=encoding" line that contradicts the BOM (e.g., if a document with a UTF-16LE BOM has an "=encoding shiftjis" line).

If a Pod processor sees any command other than the ones listed above (like "=head", or "=haed1", or "=stuff", or "=cuttlefish", or "=w123"), that processor must by default treat this as an error. It must not process the paragraph beginning with that command, must by default warn of this as an error, and may abort the parse. A Pod parser may allow a way for particular applications to add to the above list of known commands, and to stipulate, for each additional command, whether formatting codes should be processed.

Future versions of this specification may add additional commands.

34.4 Pod Formatting Codes

(Note that in previous drafts of this document and of perlpod, formatting codes were referred to as "interior sequences", and this term may still be found in the documentation for Pod parsers, and in error messages from Pod processors.)

There are two syntaxes for formatting codes:

- A formatting code starts with a capital letter (just US-ASCII [A-Z]) followed by a "<", any number of characters, and ending with the first matching ">". Examples:

```
That's what I<you> think!

What's C<dump()> for?

X<C<chmod> and C<unlink()> Under Different Operating Systems>
```

- A formatting code starts with a capital letter (just US-ASCII [A-Z]) followed by two or more "<"'s, one or more whitespace characters, any number of characters, one or more whitespace characters, and ending with the first matching sequence of two or more ">"'s, where the number of ">"'s equals the number of "<"'s in the opening of this formatting code. Examples:

```
That's what I<< you >> think!

C<<< open(X, ">>thing.dat") || die $! >>>

B<< $foo->bar(); >>
```

With this syntax, the whitespace character(s) after the "C<<<" and before the ">>" (or whatever letter) are *not* renderable – they do not signify whitespace, are merely part of the formatting codes themselves. That is, these are all synonymous:

```
C<thing>
C<< thing >>
C<<           thing     >>
C<<<   thing >>>
C<<<<
thing
               >>>>
```

and so on.

In parsing Pod, a notably tricky part is the correct parsing of (potentially nested!) formatting codes. Implementors should consult the code in the `parse_text` routine in Pod::Parser as an example of a correct implementation.

`I<text>` – italic text

See the brief discussion in Formatting Codes in *perlpod*.

`B<text>` – bold text

See the brief discussion in Formatting Codes in *perlpod*.

`C<code>` – code text

See the brief discussion in Formatting Codes in *perlpod*.

`F<filename>` – style for filenames

See the brief discussion in Formatting Codes in *perlpod*.

`X<topic name>` – an index entry

See the brief discussion in Formatting Codes in *perlpod*.

This code is unusual in that most formatters completely discard this code and its content. Other formatters will render it with invisible codes that can be used in building an index of the current document.

`Z<>` – a null (zero-effect) formatting code

Discussed briefly in Formatting Codes in *perlpod*.

This code is unusual is that it should have no content. That is, a processor may complain if it sees `Z<potatoes>`. Whether or not it complains, the *potatoes* text should ignored.

`L<name>` – a hyperlink

The complicated syntaxes of this code are discussed at length in Formatting Codes in *perlpod*, and implementation details are discussed below, in §34.6. Parsing the contents of L<content> is tricky. Notably, the content has to be checked for whether it looks like a URL, or whether it has to be split on literal "|" and/or "/" (in the right order!), and so on, *before* E<...> codes are resolved.

`E<escape>` – a character escape

See Formatting Codes in *perlpod*, and several points in Notes on Implementing Pod Processors.

`S<text>` – text contains non-breaking spaces

This formatting code is syntactically simple, but semantically complex. What it means is that each space in the printable content of this code signifies a non-breaking space.

Consider:

```
    C<$x ? $y    :  $z>

    S<C<$x ? $y     :  $z>>
```

Both signify the monospace (c[ode] style) text consisting of "$x", one space, "?", one space, ":", one space, "$z". The difference is that in the latter, with the S code, those spaces are not "normal" spaces, but instead are non-breaking spaces.

If a Pod processor sees any formatting code other than the ones listed above (as in "N<...>", or "Q<...>", etc.), that processor must by default treat this as an error. A Pod parser may allow a way for particular applications to add to the above list of known formatting codes; a Pod parser might even allow a way to stipulate, for each additional command, whether it requires some form of special processing, as L<...> does.

Future versions of this specification may add additional formatting codes.

Historical note: A few older Pod processors would not see a ">" as closing a "C<" code, if the ">" was immediately preceded by a "-". This was so that this:

```
    C<$foo->bar>
```

would parse as equivalent to this:

```
    C<$foo-E<lt>bar>
```

instead of as equivalent to a "C" formatting code containing only "$foo-", and then a "bar>" outside the "C" formatting code. This problem has since been solved by the addition of syntaxes like this:

```
    C<< $foo->bar >>
```

Compliant parsers must not treat "->" as special.

Formatting codes absolutely cannot span paragraphs. If a code is opened in one paragraph, and no closing code is found by the end of that paragraph, the Pod parser must close that formatting code, and should complain (as in "Unterminated I code in the paragraph starting at line 123: 'Time objects are not...'"). So these two paragraphs:

```
  I<I told you not to do this!

  Don't make me say it again!>
```

...must *not* be parsed as two paragraphs in italics (with the I code starting in one paragraph and starting in another.) Instead, the first paragraph should generate a warning, but that aside, the above code must parse as if it were:

```
  I<I told you not to do this!>

  Don't make me say it again!E<gt>
```

(In SGMLish jargon, all Pod commands are like block-level elements, whereas all Pod formatting codes are like inline-level elements.)

34.5 Notes on Implementing Pod Processors

The following is a long section of miscellaneous requirements and suggestions to do with Pod processing.

- Pod formatters should tolerate lines in verbatim blocks that are of any length, even if that means having to break them (possibly several times, for very long lines) to avoid text running off the side of the page. Pod formatters may warn of such line-breaking. Such warnings are particularly appropriate for lines are over 100 characters long, which are usually not intentional.
- Pod parsers must recognize *all* of the three well-known newline formats: CR, LF, and CRLF. See perlport.
- Pod parsers should accept input lines that are of any length.
- Since Perl recognizes a Unicode Byte Order Mark at the start of files as signaling that the file is Unicode encoded as in UTF-16 (whether big-endian or little-endian) or UTF-8, Pod parsers should do the same. Otherwise, the character encoding should be understood as being UTF-8 if the first highbit byte sequence in the file seems valid as a UTF-8 sequence, or otherwise as Latin-1.

  Future versions of this specification may specify how Pod can accept other encodings. Presumably treatment of other encodings in Pod parsing would be as in XML parsing: whatever the encoding declared by a particular Pod file, content is to be stored in memory as Unicode characters.
- The well known Unicode Byte Order Marks are as follows: if the file begins with the two literal byte values 0xFE 0xFF, this is the BOM for big-endian UTF-16. If the file begins with the two literal byte value 0xFF 0xFE, this is the BOM for little-endian UTF-16. If the file begins with the three literal byte values 0xEF 0xBB 0xBF, this is the BOM for UTF-8.

- A naive but sufficient heuristic for testing the first highbit byte-sequence in a BOM-less file (whether in code or in Pod!), to see whether that sequence is valid as UTF-8 (RFC 2279) is to check whether that the first byte in the sequence is in the range 0xC0 - 0xFD *and* whether the next byte is in the range 0x80 - 0xBF. If so, the parser may conclude that this file is in UTF-8, and all highbit sequences in the file should be assumed to be UTF-8. Otherwise the parser should treat the file as being in Latin-1. In the unlikely circumstance that the first highbit sequence in a truly non-UTF-8 file happens to appear to be UTF-8, one can cater to our heuristic (as well as any more intelligent heuristic) by prefacing that line with a comment line containing a highbit sequence that is clearly *not* valid as UTF-8. A line consisting of simply "#", an e-acute, and any non-highbit byte, is sufficient to establish this file's encoding.

- This document's requirements and suggestions about encodings do not apply to Pod processors running on non-ASCII platforms, notably EBCDIC platforms.

- Pod processors must treat a "=for [label] [content...]" paragraph as meaning the same thing as a "=begin [label]" paragraph, content, and an "=end [label]" paragraph. (The parser may conflate these two constructs, or may leave them distinct, in the expectation that the formatter will nevertheless treat them the same.)

- When rendering Pod to a format that allows comments (i.e., to nearly any format other than plaintext), a Pod formatter must insert comment text identifying its name and version number, and the name and version numbers of any modules it might be using to process the Pod. Minimal examples:

  ```
  %% POD::Pod2PS v3.14159, using POD::Parser v1.92

  <!-- Pod::HTML v3.14159, using POD::Parser v1.92 -->

  {\doccomm generated by Pod::Tree::RTF 3.14159 using Pod::Tree 1.08}

  .\" Pod::Man version 3.14159, using POD::Parser version 1.92
  ```

  Formatters may also insert additional comments, including: the release date of the Pod formatter program, the contact address for the author(s) of the formatter, the current time, the name of input file, the formatting options in effect, version of Perl used, etc.

  Formatters may also choose to note errors/warnings as comments, besides or instead of emitting them otherwise (as in messages to STDERR, or `die`ing).

- Pod parsers *may* emit warnings or error messages ("Unknown E code E<zslig>!") to STDERR (whether through printing to STDERR, or `warn`ing/`carp`ing, or `die`ing/`croak`ing), but *must* allow suppressing all such STDERR output, and instead allow an option for reporting errors/warnings in some other way, whether by triggering a callback, or noting errors in some attribute of the document object, or some similarly unobtrusive mechanism – or even by appending a "Pod Errors" section to the end of the parsed form of the document.

- In cases of exceptionally aberrant documents, Pod parsers may abort the parse. Even then, using `die`ing/`croak`ing is to be avoided; where possible, the parser library may simply close the input file and add text like "*** Formatting Aborted ***" to the end of the (partial) in-memory document.

- In paragraphs where formatting codes (like E<...>, B<...>) are understood (i.e., *not* verbatim paragraphs, but *including* ordinary paragraphs, and command paragraphs that produce renderable text, like "=head1"), literal whitespace should generally be considered "insignificant", in that one literal space has the same meaning as any (nonzero) number of literal spaces, literal newlines, and literal tabs (as long as this produces no blank lines, since those would terminate the paragraph). Pod parsers should compact literal whitespace in each processed paragraph, but may provide an option for overriding this (since some processing tasks do not require it), or may follow additional special rules (for example, specially treating period-space-space or period-newline sequences).

- Pod parsers should not, by default, try to coerce apostrophe (') and quote (") into smart quotes (little 9's, 66's, 99's, etc), nor try to turn backtick (‘) into anything else but a single backtick character (distinct from an openquote character!), nor "–" into anything but two minus signs. They *must never* do any of those things to text in C<...> formatting codes, and never *ever* to text in verbatim paragraphs.

- When rendering Pod to a format that has two kinds of hyphens (-), one that's a non-breaking hyphen, and another that's a breakable hyphen (as in "object-oriented", which can be split across lines as "object-", newline, "oriented"), formatters are encouraged to generally translate "-" to non-breaking hyphen, but may apply heuristics to convert some of these to breaking hyphens.
- Pod formatters should make reasonable efforts to keep words of Perl code from being broken across lines. For example, "Foo::Bar" in some formatting systems is seen as eligible for being broken across lines as "Foo::" newline "Bar" or even "Foo::-" newline "Bar". This should be avoided where possible, either by disabling all line-breaking in mid-word, or by wrapping particular words with internal punctuation in "don't break this across lines" codes (which in some formats may not be a single code, but might be a matter of inserting non-breaking zero-width spaces between every pair of characters in a word.)
- Pod parsers should, by default, expand tabs in verbatim paragraphs as they are processed, before passing them to the formatter or other processor. Parsers may also allow an option for overriding this.
- Pod parsers should, by default, remove newlines from the end of ordinary and verbatim paragraphs before passing them to the formatter. For example, while the paragraph you're reading now could be considered, in Pod source, to end with (and contain) the newline(s) that end it, it should be processed as ending with (and containing) the period character that ends this sentence.
- Pod parsers, when reporting errors, should make some effort to report an approximate line number ("Nested E<>'s in Paragraph #52, near line 633 of Thing/Foo.pm!"), instead of merely noting the paragraph number ("Nested E<>'s in Paragraph #52 of Thing/Foo.pm!"). Where this is problematic, the paragraph number should at least be accompanied by an excerpt from the paragraph ("Nested E<>'s in Paragraph #52 of Thing/Foo.pm, which begins 'Read/write accessor for the C<interest rate> attribute...'").
- Pod parsers, when processing a series of verbatim paragraphs one after another, should consider them to be one large verbatim paragraph that happens to contain blank lines. I.e., these two lines, which have a blank line between them:

  ```
          use Foo;

          print Foo->VERSION
  ```

  should be unified into one paragraph ("\tuse Foo;\n\n\tprint Foo->VERSION") before being passed to the formatter or other processor. Parsers may also allow an option for overriding this.

  While this might be too cumbersome to implement in event-based Pod parsers, it is straightforward for parsers that return parse trees.
- Pod formatters, where feasible, are advised to avoid splitting short verbatim paragraphs (under twelve lines, say) across pages.
- Pod parsers must treat a line with only spaces and/or tabs on it as a "blank line" such as separates paragraphs. (Some older parsers recognized only two adjacent newlines as a "blank line" but would not recognize a newline, a space, and a newline, as a blank line. This is noncompliant behavior.)
- Authors of Pod formatters/processors should make every effort to avoid writing their own Pod parser. There are already several in CPAN, with a wide range of interface styles – and one of them, Pod::Parser, comes with modern versions of Perl.
- Characters in Pod documents may be conveyed either as literals, or by number in E<n> codes, or by an equivalent mnemonic, as in E<eacute> which is exactly equivalent to E<233>.

  Characters in the range 32-126 refer to those well known US-ASCII characters (also defined there by Unicode, with the same meaning), which all Pod formatters must render faithfully. Characters in the ranges 0-31 and 127-159 should not be used (neither as literals, nor as E<number> codes), except for the literal byte-sequences for newline (13, 13 10, or 10), and tab (9).

  Characters in the range 160-255 refer to Latin-1 characters (also defined there by Unicode, with the same meaning). Characters above 255 should be understood to refer to Unicode characters.

- Be warned that some formatters cannot reliably render characters outside 32-126; and many are able to handle 32-126 and 160-255, but nothing above 255.

- Besides the well-known "E<lt>" and "E<gt>" codes for less-than and greater-than, Pod parsers must understand "E<sol>" for "/" (solidus, slash), and "E<verbar>" for "|" (vertical bar, pipe). Pod parsers should also understand "E<lchevron>" and "E<rchevron>" as legacy codes for characters 171 and 187, i.e., "left-pointing double angle quotation mark" = "left pointing guillemet" and "right-pointing double angle quotation mark" = "right pointing guillemet". (These look like little "<<" and ">>", and they are now preferably expressed with the HTML/XHTML codes "E<laquo>" and "E<raquo>".)

- Pod parsers should understand all "E<html>" codes as defined in the entity declarations in the most recent XHTML specification at `www.W3.org`. Pod parsers must understand at least the entities that define characters in the range 160-255 (Latin-1). Pod parsers, when faced with some unknown "E<*identifier*>" code, shouldn't simply replace it with nullstring (by default, at least), but may pass it through as a string consisting of the literal characters E, less-than, *identifier*, greater-than. Or Pod parsers may offer the alternative option of processing such unknown "E<*identifier*>" codes by firing an event especially for such codes, or by adding a special node-type to the in-memory document tree. Such "E<*identifier*>" may have special meaning to some processors, or some processors may choose to add them to a special error report.

- Pod parsers must also support the XHTML codes "E<quot>" for character 34 (doublequote, "), "E<amp>" for character 38 (ampersand, &), and "E<apos>" for character 39 (apostrophe, ').

- Note that in all cases of "E<whatever>", *whatever* (whether an htmlname, or a number in any base) must consist only of alphanumeric characters – that is, *whatever* must watch `m/\A\w+\z/`. So "E< 0 1 2 3 >" is invalid, because it contains spaces, which aren't alphanumeric characters. This presumably does not *need* special treatment by a Pod processor; " 0 1 2 3 " doesn't look like a number in any base, so it would presumably be looked up in the table of HTML-like names. Since there isn't (and cannot be) an HTML-like entity called " 0 1 2 3 ", this will be treated as an error. However, Pod processors may treat "E< 0 1 2 3 >" or "E<e-acute>" as *syntactically* invalid, potentially earning a different error message than the error message (or warning, or event) generated by a merely unknown (but theoretically valid) htmlname, as in "E<qacute>" [sic]. However, Pod parsers are not required to make this distinction.

- Note that E<number> *must not* be interpreted as simply "codepoint *number* in the current/native character set". It always means only "the character represented by codepoint *number* in Unicode." (This is identical to the semantics of &#*number*; in XML.)

  This will likely require many formatters to have tables mapping from treatable Unicode codepoints (such as the "\xE9" for the e-acute character) to the escape sequences or codes necessary for conveying such sequences in the target output format. A converter to *roff would, for example know that "\xE9" (whether conveyed literally, or via a E<...> sequence) is to be conveyed as "e\\*'". Similarly, a program rendering Pod in a Mac OS application window, would presumably need to know that "\xE9" maps to codepoint 142 in MacRoman encoding that (at time of writing) is native for Mac OS. Such Unicode2whatever mappings are presumably already widely available for common output formats. (Such mappings may be incomplete! Implementers are not expected to bend over backwards in an attempt to render Cherokee syllabics, Etruscan runes, Byzantine musical symbols, or any of the other weird things that Unicode can encode.) And if a Pod document uses a character not found in such a mapping, the formatter should consider it an unrenderable character.

- If, surprisingly, the implementor of a Pod formatter can't find a satisfactory pre-existing table mapping from Unicode characters to escapes in the target format (e.g., a decent table of Unicode characters to *roff escapes), it will be necessary to build such a table. If you are in this circumstance, you should begin with the characters in the range 0x00A0 - 0x00FF, which is mostly the heavily used accented characters. Then proceed (as patience permits and fastidiousness compels) through the characters that the (X)HTML standards groups judged important enough to merit mnemonics for. These are declared in the (X)HTML specifications at the www.W3.org site. At time of writing (September 2001), the most recent entity declaration files are:

  ```
  http://www.w3.org/TR/xhtml1/DTD/xhtml-lat1.ent
  http://www.w3.org/TR/xhtml1/DTD/xhtml-special.ent
  http://www.w3.org/TR/xhtml1/DTD/xhtml-symbol.ent
  ```

Then you can progress through any remaining notable Unicode characters in the range 0x2000-0x204D (consult the character tables at www.unicode.org), and whatever else strikes your fancy. For example, in *xhtml-symbol.ent*, there is the entry:

```
<!ENTITY infin    "&#8734;"> <!-- infinity, U+221E ISOtech -->
```

While the mapping "infin" to the character "\x{221E}" will (hopefully) have been already handled by the Pod parser, the presence of the character in this file means that it's reasonably important enough to include in a formatter's table that maps from notable Unicode characters to the codes necessary for rendering them. So for a Unicode-to-*roff mapping, for example, this would merit the entry:

```
"\x{221E}" => '\(in',
```

It is eagerly hoped that in the future, increasing numbers of formats (and formatters) will support Unicode characters directly (as (X)HTML does with `&infin;`, `&#8734;`, or `&#x221E;`), reducing the need for idiosyncratic mappings of Unicode-to-*my_escapes*.

- It is up to individual Pod formatter to display good judgment when confronted with an unrenderable character (which is distinct from an unknown E<thing> sequence that the parser couldn't resolve to anything, renderable or not). It is good practice to map Latin letters with diacritics (like "E<eacute>"/"E<233>") to the corresponding unaccented US-ASCII letters (like a simple character 101, "e"), but clearly this is often not feasible, and an unrenderable character may be represented as "?", or the like. In attempting a sane fallback (as from E<233> to "e"), Pod formatters may use the %Latin1Code_to_fallback table in Pod::Escapes, or Text::Unidecode, if available.

  For example, this Pod text:

  ```
  magic is enabled if you set C<$Currency> to 'E<euro>'.
  ```

  may be rendered as: "magic is enabled if you set `$Currency` to '*?*'" or as "magic is enabled if you set `$Currency` to '**[euro]**'", or as "magic is enabled if you set `$Currency` to '[x20AC]', etc.

  A Pod formatter may also note, in a comment or warning, a list of what unrenderable characters were encountered.

- E<...> may freely appear in any formatting code (other than in another E<...> or in an Z<>). That is, "X<The E<euro>1,000,000 Solution>" is valid, as is "L<The E<euro>1,000,000 Solution|Million::Euros>".

- Some Pod formatters output to formats that implement non-breaking spaces as an individual character (which I'll call "NBSP"), and others output to formats that implement non-breaking spaces just as spaces wrapped in a "don't break this across lines" code. Note that at the level of Pod, both sorts of codes can occur: Pod can contain a NBSP character (whether as a literal, or as a "E<160>" or "E<nbsp>" code); and Pod can contain "S<foo I<bar> baz>" codes, where "mere spaces" (character 32) in such codes are taken to represent non-breaking spaces. Pod parsers should consider supporting the optional parsing of "S<foo I<bar> baz>" as if it were "foo*NBSP*I<bar>*NBSP*baz", and, going the other way, the optional parsing of groups of words joined by NBSP's as if each group were in a S<...> code, so that formatters may use the representation that maps best to what the output format demands.

- Some processors may find that the `S<...>` code is easiest to implement by replacing each space in the parse tree under the content of the S, with an NBSP. But note: the replacement should apply *not* to spaces in *all* text, but *only* to spaces in *printable* text. (This distinction may or may not be evident in the particular tree/event model implemented by the Pod parser.) For example, consider this unusual case:

  ```
   S<L</Autoloaded Functions>>
  ```

  This means that the space in the middle of the visible link text must not be broken across lines. In other words, it's the same as this:

  ```
   L<"AutoloadedE<160>Functions"/Autoloaded Functions>
  ```

However, a misapplied space-to-NBSP replacement could (wrongly) produce something equivalent to this:

```
    L<"AutoloadedE<160>Functions"/AutoloadedE<160>Functions>
```

...which is almost definitely not going to work as a hyperlink (assuming this formatter outputs a format supporting hypertext).

Formatters may choose to just not support the S format code, especially in cases where the output format simply has no NBSP character/code and no code for "don't break this stuff across lines".

- Besides the NBSP character discussed above, implementors are reminded of the existence of the other "special" character in Latin-1, the "soft hyphen" character, also known as "discretionary hyphen", i.e. `E<173>` = `E<0xAD>` = `E<shy>`). This character expresses an optional hyphenation point. That is, it normally renders as nothing, but may render as a "-" if a formatter breaks the word at that point. Pod formatters should, as appropriate, do one of the following: 1) render this with a code with the same meaning (e.g., "\-" in RTF), 2) pass it through in the expectation that the formatter understands this character as such, or 3) delete it.

  For example:

```
    sigE<shy>action
    manuE<shy>script
    JarkE<shy>ko HieE<shy>taE<shy>nieE<shy>mi
```

  These signal to a formatter that if it is to hyphenate "sigaction" or "manuscript", then it should be done as "sig-*[linebreak]*action" or "manu-*[linebreak]*script" (and if it doesn't hyphenate it, then the `E<shy>` doesn't show up at all). And if it is to hyphenate "Jarkko" and/or "Hietaniemi", it can do so only at the points where there is a `E<shy>` code.

  In practice, it is anticipated that this character will not be used often, but formatters should either support it, or delete it.

- If you think that you want to add a new command to Pod (like, say, a "=biblio" command), consider whether you could get the same effect with a for or begin/end sequence: "=for biblio ..." or "=begin biblio" ... "=end biblio". Pod processors that don't understand "=for biblio", etc, will simply ignore it, whereas they may complain loudly if they see "=biblio".

- Throughout this document, "Pod" has been the preferred spelling for the name of the documentation format. One may also use "POD" or "pod". For the documentation that is (typically) in the Pod format, you may use "pod", or "Pod", or "POD". Understanding these distinctions is useful; but obsessing over how to spell them, usually is not.

34.6 About L<...> Codes

As you can tell from a glance at perlpod, the L<...> code is the most complex of the Pod formatting codes. The points below will hopefully clarify what it means and how processors should deal with it.

- In parsing an L<...> code, Pod parsers must distinguish at least four attributes:

  First:

  The link-text. If there is none, this must be undef. (E.g., in "L<Perl Functions|perlfunc>", the link-text is "Perl Functions". In "L<Time::HiRes>" and even "L<|Time::HiRes>", there is no link text. Note that link text may contain formatting.)

  Second:

  The possibly inferred link-text – i.e., if there was no real link text, then this is the text that we'll infer in its place. (E.g., for "L<Getopt::Std>", the inferred link text is "Getopt::Std".)

  Third:

  The name or URL, or undef if none. (E.g., in "L<Perl Functions|perlfunc>", the name – also sometimes called the page – is "perlfunc". In "L</CAVEATS>", the name is undef.)

Fourth:

The section (AKA "item" in older perlpods), or undef if none. E.g., in DESCRIPTION in *Getopt::Std*, "DESCRIPTION" is the section. (Note that this is not the same as a manpage section like the "5" in "man 5 crontab". "Section Foo" in the Pod sense means the part of the text that's introduced by the heading or item whose text is "Foo".)

Pod parsers may also note additional attributes including:

Fifth:

A flag for whether item 3 (if present) is a URL (like "http://lists.perl.org" is), in which case there should be no section attribute; a Pod name (like "perldoc" and "Getopt::Std" are); or possibly a man page name (like "crontab(5)" is).

Sixth:

The raw original L<...> content, before text is split on "|", "/", etc, and before E<...> codes are expanded.

(The above were numbered only for concise reference below. It is not a requirement that these be passed as an actual list or array.)

For example:

```
L<Foo::Bar>
  =>  undef,                         # link text
      "Foo::Bar",                    # possibly inferred link text
      "Foo::Bar",                    # name
      undef,                         # section
      'pod',                         # what sort of link
      "Foo::Bar"                     # original content

L<Perlport's section on NL's|perlport/Newlines>
  =>  "Perlport's section on NL's",   # link text
      "Perlport's section on NL's",   # possibly inferred link text
      "perlport",                    # name
      "Newlines",                    # section
      'pod',                         # what sort of link
      "Perlport's section on NL's|perlport/Newlines" # orig. content

L<perlport/Newlines>
  =>  undef,                         # link text
      '"Newlines" in perlport',      # possibly inferred link text
      "perlport",                    # name
      "Newlines",                    # section
      'pod',                         # what sort of link
      "perlport/Newlines"            # original content

L<crontab(5)/"DESCRIPTION">
  =>  undef,                         # link text
      '"DESCRIPTION" in crontab(5)',  # possibly inferred link text
      "crontab(5)",                  # name
      "DESCRIPTION",                 # section
      'man',                         # what sort of link
      'crontab(5)/"DESCRIPTION"'     # original content

L</Object Attributes>
  =>  undef,                         # link text
      '"Object Attributes"',         # possibly inferred link text
      undef,                         # name
      "Object Attributes",           # section
      'pod',                         # what sort of link
      "/Object Attributes"           # original content
```

```
L<http://www.perl.org/>
  =>  undef,                          # link text
      "http://www.perl.org/",         # possibly inferred link text
      "http://www.perl.org/",         # name
      undef,                          # section
      'url',                          # what sort of link
      "http://www.perl.org/"          # original content
```

Note that you can distinguish URL-links from anything else by the fact that they match `m/\A\w+:[^:\s]\S*\z/`. So `L<http://www.perl.com>` is a URL, but `L<HTTP::Response>` isn't.

- In case of L<...> codes with no "text|" part in them, older formatters have exhibited great variation in actually displaying the link or cross reference. For example, L<crontab(5)> would render as "the `crontab(5)` manpage", or "in the `crontab(5)` manpage" or just "`crontab(5)`".

  Pod processors must now treat "text|"-less links as follows:

```
  L<name>         =>  L<name|name>
  L</section>     =>  L<"section"|/section>
  L<name/section> =>  L<"section" in name|name/section>
```

- Note that section names might contain markup. I.e., if a section starts with:

```
  =head2 About the C<-M> Operator
```

  or with:

```
  =item About the C<-M> Operator
```

  then a link to it would look like this:

```
  L<somedoc/About the C<-M> Operator>
```

  Formatters may choose to ignore the markup for purposes of resolving the link and use only the renderable characters in the section name, as in:

```
  <h1><a name="About_the_-M_Operator">About the <code>-M</code>
  Operator</h1>

  ...

  <a href="somedoc#About_the_-M_Operator">About the <code>-M</code>
  Operator" in somedoc</a>
```

- Previous versions of perlpod distinguished `L<name/"section">` links from `L<name/item>` links (and their targets). These have been merged syntactically and semantically in the current specification, and *section* can refer either to a "=head*n* Heading Content" command or to a "=item Item Content" command. This specification does not specify what behavior should be in the case of a given document having several things all seeming to produce the same *section* identifier (e.g., in HTML, several things all producing the same *anchorname* in <a name="*anchorname*">...</a> elements). Where Pod processors can control this behavior, they should use the first such anchor. That is, `L<Foo/Bar>` refers to the *first* "Bar" section in Foo.

  But for some processors/formats this cannot be easily controlled; as with the HTML example, the behavior of multiple ambiguous <a name="*anchorname*">...</a> is most easily just left up to browsers to decide.

- Authors wanting to link to a particular (absolute) URL, must do so only with "L<scheme:...>" codes (like L<http://www.perl.org>), and must not attempt "L<Some Site Name|scheme:...>" codes. This restriction avoids many problems in parsing and rendering L<...> codes.

- In a `L<text|...>` code, text may contain formatting codes for formatting or for E<...> escapes, as in:

  ```
  L<B<ummE<234>stuff>|...>
  ```

  For `L<...>` codes without a "name|" part, only `E<...>` and `Z<>` codes may occur – no other formatting codes. That is, authors should not use "`L<B<Foo::Bar>>`".

  Note, however, that formatting codes and Z<>'s can occur in any and all parts of an L<...> (i.e., in *name*, *section*, *text*, and *url*).

  Authors must not nest L<...> codes. For example, "L<The L<Foo::Bar> man page>" should be treated as an error.

- Note that Pod authors may use formatting codes inside the "text" part of "L<text|name>" (and so on for L<text|/"sec">).

  In other words, this is valid:

  ```
  Go read L<the docs on C<$.>|perlvar/"$.">
  ```

  Some output formats that do allow rendering "L<...>" codes as hypertext, might not allow the link-text to be formatted; in that case, formatters will have to just ignore that formatting.

- At time of writing, `L<name>` values are of two types: either the name of a Pod page like `L<Foo::Bar>` (which might be a real Perl module or program in an @INC / PATH directory, or a .pod file in those places); or the name of a UNIX man page, like `L<crontab(5)>`. In theory, `L<chmod>` in ambiguous between a Pod page called "chmod", or the Unix man page "chmod" (in whatever man-section). However, the presence of a string in parens, as in "crontab(5)", is sufficient to signal that what is being discussed is not a Pod page, and so is presumably a UNIX man page. The distinction is of no importance to many Pod processors, but some processors that render to hypertext formats may need to distinguish them in order to know how to render a given `L<foo>` code.

- Previous versions of perlpod allowed for a `L<section>` syntax (as in "`L<Object Attributes>`"), which was not easily distinguishable from `L<name>` syntax. This syntax is no longer in the specification, and has been replaced by the `L<"section">` syntax (where the quotes were formerly optional). Pod parsers should tolerate the `L<section>` syntax, for a while at least. The suggested heuristic for distinguishing `L<section>` from `L<name>` is that if it contains any whitespace, it's a *section*. Pod processors may warn about this being deprecated syntax.

34.7 About =over...=back Regions

"=over"..."=back" regions are used for various kinds of list-like structures. (I use the term "region" here simply as a collective term for everything from the "=over" to the matching "=back".)

- The non-zero numeric *indentlevel* in "=over *indentlevel*" ... "=back" is used for giving the formatter a clue as to how many "spaces" (ems, or roughly equivalent units) it should tab over, although many formatters will have to convert this to an absolute measurement that may not exactly match with the size of spaces (or M's) in the document's base font. Other formatters may have to completely ignore the number. The lack of any explicit *indentlevel* parameter is equivalent to an *indentlevel* value of 4. Pod processors may complain if *indentlevel* is present but is not a positive number matching `m/\A(\d*\.)?\d+\z/`.

- Authors of Pod formatters are reminded that "=over" ... "=back" may map to several different constructs in your output format. For example, in converting Pod to (X)HTML, it can map to any of <ul>...</ul>, <ol>...</ol>, <dl>...</dl>, or <blockquote>...</blockquote>. Similarly, "=item" can map to <li> or <dt>.

- Each "=over" ... "=back" region should be one of the following:

  – An "=over" ... "=back" region containing only "=item *" commands, each followed by some number of ordinary/verbatim paragraphs, other nested "=over" ... "=back" regions, "=for..." paragraphs, and "=begin"..."=end" regions.

    (Pod processors must tolerate a bare "=item" as if it were "=item *".) Whether "*" is rendered as a literal asterisk, an "o", or as some kind of real bullet character, is left up to the Pod formatter, and may depend on the level of nesting.

  - An "=over" ... "=back" region containing only `m/\A=item\s+\d+\.?\s*\z/` paragraphs, each one (or each group of them) followed by some number of ordinary/verbatim paragraphs, other nested "=over" ... "=back" regions, "=for..." paragraphs, and/or "=begin"..."=end" codes. Note that the numbers must start at 1 in each section, and must proceed in order and without skipping numbers.

    (Pod processors must tolerate lines like "=item 1" as if they were "=item 1.", with the period.)
  - An "=over" ... "=back" region containing only "=item [text]" commands, each one (or each group of them) followed by some number of ordinary/verbatim paragraphs, other nested "=over" ... "=back" regions, or "=for..." paragraphs, and "=begin"..."=end" regions.

    The "=item [text]" paragraph should not match `m/\A=item\s+\d+\.?\s*\z/` or `m/\A=item\s+\*\s*\z/`, nor should it match just `m/\A=item\s*\z/`.
  - An "=over" ... "=back" region containing no "=item" paragraphs at all, and containing only some number of ordinary/verbatim paragraphs, and possibly also some nested "=over" ... "=back" regions, "=for..." paragraphs, and "=begin"..."=end" regions. Such an itemless "=over" ... "=back" region in Pod is equivalent in meaning to a "<blockquote>...</blockquote>" element in HTML.

  Note that with all the above cases, you can determine which type of "=over" ... "=back" you have, by examining the first (non-"=cut", non-"=pod") Pod paragraph after the "=over" command.

- Pod formatters *must* tolerate arbitrarily large amounts of text in the "=item *text...*" paragraph. In practice, most such paragraphs are short, as in:

```
=item For cutting off our trade with all parts of the world
```

  But they may be arbitrarily long:

```
=item For transporting us beyond seas to be tried for pretended
offenses

=item He is at this time transporting large armies of foreign
mercenaries to complete the works of death, desolation and
tyranny, already begun with circumstances of cruelty and perfidy
scarcely paralleled in the most barbarous ages, and totally
unworthy the head of a civilized nation.
```

- Pod processors should tolerate "=item *" / "=item *number*" commands with no accompanying paragraph. The middle item is an example:

```
=over

=item 1

Pick up dry cleaning.

=item 2

=item 3

Stop by the store.  Get Abba Zabas, Stoli, and cheap lawn chairs.

=back
```

- No "=over" ... "=back" region can contain headings. Processors may treat such a heading as an error.
- Note that an "=over" ... "=back" region should have some content. That is, authors should not have an empty region like this:

```
=over

=back
```

Pod processors seeing such a contentless "=over" ... "=back" region, may ignore it, or may report it as an error.

- Processors must tolerate an "=over" list that goes off the end of the document (i.e., which has no matching "=back"), but they may warn about such a list.
- Authors of Pod formatters should note that this construct:

```
=item Neque

=item Porro

=item Quisquam Est

Qui dolorem ipsum quia dolor sit amet, consectetur, adipisci
velit, sed quia non numquam eius modi tempora incidunt ut
labore et dolore magnam aliquam quaerat voluptatem.

=item Ut Enim
```

is semantically ambiguous, in a way that makes formatting decisions a bit difficult. On the one hand, it could be mention of an item "Neque", mention of another item "Porro", and mention of another item "Quisquam Est", with just the last one requiring the explanatory paragraph "Qui dolorem ipsum quia dolor..."; and then an item "Ut Enim". In that case, you'd want to format it like so:

```
Neque

Porro

Quisquam Est
  Qui dolorem ipsum quia dolor sit amet, consectetur, adipisci
  velit, sed quia non numquam eius modi tempora incidunt ut
  labore et dolore magnam aliquam quaerat voluptatem.

Ut Enim
```

But it could equally well be a discussion of three (related or equivalent) items, "Neque", "Porro", and "Quisquam Est", followed by a paragraph explaining them all, and then a new item "Ut Enim". In that case, you'd probably want to format it like so:

```
Neque
Porro
Quisquam Est
  Qui dolorem ipsum quia dolor sit amet, consectetur, adipisci
  velit, sed quia non numquam eius modi tempora incidunt ut
  labore et dolore magnam aliquam quaerat voluptatem.

Ut Enim
```

But (for the forseeable future), Pod does not provide any way for Pod authors to distinguish which grouping is meant by the above "=item"-cluster structure. So formatters should format it like so:

```
    Neque

    Porro

    Quisquam Est

      Qui dolorem ipsum quia dolor sit amet, consectetur, adipisci
      velit, sed quia non numquam eius modi tempora incidunt ut
      labore et dolore magnam aliquam quaerat voluptatem.

    Ut Enim
```

That is, there should be (at least roughly) equal spacing between items as between paragraphs (although that spacing may well be less than the full height of a line of text). This leaves it to the reader to use (con)textual cues to figure out whether the "Qui dolorem ipsum..." paragraph applies to the "Quisquam Est" item or to all three items "Neque", "Porro", and "Quisquam Est". While not an ideal situation, this is preferable to providing formatting cues that may be actually contrary to the author's intent.

34.8 About Data Paragraphs and "=begin/=end" Regions

Data paragraphs are typically used for inlining non-Pod data that is to be used (typically passed through) when rendering the document to a specific format:

```
=begin rtf

\par{\pard\qr\sa4500{\i Printed\~\chdate\~\chtime}\par}

=end rtf
```

The exact same effect could, incidentally, be achieved with a single "=for" paragraph:

```
=for rtf \par{\pard\qr\sa4500{\i Printed\~\chdate\~\chtime}\par}
```

(Although that is not formally a data paragraph, it has the same meaning as one, and Pod parsers may parse it as one.)

Another example of a data paragraph:

```
=begin html

I like <em>PIE</em>!

<hr>Especially pecan pie!

=end html
```

If these were ordinary paragraphs, the Pod parser would try to expand the "E</em>" (in the first paragraph) as a formatting code, just like "E<lt>" or "E<eacute>". But since this is in a "=begin *identifier*"..."=end *identifier*" region *and* the identifier "html" doesn't begin have a ":" prefix, the contents of this region are stored as data paragraphs, instead of being processed as ordinary paragraphs (or if they began with a spaces and/or tabs, as verbatim paragraphs).

As a further example: At time of writing, no "biblio" identifier is supported, but suppose some processor were written to recognize it as a way of (say) denoting a bibliographic reference (necessarily containing formatting codes in ordinary paragraphs). The fact that "biblio" paragraphs were meant for ordinary processing would be indicated by prefacing each "biblio" identifier with a colon:

```
=begin :biblio

Wirth, Niklaus.  1976.  I<Algorithms + Data Structures =
Programs.>  Prentice-Hall, Englewood Cliffs, NJ.

=end :biblio
```

This would signal to the parser that paragraphs in this begin...end region are subject to normal handling as ordinary/verbatim paragraphs (while still tagged as meant only for processors that understand the "biblio" identifier). The same effect could be had with:

```
=for :biblio
Wirth, Niklaus.  1976.  I<Algorithms + Data Structures =
Programs.>  Prentice-Hall, Englewood Cliffs, NJ.
```

The ":" on these identifiers means simply "process this stuff normally, even though the result will be for some special target". I suggest that parser APIs report "biblio" as the target identifier, but also report that it had a ":" prefix. (And similarly, with the above "html", report "html" as the target identifier, and note the *lack* of a ":" prefix.)

Note that a "=begin *identifier*"..."=end *identifier*" region where *identifier* begins with a colon, *can* contain commands. For example:

```
=begin :biblio

Wirth's classic is available in several editions, including:

=for comment
 hm, check abebooks.com for how much used copies cost.

=over

=item

Wirth, Niklaus.  1975.  I<Algorithmen und Datenstrukturen.>
Teubner, Stuttgart.  [Yes, it's in German.]

=item

Wirth, Niklaus.  1976.  I<Algorithms + Data Structures =
Programs.>  Prentice-Hall, Englewood Cliffs, NJ.

=back

=end :biblio
```

Note, however, a "=begin *identifier*"..."=end *identifier*" region where *identifier* does *not* begin with a colon, should not directly contain "=head1" ... "=head4" commands, nor "=over", nor "=back", nor "=item". For example, this may be considered invalid:

```
=begin somedata

This is a data paragraph.

=head1 Don't do this!

This is a data paragraph too.
```

```
  =end somedata
```

A Pod processor may signal that the above (specifically the "=head1" paragraph) is an error. Note, however, that the following should *not* be treated as an error:

```
  =begin somedata

  This is a data paragraph.

  =cut

  # Yup, this isn't Pod anymore.
  sub excl { (rand() > .5) ? "hoo!" : "hah!" }

  =pod

  This is a data paragraph too.

  =end somedata
```

And this too is valid:

```
  =begin someformat

  This is a data paragraph.

    And this is a data paragraph.

  =begin someotherformat

  This is a data paragraph too.

    And this is a data paragraph too.

  =begin :yetanotherformat

  =head2 This is a command paragraph!

  This is an ordinary paragraph!

    And this is a verbatim paragraph!

  =end :yetanotherformat

  =end someotherformat

  Another data paragraph!

  =end someformat
```

The contents of the above "=begin :yetanotherformat" ... "=end :yetanotherformat" region *aren't* data paragraphs, because the immediately containing region's identifier (":yetanotherformat") begins with a colon. In practice, most regions that contain data paragraphs will contain *only* data paragraphs; however, the above nesting is syntactically valid as Pod, even if it is rare. However, the handlers for some formats, like "html", will accept only data paragraphs, not nested regions; and they may complain if they see (targeted for them) nested regions, or commands, other than "=end", "=pod", and "=cut".

Also consider this valid structure:

```
=begin :biblio

Wirth's classic is available in several editions, including:

=over

=item

Wirth, Niklaus.  1975.  I<Algorithmen und Datenstrukturen.>
Teubner, Stuttgart.  [Yes, it's in German.]

=item

Wirth, Niklaus.  1976.  I<Algorithms + Data Structures =
Programs.>  Prentice-Hall, Englewood Cliffs, NJ.

=back

Buy buy buy!

=begin html

<img src='wirth_spokesmodeling_book.png'>

<hr>

=end html

Now now now!

=end :biblio
```

There, the "=begin html"..."=end html" region is nested inside the larger "=begin :biblio"..."=end :biblio" region. Note that the content of the "=begin html"..."=end html" region is data paragraph(s), because the immediately containing region's identifier ("html") *doesn't* begin with a colon.

Pod parsers, when processing a series of data paragraphs one after another (within a single region), should consider them to be one large data paragraph that happens to contain blank lines. So the content of the above "=begin html"..."=end html" *may* be stored as two data paragraphs (one consisting of "<img src='wirth_spokesmodeling_book.png'>\n" and another consisting of "<hr>\n"), but *should* be stored as a single data paragraph (consisting of "<img src='wirth_spokesmodeling_book.png'>\n\n<hr>\n").

Pod processors should tolerate empty "=begin *something*"..."=end *something*" regions, empty "=begin :*something*"..."=end :*something*" regions, and contentless "=for *something*" and "=for :*something*" paragraphs. I.e., these should be tolerated:

```
=for html

=begin html

=end html

=begin :biblio

=end :biblio
```

Incidentally, note that there's no easy way to express a data paragraph starting with something that looks like a command. Consider:

```
=begin stuff

=shazbot

=end stuff
```

There, "=shazbot" will be parsed as a Pod command "shazbot", not as a data paragraph "=shazbot\n". However, you can express a data paragraph consisting of "=shazbot\n" using this code:

```
=for stuff =shazbot
```

The situation where this is necessary, is presumably quite rare.

Note that =end commands must match the currently open =begin command. That is, they must properly nest. For example, this is valid:

```
=begin outer

X

=begin inner

Y

=end inner

Z

=end outer
```

while this is invalid:

```
=begin outer

X

=begin inner

Y

=end outer

Z

=end inner
```

This latter is improper because when the "=end outer" command is seen, the currently open region has the formatname "inner", not "outer". (It just happens that "outer" is the format name of a higher-up region.) This is an error. Processors must by default report this as an error, and may halt processing the document containing that error. A corollary of this is that regions cannot "overlap" – i.e., the latter block above does not represent a region called "outer" which contains X and Y, overlapping a region called "inner" which contains Y and Z. But because it is invalid (as all apparently overlapping regions would be), it doesn't represent that, or anything at all.

Similarly, this is invalid:

```
=begin thing

=end hting
```

This is an error because the region is opened by "thing", and the "=end" tries to close "hting" [sic].

This is also invalid:

```
=begin thing

=end
```

This is invalid because every "=end" command must have a formatname parameter.

perlrun

How to execute the Perl interpreter

35.1 SYNOPSIS

perl [**-sTtuUWX**] [**-hv**] [**-V**[:*configvar*]] [**-cw**] [**-d**[:*debugger*]] [**-D**[*number/list*]]
[**-pna**] [**-F***pattern*] [**-l**[*octal*]] [**-0**[*octal/hexadecimal*]] [**-I***dir*] [**-m**[**-**]*module*] [**-M**[**-**]*'module...'*] [**-P**] [**-S**]
[**-x**[*dir*]] [**-i**[*extension*]] [**-e** *'command'*] [**–**] [*programfile*] [*argument*]... [**-C [*number/list*]**]]>

35.2 DESCRIPTION

The normal way to run a Perl program is by making it directly executable, or else by passing the name of the source file as an argument on the command line. (An interactive Perl environment is also possible–see *perldebug* for details on how to do that.) Upon startup, Perl looks for your program in one of the following places:

1. Specified line by line via **-e** switches on the command line.
2. Contained in the file specified by the first filename on the command line. (Note that systems supporting the #! notation invoke interpreters this way. See Location of Perl.)
3. Passed in implicitly via standard input. This works only if there are no filename arguments–to pass arguments to a STDIN-read program you must explicitly specify a "-" for the program name.

With methods 2 and 3, Perl starts parsing the input file from the beginning, unless you've specified a **-x** switch, in which case it scans for the first line starting with #! and containing the word "perl", and starts there instead. This is useful for running a program embedded in a larger message. (In this case you would indicate the end of the program using the `__END__` token.)

The #! line is always examined for switches as the line is being parsed. Thus, if you're on a machine that allows only one argument with the #! line, or worse, doesn't even recognize the #! line, you still can get consistent switch behavior regardless of how Perl was invoked, even if **-x** was used to find the beginning of the program.

Because historically some operating systems silently chopped off kernel interpretation of the #! line after 32 characters, some switches may be passed in on the command line, and some may not; you could even get a "-" without its letter, if you're not careful. You probably want to make sure that all your switches fall either before or after that 32-character boundary. Most switches don't actually care if they're processed redundantly, but getting a "-" instead of a complete switch could cause Perl to try to execute standard input instead of your program. And a partial **-I** switch could also cause odd results.

Some switches do care if they are processed twice, for instance combinations of **-l** and **-0**. Either put all the switches after the 32-character boundary (if applicable), or replace the use of **-0***digits* by `BEGIN{ $/ = "\0digits"; }`.

Parsing of the #! switches starts wherever "perl" is mentioned in the line. The sequences "-*" and "- " are specifically ignored so that you could, if you were so inclined, say

```
    #!/bin/sh -- # -*- perl -*- -p
    eval 'exec perl -wS $0 ${1+"$@"}'
        if $running_under_some_shell;
```

to let Perl see the **-p** switch.

A similar trick involves the **env** program, if you have it.

```
    #!/usr/bin/env perl
```

The examples above use a relative path to the perl interpreter, getting whatever version is first in the user's path. If you want a specific version of Perl, say, perl5.005_57, you should place that directly in the #! line's path.

If the #! line does not contain the word "perl", the program named after the #! is executed instead of the Perl interpreter. This is slightly bizarre, but it helps people on machines that don't do #!, because they can tell a program that their SHELL is */usr/bin/perl*, and Perl will then dispatch the program to the correct interpreter for them.

After locating your program, Perl compiles the entire program to an internal form. If there are any compilation errors, execution of the program is not attempted. (This is unlike the typical shell script, which might run part-way through before finding a syntax error.)

If the program is syntactically correct, it is executed. If the program runs off the end without hitting an exit() or die() operator, an implicit `exit(0)` is provided to indicate successful completion.

35.2.1 #! and quoting on non-Unix systems

Unix's #! technique can be simulated on other systems:

OS/2

Put

```
    extproc perl -S -your_switches
```

as the first line in `*.cmd` file (**-S** due to a bug in cmd.exe's 'extproc' handling).

MS-DOS

Create a batch file to run your program, and codify it in `ALTERNATE_SHEBANG` (see the *dosish.h* file in the source distribution for more information).

Win95/NT

The Win95/NT installation, when using the ActiveState installer for Perl, will modify the Registry to associate the *.pl* extension with the perl interpreter. If you install Perl by other means (including building from the sources), you may have to modify the Registry yourself. Note that this means you can no longer tell the difference between an executable Perl program and a Perl library file.

Macintosh

A Macintosh perl program will have the appropriate Creator and Type, so that double-clicking them will invoke the perl application.

VMS

Put

```
    $ perl -mysw 'f$env("procedure")' 'p1' 'p2' 'p3' 'p4' 'p5' 'p6' 'p7' 'p8' !
    $ exit++ + ++$status != 0 and $exit = $status = undef;
```

at the top of your program, where **-mysw** are any command line switches you want to pass to Perl. You can now invoke the program directly, by saying `perl program`, or as a DCL procedure, by saying `@program` (or implicitly via *DCL$ PATH* by just using the name of the program).

This incantation is a bit much to remember, but Perl will display it for you if you say `perl "-V:startperl"`.

Command-interpreters on non-Unix systems have rather different ideas on quoting than Unix shells. You'll need to learn the special characters in your command-interpreter (*, \ and " are common) and how to protect whitespace and these characters to run one-liners (see **-e** below).

On some systems, you may have to change single-quotes to double ones, which you must *not* do on Unix or Plan 9 systems. You might also have to change a single % to a %%.

For example:

```
# Unix
perl -e 'print "Hello world\n"'

# MS-DOS, etc.
perl -e "print \"Hello world\n\""

# Macintosh
print "Hello world\n"
 (then Run "Myscript" or Shift-Command-R)

# VMS
perl -e "print ""Hello world\n"""
```

The problem is that none of this is reliable: it depends on the command and it is entirely possible neither works. If **4DOS** were the command shell, this would probably work better:

```
perl -e "print <Ctrl-x>"Hello world\n<Ctrl-x>""
```

CMD.EXE in Windows NT slipped a lot of standard Unix functionality in when nobody was looking, but just try to find documentation for its quoting rules.

Under the Macintosh, it depends which environment you are using. The MacPerl shell, or MPW, is much like Unix shells in its support for several quoting variants, except that it makes free use of the Macintosh's non-ASCII characters as control characters.

There is no general solution to all of this. It's just a mess.

35.2.2 Location of Perl

It may seem obvious to say, but Perl is useful only when users can easily find it. When possible, it's good for both */usr/bin/perl* and */usr/local/bin/perl* to be symlinks to the actual binary. If that can't be done, system administrators are strongly encouraged to put (symlinks to) perl and its accompanying utilities into a directory typically found along a user's PATH, or in some other obvious and convenient place.

In this documentation, `#!/usr/bin/perl` on the first line of the program will stand in for whatever method works on your system. You are advised to use a specific path if you care about a specific version.

```
#!/usr/local/bin/perl5.00554
```

or if you just want to be running at least version, place a statement like this at the top of your program:

```
use 5.005_54;
```

35.2.3 Command Switches

As with all standard commands, a single-character switch may be clustered with the following switch, if any.

```
    #!/usr/bin/perl -spi.orig   # same as -s -p -i.orig
```

Switches include:

-0[*octal/hexadecimal*]

specifies the input record separator (`$/`) as an octal or hexadecimal number. If there are no digits, the null character is the separator. Other switches may precede or follow the digits. For example, if you have a version of **find** which can print filenames terminated by the null character, you can say this:

```
    find . -name '*.orig' -print0 | perl -n0e unlink
```

The special value 00 will cause Perl to slurp files in paragraph mode. The value 0777 will cause Perl to slurp files whole because there is no legal byte with that value.

If you want to specify any Unicode character, use the hexadecimal format: `-0xHHH...`, where the `H` are valid hexadecimal digits. (This means that you cannot use the `-x` with a directory name that consists of hexadecimal digits.)

-a

turns on autosplit mode when used with a **-n** or **-p**. An implicit split command to the @F array is done as the first thing inside the implicit while loop produced by the **-n** or **-p**.

```
    perl -ane 'print pop(@F), "\n";'
```

is equivalent to

```
    while (<>) {
        @F = split(' ');
        print pop(@F), "\n";
    }
```

An alternate delimiter may be specified using **-F**.

-C [*number/list*]

The `-C` flag controls some Unicode of the Perl Unicode features.

As of 5.8.1, the `-C` can be followed either by a number or a list of option letters. The letters, their numeric values, and effects are as follows; listing the letters is equal to summing the numbers.

```
    I     1    STDIN is assumed to be in UTF-8
    O     2    STDOUT will be in UTF-8
    E     4    STDERR will be in UTF-8
    S     7    I + O + E
    i     8    UTF-8 is the default PerlIO layer for input streams
    o    16    UTF-8 is the default PerlIO layer for output streams
    D    24    i + o
    A    32    the @ARGV elements are expected to be strings encoded in UTF-8
    L    64    normally the "IOEioA" are unconditional,
               the L makes them conditional on the locale environment
               variables (the LC_ALL, LC_TYPE, and LANG, in the order
               of decreasing precedence) -- if the variables indicate
               UTF-8, then the selected "IOEioA" are in effect
```

For example, `-COE` and `-C6` will both turn on UTF-8-ness on both STDOUT and STDERR. Repeating letters is just redundant, not cumulative nor toggling.

The `io` options mean that any subsequent open() (or similar I/O operations) will have the `:utf8` PerlIO layer implicitly applied to them, in other words, UTF-8 is expected from any input stream, and UTF-8 is produced to any output stream. This is just the default, with explicit layers in open() and with binmode() one can manipulate streams as usual.

`-C` on its own (not followed by any number or option list), or the empty string `""` for the `PERL_UNICODE` environment variable, has the same effect as `-CSDL`. In other words, the standard I/O handles and the default `open()` layer are UTF-8-fied **but** only if the locale environment variables indicate a UTF-8 locale. This behaviour follows the *implicit* (and problematic) UTF-8 behaviour of Perl 5.8.0.

You can use `-C0` (or `"0"` for `PERL_UNICODE`) to explicitly disable all the above Unicode features.

The read-only magic variable `${^UNICODE}` reflects the numeric value of this setting. This is variable is set during Perl startup and is thereafter read-only. If you want runtime effects, use the three-arg open() (see open in *perlfunc*), the two-arg binmode() (see binmode in *perlfunc*), and the open pragma (see *open*).

(In Perls earlier than 5.8.1 the `-C` switch was a Win32-only switch that enabled the use of Unicode-aware "wide system call" Win32 APIs. This feature was practically unused, however, and the command line switch was therefore "recycled".)

-c

causes Perl to check the syntax of the program and then exit without executing it. Actually, it *will* execute `BEGIN`, `CHECK`, and `use` blocks, because these are considered as occurring outside the execution of your program. `INIT` and `END` blocks, however, will be skipped.

-d

runs the program under the Perl debugger. See *perldebug*.

-d:*foo[=bar,baz]*

runs the program under the control of a debugging, profiling, or tracing module installed as Devel::foo. E.g., **-d:DProf** executes the program using the Devel::DProf profiler. As with the **-M** flag, options may be passed to the Devel::foo package where they will be received and interpreted by the Devel::foo::import routine. The comma-separated list of options must follow a = character. See *perldebug*.

-D*letters*

-D*number*

sets debugging flags. To watch how it executes your program, use **-Dtls**. (This works only if debugging is compiled into your Perl.) Another nice value is **-Dx**, which lists your compiled syntax tree. And **-Dr** displays compiled regular expressions; the format of the output is explained in *perldebguts*.

As an alternative, specify a number instead of list of letters (e.g., **-D14** is equivalent to **-Dtls**):

```
        1  p  Tokenizing and parsing
        2  s  Stack snapshots
                with v, displays all stacks
        4  l  Context (loop) stack processing
        8  t  Trace execution
       16  o  Method and overloading resolution
       32  c  String/numeric conversions
       64  P  Print profiling info, preprocessor command for -P, source file input state
      128  m  Memory allocation
      256  f  Format processing
      512  r  Regular expression parsing and execution
     1024  x  Syntax tree dump
     2048  u  Tainting checks
     4096     (Obsolete, previously used for LEAKTEST)
     8192  H  Hash dump -- usurps values()
```

```
    16384  X  Scratchpad allocation
    32768  D  Cleaning up
    65536  S  Thread synchronization
   131072  T  Tokenising
   262144  R  Include reference counts of dumped variables (eg when using -Ds)
   524288  J  Do not s,t,P-debug (Jump over) opcodes within package DB
  1048576  v  Verbose: use in conjunction with other flags
  2097152  C  Copy On Write
```

All these flags require **-DDEBUGGING** when you compile the Perl executable (but see *Devel::Peek*, *re* which may change this). See the *INSTALL* file in the Perl source distribution for how to do this. This flag is automatically set if you include **-g** option when `Configure` asks you about optimizer/debugger flags.

If you're just trying to get a print out of each line of Perl code as it executes, the way that `sh -x` provides for shell scripts, you can't use Perl's **-D** switch. Instead do this

```
# If you have "env" utility
env=PERLDB_OPTS="NonStop=1 AutoTrace=1 frame=2" perl -dS program

# Bourne shell syntax
$ PERLDB_OPTS="NonStop=1 AutoTrace=1 frame=2" perl -dS program

# csh syntax
% (setenv PERLDB_OPTS "NonStop=1 AutoTrace=1 frame=2"; perl -dS program)
```

See *perldebug* for details and variations.

-e *commandline*

may be used to enter one line of program. If **-e** is given, Perl will not look for a filename in the argument list. Multiple **-e** commands may be given to build up a multi-line script. Make sure to use semicolons where you would in a normal program.

-F*pattern*

specifies the pattern to split on if **-a** is also in effect. The pattern may be surrounded by `//`, `""`, or ", otherwise it will be put in single quotes.

-h

prints a summary of the options.

-i[*extension*]

specifies that files processed by the <> construct are to be edited in-place. It does this by renaming the input file, opening the output file by the original name, and selecting that output file as the default for print() statements. The extension, if supplied, is used to modify the name of the old file to make a backup copy, following these rules:

If no extension is supplied, no backup is made and the current file is overwritten.

If the extension doesn't contain a *, then it is appended to the end of the current filename as a suffix. If the extension does contain one or more * characters, then each * is replaced with the current filename. In Perl terms, you could think of this as:

```
($backup = $extension) =~ s/\*/$file_name/g;
```

This allows you to add a prefix to the backup file, instead of (or in addition to) a suffix:

```
$ perl -pi'orig_*' -e 's/bar/baz/' fileA    # backup to 'orig_fileA'
```

Or even to place backup copies of the original files into another directory (provided the directory already exists):

```
    $ perl -pi'old/*.orig' -e 's/bar/baz/' fileA # backup to 'old/fileA.orig'
```

These sets of one-liners are equivalent:

```
    $ perl -pi -e 's/bar/baz/' fileA            # overwrite current file
    $ perl -pi'*' -e 's/bar/baz/' fileA         # overwrite current file

    $ perl -pi'.orig' -e 's/bar/baz/' fileA     # backup to 'fileA.orig'
    $ perl -pi'*.orig' -e 's/bar/baz/' fileA    # backup to 'fileA.orig'
```

From the shell, saying

```
    $ perl -p -i.orig -e "s/foo/bar/; ... "
```

is the same as using the program:

```
    #!/usr/bin/perl -pi.orig
    s/foo/bar/;
```

which is equivalent to

```
    #!/usr/bin/perl
    $extension = '.orig';
    LINE: while (<>) {
        if ($ARGV ne $oldargv) {
            if ($extension !~ /\*/) {
                $backup = $ARGV . $extension;
            }
            else {
                ($backup = $extension) =~ s/\*/$ARGV/g;
            }
            rename($ARGV, $backup);
            open(ARGVOUT, ">$ARGV");
            select(ARGVOUT);
            $oldargv = $ARGV;
        }
        s/foo/bar/;
    }
    continue {
        print;  # this prints to original filename
    }
    select(STDOUT);
```

except that the **-i** form doesn't need to compare $ARGV to $oldargv to know when the filename has changed. It does, however, use ARGVOUT for the selected filehandle. Note that STDOUT is restored as the default output filehandle after the loop.

As shown above, Perl creates the backup file whether or not any output is actually changed. So this is just a fancy way to copy files:

```
    $ perl -p -i'/some/file/path/*' -e 1 file1 file2 file3...
or
    $ perl -p -i'.orig' -e 1 file1 file2 file3...
```

You can use `eof` without parentheses to locate the end of each input file, in case you want to append to each file, or reset line numbering (see example in eof in *perlfunc*).

If, for a given file, Perl is unable to create the backup file as specified in the extension then it will skip that file and continue on with the next one (if it exists).

For a discussion of issues surrounding file permissions and **-i**, see Why does Perl let me delete read-only files? Why does -i clobber protected files? Isn't this a bug in Perl? in *perlfaq5*.

You cannot use **-i** to create directories or to strip extensions from files.

Perl does not expand ˜ in filenames, which is good, since some folks use it for their backup files:

```
$ perl -pi~ -e 's/foo/bar/' file1 file2 file3...
```

Finally, the **-i** switch does not impede execution when no files are given on the command line. In this case, no backup is made (the original file cannot, of course, be determined) and processing proceeds from STDIN to STDOUT as might be expected.

-I*directory*

Directories specified by **-I** are prepended to the search path for modules (`@INC`), and also tells the C preprocessor where to search for include files. The C preprocessor is invoked with **-P**; by default it searches /usr/include and /usr/lib/perl.

-l[*octnum*]

enables automatic line-ending processing. It has two separate effects. First, it automatically chomps `$/` (the input record separator) when used with **-n** or **-p**. Second, it assigns `$\` (the output record separator) to have the value of *octnum* so that any print statements will have that separator added back on. If *octnum* is omitted, sets `$\` to the current value of `$/`. For instance, to trim lines to 80 columns:

```
perl -lpe 'substr($_, 80) = ""'
```

Note that the assignment `$\ = $/` is done when the switch is processed, so the input record separator can be different than the output record separator if the **-l** switch is followed by a **-0** switch:

```
gnufind / -print0 | perl -ln0e 'print "found $_" if -p'
```

This sets `$\` to newline and then sets `$/` to the null character.

-m[- *module*]

-M[- *module*]

-M[- *'module ...'*]

-[mM][- *module=arg[,arg]...*]

-m*module* executes `use` *module* `();` before executing your program.

-M*module* executes `use` *module* `;` before executing your program. You can use quotes to add extra code after the module name, e.g., `'-Mmodule qw(foo bar)'`.

If the first character after the **-M** or **-m** is a dash (`-`) then the 'use' is replaced with 'no'.

A little builtin syntactic sugar means you can also say **-mmodule=foo,bar** or **-Mmodule=foo,bar** as a shortcut for `'-Mmodule qw(foo bar)'`. This avoids the need to use quotes when importing symbols. The actual code generated by **-Mmodule=foo,bar** is `use module split(/,/,q{foo,bar})`. Note that the = form removes the distinction between **-m** and **-M**.

-n

causes Perl to assume the following loop around your program, which makes it iterate over filename arguments somewhat like **sed -n** or **awk**:

```
  LINE:
    while (<>) {
        ...             # your program goes here
    }
```

Note that the lines are not printed by default. See **-p** to have lines printed. If a file named by an argument cannot be opened for some reason, Perl warns you about it and moves on to the next file.

Here is an efficient way to delete all files that haven't been modifed for at least a week:

```
    find . -mtime +7 -print | perl -nle unlink
```

This is faster than using the **-exec** switch of **find** because you don't have to start a process on every filename found. It does suffer from the bug of mishandling newlines in pathnames, which you can fix if you follow the example under **-0**.

`BEGIN` and `END` blocks may be used to capture control before or after the implicit program loop, just as in **awk**.

-p

causes Perl to assume the following loop around your program, which makes it iterate over filename arguments somewhat like **sed**:

```
  LINE:
    while (<>) {
        ...             # your program goes here
    } continue {
        print or die "-p destination: $!\n";
    }
```

If a file named by an argument cannot be opened for some reason, Perl warns you about it, and moves on to the next file. Note that the lines are printed automatically. An error occurring during printing is treated as fatal. To suppress printing use the **-n** switch. A **-p** overrides a **-n** switch.

`BEGIN` and `END` blocks may be used to capture control before or after the implicit loop, just as in **awk**.

-P

NOTE: Use of -P is strongly discouraged because of its inherent problems, including poor portability.

This option causes your program to be run through the C preprocessor before compilation by Perl. Because both comments and **cpp** directives begin with the # character, you should avoid starting comments with any words recognized by the C preprocessor such as `"if"`, `"else"`, or `"define"`.

If you're considering using `-P`, you might also want to look at the Filter::cpp module from CPAN.

The problems of -P include, but are not limited to:

- The `#!` line is stripped, so any switches there don't apply.
- A `-P` on a `#!` line doesn't work.
- **All** lines that begin with (whitespace and) a # but do not look like cpp commands, are stripped, including anything inside Perl strings, regular expressions, and here-docs .
- In some platforms the C preprocessor knows too much: it knows about the C++ -style until-end-of-line comments starting with `"//"`. This will cause problems with common Perl constructs like

  ```
  s/foo//;
  ```

  because after -P this will became illegal code

  ```
  s/foo
  ```

  The workaround is to use some other quoting separator than `"/"`, like for example `"!"`:

```
        s!foo!!;
```

- It requires not only a working C preprocessor but also a working *sed*. If not on UNIX, you are probably out of luck on this.
- Script line numbers are not preserved.
- The `-x` does not work with `-P`.

-s

enables rudimentary switch parsing for switches on the command line after the program name but before any filename arguments (or before an argument of **–**). This means you can have switches with two leading dashes (**–help**). Any switch found there is removed from @ARGV and sets the corresponding variable in the Perl program. The following program prints "1" if the program is invoked with a **-xyz** switch, and "abc" if it is invoked with **-xyz=abc**.

```
    #!/usr/bin/perl -s
    if ($xyz) { print "$xyz\n" }
```

Do note that **–help** creates the variable ${-help}, which is not compliant with `strict refs`.

-S

makes Perl use the PATH environment variable to search for the program (unless the name of the program contains directory separators).

On some platforms, this also makes Perl append suffixes to the filename while searching for it. For example, on Win32 platforms, the ".bat" and ".cmd" suffixes are appended if a lookup for the original name fails, and if the name does not already end in one of those suffixes. If your Perl was compiled with DEBUGGING turned on, using the -Dp switch to Perl shows how the search progresses.

Typically this is used to emulate #! startup on platforms that don't support #!. This example works on many platforms that have a shell compatible with Bourne shell:

```
    #!/usr/bin/perl
    eval 'exec /usr/bin/perl -wS $0 ${1+"$@"}'
            if $running_under_some_shell;
```

The system ignores the first line and feeds the program to */bin/sh*, which proceeds to try to execute the Perl program as a shell script. The shell executes the second line as a normal shell command, and thus starts up the Perl interpreter. On some systems $0 doesn't always contain the full pathname, so the **-S** tells Perl to search for the program if necessary. After Perl locates the program, it parses the lines and ignores them because the variable $running_under_some_shell is never true. If the program will be interpreted by csh, you will need to replace `${1+"$@"}` with `$*`, even though that doesn't understand embedded spaces (and such) in the argument list. To start up sh rather than csh, some systems may have to replace the #! line with a line containing just a colon, which will be politely ignored by Perl. Other systems can't control that, and need a totally devious construct that will work under any of **csh**, **sh**, or Perl, such as the following:

```
        eval '(exit $?0)' && eval 'exec perl -wS $0 ${1+"$@"}'
        & eval 'exec /usr/bin/perl -wS $0 $argv:q'
                if $running_under_some_shell;
```

If the filename supplied contains directory separators (i.e., is an absolute or relative pathname), and if that file is not found, platforms that append file extensions will do so and try to look for the file with those extensions added, one by one.

On DOS-like platforms, if the program does not contain directory separators, it will first be searched for in the current directory before being searched for on the PATH. On Unix platforms, the program will be searched for strictly on the PATH.

-t

Like **-T**, but taint checks will issue warnings rather than fatal errors. These warnings can be controlled normally with `no warnings qw(taint)`.

NOTE: this is not a substitute for -T. This is meant only to be used as a temporary development aid while securing legacy code: for real production code and for new secure code written from scratch always use the real **-T**.

-T

forces "taint" checks to be turned on so you can test them. Ordinarily these checks are done only when running setuid or setgid. It's a good idea to turn them on explicitly for programs that run on behalf of someone else whom you might not necessarily trust, such as CGI programs or any internet servers you might write in Perl. See *perlsec* for details. For security reasons, this option must be seen by Perl quite early; usually this means it must appear early on the command line or in the #! line for systems which support that construct.

-u

This obsolete switch causes Perl to dump core after compiling your program. You can then in theory take this core dump and turn it into an executable file by using the **undump** program (not supplied). This speeds startup at the expense of some disk space (which you can minimize by stripping the executable). (Still, a "hello world" executable comes out to about 200K on my machine.) If you want to execute a portion of your program before dumping, use the dump() operator instead. Note: availability of **undump** is platform specific and may not be available for a specific port of Perl.

This switch has been superseded in favor of the new Perl code generator backends to the compiler. See *B* and *B::Bytecode* for details.

-U

allows Perl to do unsafe operations. Currently the only "unsafe" operations are the unlinking of directories while running as superuser, and running setuid programs with fatal taint checks turned into warnings. Note that the **-w** switch (or the `$^W` variable) must be used along with this option to actually *generate* the taint-check warnings.

-v

prints the version and patchlevel of your perl executable.

-V

prints summary of the major perl configuration values and the current values of @INC.

-V:*name*

Prints to STDOUT the value of the named configuration variable(s), with multiples when your query looks like a regex. For example,

```
$ perl -V:lib.
    libs='-lnsl -lgdbm -ldb -ldl -lm -lcrypt -lutil -lc';
    libc='/lib/libc-2.2.4.so';
$ perl -V:lib.*
    libpth='/usr/local/lib /lib /usr/lib';
    libs='-lnsl -lgdbm -ldb -ldl -lm -lcrypt -lutil -lc';
    lib_ext='.a';
    libc='/lib/libc-2.2.4.so';
    libperl='libperl.a';
    ....
```

Additionally, extra colons can be used to control formatting. A trailing colon suppresses the linefeed and terminator ';', allowing you to embed queries into shell commands. (mnemonic: PATH separator ':'.)

```
$ echo "compression-vars: " `perl -V:z.*: ` " are here !"
compression-vars:  zcat='' zip='zip'  are here !
```

A leading colon removes the 'name=' part of the response, this allows you to map to the name you need.

```
$ echo "goodvfork="`./perl -Ilib -V::usevfork`
goodvfork=false;
```

Leading and trailing colons can be used together if you need positional parameter values without the names. Note that in the case below, the PERL_API params are returned in alphabetical order.

```
$ echo building_on `perl -V::osname: -V::PERL_API_.*:` now
building_on 'linux' '5' '1' '9' now
```

-w

prints warnings about dubious constructs, such as variable names that are mentioned only once and scalar variables that are used before being set, redefined subroutines, references to undefined filehandles or filehandles opened read-only that you are attempting to write on, values used as a number that doesn't look like numbers, using an array as though it were a scalar, if your subroutines recurse more than 100 deep, and innumerable other things.

This switch really just enables the internal `$^W` variable. You can disable or promote into fatal errors specific warnings using `__WARN__` hooks, as described in *perlvar* and warn in *perlfunc*. See also *perldiag* and *perltrap*. A new, fine-grained warning facility is also available if you want to manipulate entire classes of warnings; see *warnings* or *perllexwarn*.

-W

Enables all warnings regardless of `no warnings` or `$^W`. See *perllexwarn*.

-X

Disables all warnings regardless of `use warnings` or `$^W`. See *perllexwarn*.

-x

-x *directory*

tells Perl that the program is embedded in a larger chunk of unrelated ASCII text, such as in a mail message. Leading garbage will be discarded until the first line that starts with #! and contains the string "perl". Any meaningful switches on that line will be applied. If a directory name is specified, Perl will switch to that directory before running the program. The **-x** switch controls only the disposal of leading garbage. The program must be terminated with `__END__` if there is trailing garbage to be ignored (the program can process any or all of the trailing garbage via the DATA filehandle if desired).

35.3 ENVIRONMENT

HOME

Used if chdir has no argument.

LOGDIR

Used if chdir has no argument and HOME is not set.

PATH

Used in executing subprocesses, and in finding the program if **-S** is used.

PERL5LIB

A list of directories in which to look for Perl library files before looking in the standard library and the current directory. Any architecture-specific directories under the specified locations are automatically included if they exist. If PERL5LIB is not defined, PERLLIB is used. Directories are separated (like in PATH) by a colon on unixish platforms and by a semicolon on Windows (the proper path separator being given by the command `perl -V:path_sep`).

When running taint checks (either because the program was running setuid or setgid, or the **-T** switch was used), neither variable is used. The program should instead say:

```
    use lib "/my/directory";
```

PERL5OPT

Command-line options (switches). Switches in this variable are taken as if they were on every Perl command line. Only the **-[DIMUdmtw]** switches are allowed. When running taint checks (because the program was running setuid or setgid, or the **-T** switch was used), this variable is ignored. If PERL5OPT begins with **-T**, tainting will be enabled, and any subsequent options ignored.

PERLIO

A space (or colon) separated list of PerlIO layers. If perl is built to use PerlIO system for IO (the default) these layers effect perl's IO.

It is conventional to start layer names with a colon e.g. `:perlio` to emphasise their similarity to variable "attributes". But the code that parses layer specification strings (which is also used to decode the PERLIO environment variable) treats the colon as a separator.

An unset or empty PERLIO is equivalent to `:stdio`.

The list becomes the default for *all* perl's IO. Consequently only built-in layers can appear in this list, as external layers (such as :encoding()) need IO in order to load them!. See "open pragma" for how to add external encodings as defaults.

The layers that it makes sense to include in the PERLIO environment variable are briefly summarised below. For more details see *PerlIO*.

:bytes

A pseudolayer that turns *off* the `:utf8` flag for the layer below. Unlikely to be useful on its own in the global PERLIO environment variable. You perhaps were thinking of `:crlf:bytes` or `:perlio:bytes`.

:crlf

A layer which does CRLF to "\n" translation distinguishing "text" and "binary" files in the manner of MS-DOS and similar operating systems. (It currently does *not* mimic MS-DOS as far as treating of Control-Z as being an end-of-file marker.)

:mmap

A layer which implements "reading" of files by using `mmap()` to make (whole) file appear in the process's address space, and then using that as PerlIO's "buffer".

:perlio

This is a re-implementation of "stdio-like" buffering written as a PerlIO "layer". As such it will call whatever layer is below it for its operations (typically `:unix`).

:pop

An experimental pseudolayer that removes the topmost layer. Use with the same care as is reserved for nitroglycerin.

:raw

A pseudolayer that manipulates other layers. Applying the `:raw` layer is equivalent to calling `binmode($fh)`. It makes the stream pass each byte as-is without any translation. In particular CRLF translation, and/or :utf8 intuited from locale are disabled.

Unlike in the earlier versions of Perl `:raw` is *not* just the inverse of `:crlf` - other layers which would affect the binary nature of the stream are also removed or disabled.

:stdio

This layer provides PerlIO interface by wrapping system's ANSI C "stdio" library calls. The layer provides both buffering and IO. Note that `:stdio` layer does *not* do CRLF translation even if that is platforms normal behaviour. You will need a `:crlf` layer above it to do that.

:unix

Low level layer which calls `read`, `write` and `lseek` etc.

:utf8

A pseudolayer that turns on a flag on the layer below to tell perl that output should be in utf8 and that input should be regarded as already in utf8 form. May be useful in PERLIO environment variable to make UTF-8 the default. (To turn off that behaviour use `:bytes` layer.)

:win32

On Win32 platforms this *experimental* layer uses native "handle" IO rather than unix-like numeric file descriptor layer. Known to be buggy in this release.

On all platforms the default set of layers should give acceptable results.

For UNIX platforms that will equivalent of "unix perlio" or "stdio". Configure is setup to prefer "stdio" implementation if system's library provides for fast access to the buffer, otherwise it uses the "unix perlio" implementation.

On Win32 the default in this release is "unix crlf". Win32's "stdio" has a number of bugs/mis-features for perl IO which are somewhat C compiler vendor/version dependent. Using our own `crlf` layer as the buffer avoids those issues and makes things more uniform. The `crlf` layer provides CRLF to/from "\n" conversion as well as buffering.

This release uses `unix` as the bottom layer on Win32 and so still uses C compiler's numeric file descriptor routines. There is an experimental native `win32` layer which is expected to be enhanced and should eventually be the default under Win32.

PERLIO_DEBUG

If set to the name of a file or device then certain operations of PerlIO sub-system will be logged to that file (opened as append). Typical uses are UNIX:

```
PERLIO_DEBUG=/dev/tty perl script ...
```

and Win32 approximate equivalent:

```
set PERLIO_DEBUG=CON
perl script ...
```

PERLLIB

A list of directories in which to look for Perl library files before looking in the standard library and the current directory. If PERL5LIB is defined, PERLLIB is not used.

PERL5DB

The command used to load the debugger code. The default is:

```
    BEGIN { require 'perl5db.pl' }
```

PERL5SHELL (specific to the Win32 port)

May be set to an alternative shell that perl must use internally for executing "backtick" commands or system(). Default is `cmd.exe /x/d/c` on WindowsNT and `command.com /c` on Windows95. The value is considered to be space-separated. Precede any character that needs to be protected (like a space or backslash) with a backslash.

Note that Perl doesn't use COMSPEC for this purpose because COMSPEC has a high degree of variability among users, leading to portability concerns. Besides, perl can use a shell that may not be fit for interactive use, and setting COMSPEC to such a shell may interfere with the proper functioning of other programs (which usually look in COMSPEC to find a shell fit for interactive use).

PERL_DEBUG_MSTATS

Relevant only if perl is compiled with the malloc included with the perl distribution (that is, if `perl -V:d_mymalloc` is 'define'). If set, this causes memory statistics to be dumped after execution. If set to an integer greater than one, also causes memory statistics to be dumped after compilation.

PERL_DESTRUCT_LEVEL

Relevant only if your perl executable was built with **-DDEBUGGING**, this controls the behavior of global destruction of objects and other references. See PERL_DESTRUCT_LEVEL in *perlhack* for more information.

PERL_DL_NONLAZY

Set to one to have perl resolve **all** undefined symbols when it loads a dynamic library. The default behaviour is to resolve symbols when they are used. Setting this variable is useful during testing of extensions as it ensures that you get an error on misspelled function names even if the test suite doesn't call it.

PERL_ENCODING

If using the `encoding` pragma without an explicit encoding name, the PERL_ENCODING environment variable is consulted for an encoding name.

PERL_HASH_SEED

(Since Perl 5.8.1.) Used to randomise Perl's internal hash function. To emulate the pre-5.8.1 behaviour, set to an integer (zero means exactly the same order as 5.8.0). "Pre-5.8.1" means, among other things, that hash keys will be ordered the same between different runs of Perl.

The default behaviour is to randomise unless the PERL_HASH_SEED is set. If Perl has been compiled with `-DUSE_HASH_SEED_EXPLICIT`, the default behaviour is **not** to randomise unless the PERL_HASH_SEED is set.

If PERL_HASH_SEED is unset or set to a non-numeric string, Perl uses the pseudorandom seed supplied by the operating system and libraries. This means that each different run of Perl will have a different ordering of the results of keys(), values(), and each().

Please note that the hash seed is sensitive information. Hashes are randomized to protect against local and remote attacks against Perl code. By manually setting a seed this protection may be partially or completely lost.

See Algorithmic Complexity Attacks in *perlsec* and PERL_HASH_SEED_DEBUG for more information.

PERL_HASH_SEED_DEBUG

(Since Perl 5.8.1.) Set to one to display (to STDERR) the value of the hash seed at the beginning of execution. This, combined with PERL_HASH_SEED is intended to aid in debugging nondeterministic behavior caused by hash randomization.

Note that the hash seed is sensitive information: by knowing it one can craft a denial-of-service attack against Perl code, even remotely, see Algorithmic Complexity Attacks in *perlsec* for more information. **Do not disclose the hash seed** to people who don't need to know it. See also hash_seed() of *Hash::Util*.

PERL_ROOT (specific to the VMS port)

A translation concealed rooted logical name that contains perl and the logical device for the @INC path on VMS only. Other logical names that affect perl on VMS include PERLSHR, PERL_ENV_TABLES, and SYS$TIMEZONE_DIFFERENTIAL but are optional and discussed further in *perlvms* and in *README.vms* in the Perl source distribution.

PERL_SIGNALS

In Perls 5.8.1 and later. If set to `unsafe` the pre-Perl-5.8.0 signals behaviour (immediate but unsafe) is restored. If set to `safe` the safe (or deferred) signals are used. See Deferred Signals (Safe signals) in *perlipc*.

PERL_UNICODE

Equivalent to the **-C** command-line switch. Note that this is not a boolean variable– setting this to `"1"` is not the right way to "enable Unicode" (whatever that would mean). You can use `"0"` to "disable Unicode", though (or alternatively unset PERL_UNICODE in your shell before starting Perl). See the description of the `-C` switch for more information.

SYS$ LOGIN (specific to the VMS port)

Used if chdir has no argument and HOME and LOGDIR are not set.

Perl also has environment variables that control how Perl handles data specific to particular natural languages. See *perllocale*.

Apart from these, Perl uses no other environment variables, except to make them available to the program being executed, and to child processes. However, programs running setuid would do well to execute the following lines before doing anything else, just to keep people honest:

```
    $ENV{PATH}  = '/bin:/usr/bin';    # or whatever you need
    $ENV{SHELL} = '/bin/sh' if exists $ENV{SHELL};
    delete @ENV{qw(IFS CDPATH ENV BASH_ENV)};
```

Chapter 36

perldiag

Various Perl diagnostics

36.1 DESCRIPTION

These messages are classified as follows (listed in increasing order of desperation):

```
    (W) A warning (optional).
    (D) A deprecation (optional).
    (S) A severe warning (default).
    (F) A fatal error (trappable).
    (P) An internal error you should never see (trappable).
    (X) A very fatal error (nontrappable).
    (A) An alien error message (not generated by Perl).
```

The majority of messages from the first three classifications above (W, D & S) can be controlled using the `warnings` pragma.

If a message can be controlled by the `warnings` pragma, its warning category is included with the classification letter in the description below.

Optional warnings are enabled by using the `warnings` pragma or the **-w** and **-W** switches. Warnings may be captured by setting `$SIG{__WARN__}` to a reference to a routine that will be called on each warning instead of printing it. See *perlvar*.

Default warnings are always enabled unless they are explicitly disabled with the `warnings` pragma or the **-X** switch.

Trappable errors may be trapped using the eval operator. See eval in *perlfunc*. In almost all cases, warnings may be selectively disabled or promoted to fatal errors using the `warnings` pragma. See *warnings*.

The messages are in alphabetical order, without regard to upper or lower-case. Some of these messages are generic. Spots that vary are denoted with a %s or other printf-style escape. These escapes are ignored by the alphabetical order, as are all characters other than letters. To look up your message, just ignore anything that is not a letter.

accept() on closed socket %s

> (W closed) You tried to do an accept on a closed socket. Did you forget to check the return value of your socket() call? See accept in *perlfunc*.

Allocation too large: %lx

> (X) You can't allocate more than 64K on an MS-DOS machine.

'!' allowed only after types %s

> (F) The '!' is allowed in pack() or unpack() only after certain types. See pack in *perlfunc*.

Ambiguous call resolved as CORE::%s(), qualify as such or use &

(W ambiguous) A subroutine you have declared has the same name as a Perl keyword, and you have used the name without qualification for calling one or the other. Perl decided to call the builtin because the subroutine is not imported.

To force interpretation as a subroutine call, either put an ampersand before the subroutine name, or qualify the name with its package. Alternatively, you can import the subroutine (or pretend that it's imported with the `use subs` pragma).

To silently interpret it as the Perl operator, use the `CORE::` prefix on the operator (e.g. `CORE::log($x)`) or declare the subroutine to be an object method (see Subroutine Attributes in *perlsub* or *attributes*).

Ambiguous range in transliteration operator

(F) You wrote something like `tr/a-z-0//` which doesn't mean anything at all. To include a `-` character in a transliteration, put it either first or last. (In the past, `tr/a-z-0//` was synonymous with `tr/a-y//`, which was probably not what you would have expected.)

Ambiguous use of %s resolved as %s

(W ambiguous)(S) You said something that may not be interpreted the way you thought. Normally it's pretty easy to disambiguate it by supplying a missing quote, operator, parenthesis pair or declaration.

'|' and '<' may not both be specified on command line

(F) An error peculiar to VMS. Perl does its own command line redirection, and found that STDIN was a pipe, and that you also tried to redirect STDIN using '<'. Only one STDIN stream to a customer, please.

'|' and '>' may not both be specified on command line

(F) An error peculiar to VMS. Perl does its own command line redirection, and thinks you tried to redirect stdout both to a file and into a pipe to another command. You need to choose one or the other, though nothing's stopping you from piping into a program or Perl script which 'splits' output into two streams, such as

```
open(OUT,">$ARGV[0]") or die "Can't write to $ARGV[0]: $!";
while (<STDIN>) {
    print;
    print OUT;
}
close OUT;
```

Applying %s to %s will act on scalar(%s)

(W misc) The pattern match (`//`), substitution (`s///`), and transliteration (`tr///`) operators work on scalar values. If you apply one of them to an array or a hash, it will convert the array or hash to a scalar value – the length of an array, or the population info of a hash – and then work on that scalar value. This is probably not what you meant to do. See grep in *perlfunc* and map in *perlfunc* for alternatives.

Args must match #! line

(F) The setuid emulator requires that the arguments Perl was invoked with match the arguments specified on the #! line. Since some systems impose a one-argument limit on the #! line, try combining switches; for example, turn `-w -U` into `-wU`.

Arg too short for msgsnd

(F) msgsnd() requires a string at least as long as sizeof(long).

%s argument is not a HASH or ARRAY element

(F) The argument to exists() must be a hash or array element, such as:

```
$foo{$bar}
$ref->{"susie"}[12]
```

%s argument is not a HASH or ARRAY element or slice

(F) The argument to delete() must be either a hash or array element, such as:

```
$foo{$bar}
$ref->{"susie"}[12]
```

or a hash or array slice, such as:

```
@foo[$bar, $baz, $xyzzy]
@{$ref->[12]}{"susie", "queue"}
```

%s argument is not a subroutine name

(F) The argument to exists() for `exists &sub` must be a subroutine name, and not a subroutine call. `exists &sub()` will generate this error.

Argument "%s" isn't numeric%s

(W numeric) The indicated string was fed as an argument to an operator that expected a numeric value instead. If you're fortunate the message will identify which operator was so unfortunate.

Argument list not closed for PerlIO layer "%s"

(W layer) When pushing a layer with arguments onto the Perl I/O system you forgot the) that closes the argument list. (Layers take care of transforming data between external and internal representations.) Perl stopped parsing the layer list at this point and did not attempt to push this layer. If your program didn't explicitly request the failing operation, it may be the result of the value of the environment variable PERLIO.

Array @%s missing the @ in argument %d of %s()

(D deprecated) Really old Perl let you omit the @ on array names in some spots. This is now heavily deprecated.

assertion botched: %s

(P) The malloc package that comes with Perl had an internal failure.

Assertion failed: file "%s"

(P) A general assertion failed. The file in question must be examined.

Assignment to both a list and a scalar

(F) If you assign to a conditional operator, the 2nd and 3rd arguments must either both be scalars or both be lists. Otherwise Perl won't know which context to supply to the right side.

A thread exited while %d threads were running

(W) When using threaded Perl, a thread (not necessarily the main thread) exited while there were still other threads running. Usually it's a good idea to first collect the return values of the created threads by joining them, and only then exit from the main thread. See *threads*.

Attempt to access disallowed key '%s' in a restricted hash

(F) The failing code has attempted to get or set a key which is not in the current set of allowed keys of a restricted hash.

Attempt to bless into a reference

(F) The CLASSNAME argument to the bless() operator is expected to be the name of the package to bless the resulting object into. You've supplied instead a reference to something: perhaps you wrote

```
bless $self, $proto;
```

when you intended

```
    bless $self, ref($proto) || $proto;
```

If you actually want to bless into the stringified version of the reference supplied, you need to stringify it yourself, for example by:

```
    bless $self, "$proto";
```

Attempt to delete disallowed key '%s' from a restricted hash

(F) The failing code attempted to delete from a restricted hash a key which is not in its key set.

Attempt to delete readonly key '%s' from a restricted hash

(F) The failing code attempted to delete a key whose value has been declared readonly from a restricted hash.

Attempt to free non-arena SV: 0x%lx

(P internal) All SV objects are supposed to be allocated from arenas that will be garbage collected on exit. An SV was discovered to be outside any of those arenas.

Attempt to free nonexistent shared string

(P internal) Perl maintains a reference counted internal table of strings to optimize the storage and access of hash keys and other strings. This indicates someone tried to decrement the reference count of a string that can no longer be found in the table.

Attempt to free temp prematurely

(W debugging) Mortalized values are supposed to be freed by the free_tmps() routine. This indicates that something else is freeing the SV before the free_tmps() routine gets a chance, which means that the free_tmps() routine will be freeing an unreferenced scalar when it does try to free it.

Attempt to free unreferenced glob pointers

(P internal) The reference counts got screwed up on symbol aliases.

Attempt to free unreferenced scalar

(W internal) Perl went to decrement the reference count of a scalar to see if it would go to 0, and discovered that it had already gone to 0 earlier, and should have been freed, and in fact, probably was freed. This could indicate that SvREFCNT_dec() was called too many times, or that SvREFCNT_inc() was called too few times, or that the SV was mortalized when it shouldn't have been, or that memory has been corrupted.

Attempt to join self

(F) You tried to join a thread from within itself, which is an impossible task. You may be joining the wrong thread, or you may need to move the join() to some other thread.

Attempt to pack pointer to temporary value

(W pack) You tried to pass a temporary value (like the result of a function, or a computed expression) to the "p" pack() template. This means the result contains a pointer to a location that could become invalid anytime, even before the end of the current statement. Use literals or global values as arguments to the "p" pack() template to avoid this warning.

Attempt to use reference as lvalue in substr

(W substr) You supplied a reference as the first argument to substr() used as an lvalue, which is pretty strange. Perhaps you forgot to dereference it first. See substr in *perlfunc*.

Bad arg length for %s, is %d, should be %s

(F) You passed a buffer of the wrong size to one of msgctl(), semctl() or shmctl(). In C parlance, the correct sizes are, respectively, sizeof(struct msqid_ds *), sizeof(struct semid_ds *), and sizeof(struct shmid_ds *).

Bad evalled substitution pattern

(F) You've used the `/e` switch to evaluate the replacement for a substitution, but perl found a syntax error in the code to evaluate, most likely an unexpected right brace '}'.

Bad filehandle: %s

(F) A symbol was passed to something wanting a filehandle, but the symbol has no filehandle associated with it. Perhaps you didn't do an open(), or did it in another package.

Bad free() ignored

(S malloc) An internal routine called free() on something that had never been malloc()ed in the first place. Mandatory, but can be disabled by setting environment variable `PERL_BADFREE` to 0.

This message can be seen quite often with DB_File on systems with "hard" dynamic linking, like `AIX` and `OS/2`. It is a bug of `Berkeley DB` which is left unnoticed if `DB` uses *forgiving* system malloc().

Bad hash

(P) One of the internal hash routines was passed a null HV pointer.

Bad index while coercing array into hash

(F) The index looked up in the hash found as the 0'th element of a pseudo-hash is not legal. Index values must be at 1 or greater. See *perlref*.

Badly placed ()'s

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

Bad name after %s::

(F) You started to name a symbol by using a package prefix, and then didn't finish the symbol. In particular, you can't interpolate outside of quotes, so

```
    $var = 'myvar';
    $sym = mypack::$var;
```

is not the same as

```
    $var = 'myvar';
    $sym = "mypack::$var";
```

Bad realloc() ignored

(S malloc) An internal routine called realloc() on something that had never been malloc()ed in the first place. Mandatory, but can be disabled by setting environment variable `PERL_BADFREE` to 1.

Bad symbol for array

(P) An internal request asked to add an array entry to something that wasn't a symbol table entry.

Bad symbol for filehandle

(P) An internal request asked to add a filehandle entry to something that wasn't a symbol table entry.

Bad symbol for hash

(P) An internal request asked to add a hash entry to something that wasn't a symbol table entry.

Bareword found in conditional

(W bareword) The compiler found a bareword where it expected a conditional, which often indicates that an || or && was parsed as part of the last argument of the previous construct, for example:

```
    open FOO || die;
```

It may also indicate a misspelled constant that has been interpreted as a bareword:

```
use constant TYPO => 1;
if (TYOP) { print "foo" }
```

The `strict` pragma is useful in avoiding such errors.

Bareword "%s" not allowed while "strict subs" in use

(F) With "strict subs" in use, a bareword is only allowed as a subroutine identifier, in curly brackets or to the left of the "=>" symbol. Perhaps you need to predeclare a subroutine?

Bareword "%s" refers to nonexistent package

(W bareword) You used a qualified bareword of the form `Foo::`, but the compiler saw no other uses of that namespace before that point. Perhaps you need to predeclare a package?

BEGIN failed–compilation aborted

(F) An untrapped exception was raised while executing a BEGIN subroutine. Compilation stops immediately and the interpreter is exited.

BEGIN not safe after errors–compilation aborted

(F) Perl found a `BEGIN {}` subroutine (or a `use` directive, which implies a `BEGIN {}`) after one or more compilation errors had already occurred. Since the intended environment for the `BEGIN {}` could not be guaranteed (due to the errors), and since subsequent code likely depends on its correct operation, Perl just gave up.

\1 better written as $ 1

(W syntax) Outside of patterns, backreferences live on as variables. The use of backslashes is grandfathered on the right-hand side of a substitution, but stylistically it's better to use the variable form because other Perl programmers will expect it, and it works better if there are more than 9 backreferences.

Binary number > 0b11111111111111111111111111111111 non-portable

(W portable) The binary number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

bind() on closed socket %s

(W closed) You tried to do a bind on a closed socket. Did you forget to check the return value of your socket() call? See bind in *perlfunc*.

binmode() on closed filehandle %s

(W unopened) You tried binmode() on a filehandle that was never opened. Check you control flow and number of arguments.

Bit vector size > 32 non-portable

(W portable) Using bit vector sizes larger than 32 is non-portable.

Bizarre copy of %s in %s

(P) Perl detected an attempt to copy an internal value that is not copyable.

Buffer overflow in prime_env_iter: %s

(W internal) A warning peculiar to VMS. While Perl was preparing to iterate over %ENV, it encountered a logical name or symbol definition which was too long, so it was truncated to the string shown.

Callback called exit

(F) A subroutine invoked from an external package via call_sv() exited by calling exit.

%s() called too early to check prototype

(W prototype) You've called a function that has a prototype before the parser saw a definition or declaration for it, and Perl could not check that the call conforms to the prototype. You need to either add an early prototype declaration for the subroutine in question, or move the subroutine definition ahead of the call to get proper prototype checking. Alternatively, if you are certain that you're calling the function correctly, you may put an ampersand before the name to avoid the warning. See *perlsub*.

Cannot compress integer in pack

(F) An argument to pack("w",...) was too large to compress. The BER compressed integer format can only be used with positive integers, and you attempted to compress Infinity or a very large number (> 1e308). See pack in *perlfunc*.

Cannot compress negative numbers in pack

(F) An argument to pack("w",...) was negative. The BER compressed integer format can only be used with positive integers. See pack in *perlfunc*.

Can only compress unsigned integers in pack

(F) An argument to pack("w",...) was not an integer. The BER compressed integer format can only be used with positive integers, and you attempted to compress something else. See pack in *perlfunc*.

Can't bless non-reference value

(F) Only hard references may be blessed. This is how Perl "enforces" encapsulation of objects. See *perlobj*.

Can't call method "%s" in empty package "%s"

(F) You called a method correctly, and it correctly indicated a package functioning as a class, but that package doesn't have ANYTHING defined in it, let alone methods. See *perlobj*.

Can't call method "%s" on an undefined value

(F) You used the syntax of a method call, but the slot filled by the object reference or package name contains an undefined value. Something like this will reproduce the error:

```
$BADREF = undef;
process $BADREF 1,2,3;
$BADREF->process(1,2,3);
```

Can't call method "%s" on unblessed reference

(F) A method call must know in what package it's supposed to run. It ordinarily finds this out from the object reference you supply, but you didn't supply an object reference in this case. A reference isn't an object reference until it has been blessed. See *perlobj*.

Can't call method "%s" without a package or object reference

(F) You used the syntax of a method call, but the slot filled by the object reference or package name contains an expression that returns a defined value which is neither an object reference nor a package name. Something like this will reproduce the error:

```
$BADREF = 42;
process $BADREF 1,2,3;
$BADREF->process(1,2,3);
```

Can't chdir to %s

(F) You called `perl -x/foo/bar`, but `/foo/bar` is not a directory that you can chdir to, possibly because it doesn't exist.

Can't check filesystem of script "%s" for nosuid

(P) For some reason you can't check the filesystem of the script for nosuid.

Can't coerce array into hash

(F) You used an array where a hash was expected, but the array has no information on how to map from keys to array indices. You can do that only with arrays that have a hash reference at index 0.

Can't coerce %s to integer in %s

(F) Certain types of SVs, in particular real symbol table entries (typeglobs), can't be forced to stop being what they are. So you can't say things like:

```
    *foo += 1;
```

You CAN say

```
    $foo = *foo;
    $foo += 1;
```

but then $foo no longer contains a glob.

Can't coerce %s to number in %s

(F) Certain types of SVs, in particular real symbol table entries (typeglobs), can't be forced to stop being what they are.

Can't coerce %s to string in %s

(F) Certain types of SVs, in particular real symbol table entries (typeglobs), can't be forced to stop being what they are.

Can't create pipe mailbox

(P) An error peculiar to VMS. The process is suffering from exhausted quotas or other plumbing problems.

Can't declare class for non-scalar %s in "%s"

(F) Currently, only scalar variables can be declared with a specific class qualifier in a "my" or "our" declaration. The semantics may be extended for other types of variables in future.

Can't declare %s in "%s"

(F) Only scalar, array, and hash variables may be declared as "my" or "our" variables. They must have ordinary identifiers as names.

Can't do inplace edit: %s is not a regular file

(S inplace) You tried to use the **-i** switch on a special file, such as a file in /dev, or a FIFO. The file was ignored.

Can't do inplace edit on %s: %s

(S inplace) The creation of the new file failed for the indicated reason.

Can't do inplace edit without backup

(F) You're on a system such as MS-DOS that gets confused if you try reading from a deleted (but still opened) file. You have to say `-i.bak`, or some such.

Can't do inplace edit: %s would not be unique

(S inplace) Your filesystem does not support filenames longer than 14 characters and Perl was unable to create a unique filename during inplace editing with the **-i** switch. The file was ignored.

Can't do {n,m} with n > m in regex; marked by <– HERE in m/%s/

(F) Minima must be less than or equal to maxima. If you really want your regexp to match something 0 times, just put `{0}`. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Can't do setegid!

(P) The setegid() call failed for some reason in the setuid emulator of suidperl.

Can't do seteuid!

(P) The setuid emulator of suidperl failed for some reason.

Can't do setuid

(F) This typically means that ordinary perl tried to exec suidperl to do setuid emulation, but couldn't exec it. It looks for a name of the form sperl5.000 in the same directory that the perl executable resides under the name perl5.000, typically /usr/local/bin on Unix machines. If the file is there, check the execute permissions. If it isn't, ask your sysadmin why he and/or she removed it.

Can’t do waitpid with flags

(F) This machine doesn’t have either waitpid() or wait4(), so only waitpid() without flags is emulated.

Can’t emulate -%s on #! line

(F) The #! line specifies a switch that doesn’t make sense at this point. For example, it’d be kind of silly to put a **-x** on the #! line.

Can’t exec "%s": %s

(W exec) A system(), exec(), or piped open call could not execute the named program for the indicated reason. Typical reasons include: the permissions were wrong on the file, the file wasn’t found in `$ENV{PATH}`, the executable in question was compiled for another architecture, or the #! line in a script points to an interpreter that can’t be run for similar reasons. (Or maybe your system doesn’t support #! at all.)

Can’t exec %s

(F) Perl was trying to execute the indicated program for you because that’s what the #! line said. If that’s not what you wanted, you may need to mention "perl" on the #! line somewhere.

Can’t execute %s

(F) You used the **-S** switch, but the copies of the script to execute found in the PATH did not have correct permissions.

Can’t find an opnumber for "%s"

(F) A string of a form `CORE::word` was given to prototype(), but there is no builtin with the name `word`.

Can’t find %s character property "%s"

(F) You used `\p{}` or `\P{}` but the character property by that name could not be found. Maybe you misspelled the name of the property (remember that the names of character properties consist only of alphanumeric characters), or maybe you forgot the `Is` or `In` prefix?

Can’t find label %s

(F) You said to goto a label that isn’t mentioned anywhere that it’s possible for us to go to. See goto in *perlfunc*.

Can’t find %s on PATH

(F) You used the **-S** switch, but the script to execute could not be found in the PATH.

Can’t find %s on PATH, ’.’ not in PATH

(F) You used the **-S** switch, but the script to execute could not be found in the PATH, or at least not with the correct permissions. The script exists in the current directory, but PATH prohibits running it.

Can’t find %s property definition %s

(F) You may have tried to use `\p` which means a Unicode property (for example `\p{Lu}` is all uppercase letters). If you did mean to use a Unicode property, see *perlunicode* for the list of known properties. If you didn’t mean to use a Unicode property, escape the `\p`, either by `\\p` (just the `\p`) or by `\Q\p` (the rest of the string, until possible `\E`).

Can’t find string terminator %s anywhere before EOF

(F) Perl strings can stretch over multiple lines. This message means that the closing delimiter was omitted. Because bracketed quotes count nesting levels, the following is missing its final parenthesis:

```
    print q(The character ’(’ starts a side comment.);
```

If you’re getting this error from a here-document, you may have included unseen whitespace before or after your closing tag. A good programmer’s editor will have a way to help you find these characters.

Can’t fork

(F) A fatal error occurred while trying to fork while opening a pipeline.

Can't get filespec - stale stat buffer?

(S) A warning peculiar to VMS. This arises because of the difference between access checks under VMS and under the Unix model Perl assumes. Under VMS, access checks are done by filename, rather than by bits in the stat buffer, so that ACLs and other protections can be taken into account. Unfortunately, Perl assumes that the stat buffer contains all the necessary information, and passes it, instead of the filespec, to the access checking routine. It will try to retrieve the filespec using the device name and FID present in the stat buffer, but this works only if you haven't made a subsequent call to the CRTL stat() routine, because the device name is overwritten with each call. If this warning appears, the name lookup failed, and the access checking routine gave up and returned FALSE, just to be conservative. (Note: The access checking routine knows about the Perl `stat` operator and file tests, so you shouldn't ever see this warning in response to a Perl command; it arises only if some internal code takes stat buffers lightly.)

Can't get pipe mailbox device name

(P) An error peculiar to VMS. After creating a mailbox to act as a pipe, Perl can't retrieve its name for later use.

Can't get SYSGEN parameter value for MAXBUF

(P) An error peculiar to VMS. Perl asked $GETSYI how big you want your mailbox buffers to be, and didn't get an answer.

Can't "goto" into the middle of a foreach loop

(F) A "goto" statement was executed to jump into the middle of a foreach loop. You can't get there from here. See goto in *perlfunc*.

Can't "goto" out of a pseudo block

(F) A "goto" statement was executed to jump out of what might look like a block, except that it isn't a proper block. This usually occurs if you tried to jump out of a sort() block or subroutine, which is a no-no. See goto in *perlfunc*.

Can't goto subroutine from an eval-string

(F) The "goto subroutine" call can't be used to jump out of an eval "string". (You can use it to jump out of an eval {BLOCK}, but you probably don't want to.)

Can't goto subroutine outside a subroutine

(F) The deeply magical "goto subroutine" call can only replace one subroutine call for another. It can't manufacture one out of whole cloth. In general you should be calling it out of only an AUTOLOAD routine anyway. See goto in *perlfunc*.

Can't ignore signal CHLD, forcing to default

(W signal) Perl has detected that it is being run with the SIGCHLD signal (sometimes known as SIGCLD) disabled. Since disabling this signal will interfere with proper determination of exit status of child processes, Perl has reset the signal to its default value. This situation typically indicates that the parent program under which Perl may be running (e.g. cron) is being very careless.

Can't "last" outside a loop block

(F) A "last" statement was executed to break out of the current block, except that there's this itty bitty problem called there isn't a current block. Note that an "if" or "else" block doesn't count as a "loopish" block, as doesn't a block given to sort(), map() or grep(). You can usually double the curlies to get the same effect though, because the inner curlies will be considered a block that loops once. See last in *perlfunc*.

Can't localize lexical variable %s

(F) You used local on a variable name that was previously declared as a lexical variable using "my". This is not allowed. If you want to localize a package variable of the same name, qualify it with the package name.

Can't localize pseudo-hash element

(F) You said something like `local $ar->{'key'}`, where $ar is a reference to a pseudo-hash. That hasn't been implemented yet, but you can get a similar effect by localizing the corresponding array element directly – `local $ar->[$ar->[0]{'key'}]`.

Can't localize through a reference

(F) You said something like `local $$ref`, which Perl can't currently handle, because when it goes to restore the old value of whatever $ref pointed to after the scope of the local() is finished, it can't be sure that $ref will still be a reference.

Can't locate %s

(F) You said to `do` (or `require`, or `use`) a file that couldn't be found. Perl looks for the file in all the locations mentioned in @INC, unless the file name included the full path to the file. Perhaps you need to set the PERL5LIB or PERL5OPT environment variable to say where the extra library is, or maybe the script needs to add the library name to @INC. Or maybe you just misspelled the name of the file. See require in *perlfunc* and *lib*.

Can't locate auto/%s.al in @INC

(F) A function (or method) was called in a package which allows autoload, but there is no function to autoload. Most probable causes are a misprint in a function/method name or a failure to `AutoSplit` the file, say, by doing `make install`.

Can't locate object method "%s" via package "%s"

(F) You called a method correctly, and it correctly indicated a package functioning as a class, but that package doesn't define that particular method, nor does any of its base classes. See *perlobj*.

Can't locate package %s for @%s::ISA

(W syntax) The @ISA array contained the name of another package that doesn't seem to exist.

Can't locate PerlIO%s

(F) You tried to use in open() a PerlIO layer that does not exist, e.g. open(FH, ">:nosuchlayer", "somefile").

Can't make list assignment to \%ENV on this system

(F) List assignment to %ENV is not supported on some systems, notably VMS.

Can't modify %s in %s

(F) You aren't allowed to assign to the item indicated, or otherwise try to change it, such as with an auto-increment.

Can't modify nonexistent substring

(P) The internal routine that does assignment to a substr() was handed a NULL.

Can't modify non-lvalue subroutine call

(F) Subroutines meant to be used in lvalue context should be declared as such, see Lvalue subroutines in *perlsub*.

Can't msgrcv to read-only var

(F) The target of a msgrcv must be modifiable to be used as a receive buffer.

Can't "next" outside a loop block

(F) A "next" statement was executed to reiterate the current block, but there isn't a current block. Note that an "if" or "else" block doesn't count as a "loopish" block, as doesn't a block given to sort(), map() or grep(). You can usually double the curlies to get the same effect though, because the inner curlies will be considered a block that loops once. See next in *perlfunc*.

Can't open %s: %s

(S inplace) The implicit opening of a file through use of the <> filehandle, either implicitly under the `-n` or `-p` command-line switches, or explicitly, failed for the indicated reason. Usually this is because you don't have read permission for a file which you named on the command line.

Can't open a reference

(W io) You tried to open a scalar reference for reading or writing, using the 3-arg open() syntax :

```
    open FH, '>', $ref;
```

but your version of perl is compiled without perlio, and this form of open is not supported.

Can't open bidirectional pipe

(W pipe) You tried to say `open(CMD, "|cmd|")`, which is not supported. You can try any of several modules in the Perl library to do this, such as IPC::Open2. Alternately, direct the pipe's output to a file using ">", and then read it in under a different file handle.

Can't open error file %s as stderr

(F) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the file specified after '2>' or '2>>' on the command line for writing.

Can't open input file %s as stdin

(F) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the file specified after '<' on the command line for reading.

Can't open output file %s as stdout

(F) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the file specified after '>' or '>>' on the command line for writing.

Can't open output pipe (name: %s)

(P) An error peculiar to VMS. Perl does its own command line redirection, and couldn't open the pipe into which to send data destined for stdout.

Can't open perl script%s

(F) The script you specified can't be opened for the indicated reason.

Can't read CRTL environ

(S) A warning peculiar to VMS. Perl tried to read an element of %ENV from the CRTL's internal environment array and discovered the array was missing. You need to figure out where your CRTL misplaced its environ or define *PERL_ENV_TABLES* (see *perlvms*) so that environ is not searched.

Can't redefine active sort subroutine %s

(F) Perl optimizes the internal handling of sort subroutines and keeps pointers into them. You tried to redefine one such sort subroutine when it was currently active, which is not allowed. If you really want to do this, you should write `sort { &func } @x` instead of `sort func @x`.

Can't "redo" outside a loop block

(F) A "redo" statement was executed to restart the current block, but there isn't a current block. Note that an "if" or "else" block doesn't count as a "loopish" block, as doesn't a block given to sort(), map() or grep(). You can usually double the curlies to get the same effect though, because the inner curlies will be considered a block that loops once. See redo in *perlfunc*.

Can't remove %s: %s, skipping file

(S inplace) You requested an inplace edit without creating a backup file. Perl was unable to remove the original file to replace it with the modified file. The file was left unmodified.

Can't rename %s to %s: %s, skipping file

(S inplace) The rename done by the **-i** switch failed for some reason, probably because you don't have write permission to the directory.

Can't reopen input pipe (name: %s) in binary mode

(P) An error peculiar to VMS. Perl thought stdin was a pipe, and tried to reopen it to accept binary data. Alas, it failed.

Can't resolve method '%s' overloading '%s' in package '%s'

(F|P) Error resolving overloading specified by a method name (as opposed to a subroutine reference): no such method callable via the package. If method name is `???`, this is an internal error.

Can’t reswap uid and euid

(P) The setreuid() call failed for some reason in the setuid emulator of suidperl.

Can’t return %s from lvalue subroutine

(F) Perl detected an attempt to return illegal lvalues (such as temporary or readonly values) from a subroutine used as an lvalue. This is not allowed.

Can’t return outside a subroutine

(F) The return statement was executed in mainline code, that is, where there was no subroutine call to return out of. See *perlsub*.

Can’t return %s to lvalue scalar context

(F) You tried to return a complete array or hash from an lvalue subroutine, but you called the subroutine in a way that made Perl think you meant to return only one value. You probably meant to write parentheses around the call to the subroutine, which tell Perl that the call should be in list context.

Can’t stat script "%s"

(P) For some reason you can’t fstat() the script even though you have it open already. Bizarre.

Can’t swap uid and euid

(P) The setreuid() call failed for some reason in the setuid emulator of suidperl.

Can’t take log of %g

(F) For ordinary real numbers, you can’t take the logarithm of a negative number or zero. There’s a Math::Complex package that comes standard with Perl, though, if you really want to do that for the negative numbers.

Can’t take sqrt of %g

(F) For ordinary real numbers, you can’t take the square root of a negative number. There’s a Math::Complex package that comes standard with Perl, though, if you really want to do that.

Can’t undef active subroutine

(F) You can’t undefine a routine that’s currently running. You can, however, redefine it while it’s running, and you can even undef the redefined subroutine while the old routine is running. Go figure.

Can’t unshift

(F) You tried to unshift an "unreal" array that can’t be unshifted, such as the main Perl stack.

Can’t upgrade that kind of scalar

(P) The internal sv_upgrade routine adds "members" to an SV, making it into a more specialized kind of SV. The top several SV types are so specialized, however, that they cannot be interconverted. This message indicates that such a conversion was attempted.

Can’t upgrade to undef

(P) The undefined SV is the bottom of the totem pole, in the scheme of upgradability. Upgrading to undef indicates an error in the code calling sv_upgrade.

Can’t use anonymous symbol table for method lookup

(P) The internal routine that does method lookup was handed a symbol table that doesn’t have a name. Symbol tables can become anonymous for example by undefining stashes: `undef %Some::Package::`.

Can’t use an undefined value as %s reference

(F) A value used as either a hard reference or a symbolic reference must be a defined value. This helps to delurk some insidious errors.

Can’t use bareword ("%s") as %s ref while "strict refs" in use

(F) Only hard references are allowed by "strict refs". Symbolic references are disallowed. See *perlref*.

Can't use %! because Errno.pm is not available

(F) The first time the %! hash is used, perl automatically loads the Errno.pm module. The Errno module is expected to tie the %! hash to provide symbolic names for `$!` errno values.

Can't use %s for loop variable

(F) Only a simple scalar variable may be used as a loop variable on a foreach.

Can't use global %s in "my"

(F) You tried to declare a magical variable as a lexical variable. This is not allowed, because the magic can be tied to only one location (namely the global variable) and it would be incredibly confusing to have variables in your program that looked like magical variables but weren't.

Can't use "my %s" in sort comparison

(F) The global variables $a and $b are reserved for sort comparisons. You mentioned $a or $b in the same line as the <=> or cmp operator, and the variable had earlier been declared as a lexical variable. Either qualify the sort variable with the package name, or rename the lexical variable.

Can't use %s ref as %s ref

(F) You've mixed up your reference types. You have to dereference a reference of the type needed. You can use the ref() function to test the type of the reference, if need be.

Can't use string ("%s") as %s ref while "strict refs" in use

(F) Only hard references are allowed by "strict refs". Symbolic references are disallowed. See *perlref*.

Can't use subscript on %s

(F) The compiler tried to interpret a bracketed expression as a subscript. But to the left of the brackets was an expression that didn't look like an array reference, or anything else subscriptable.

Can't use \%c to mean $ %c in expression

(W syntax) In an ordinary expression, backslash is a unary operator that creates a reference to its argument. The use of backslash to indicate a backreference to a matched substring is valid only as part of a regular expression pattern. Trying to do this in ordinary Perl code produces a value that prints out looking like SCALAR(0xdecaf). Use the $1 form instead.

Can't weaken a nonreference

(F) You attempted to weaken something that was not a reference. Only references can be weakened.

Can't x= to read-only value

(F) You tried to repeat a constant value (often the undefined value) with an assignment operator, which implies modifying the value itself. Perhaps you need to copy the value to a temporary, and repeat that.

Character in "C" format wrapped in pack

(W pack) You said

```
    pack("C", $x)
```

where $x is either less than 0 or more than 255; the `"C"` format is only for encoding native operating system characters (ASCII, EBCDIC, and so on) and not for Unicode characters, so Perl behaved as if you meant

```
    pack("C", $x & 255)
```

If you actually want to pack Unicode codepoints, use the `"U"` format instead.

Character in "c" format wrapped in pack

(W pack) You said

```
    pack("c", $x)
```

where $x is either less than -128 or more than 127; the `"c"` format is only for encoding native operating system characters (ASCII, EBCDIC, and so on) and not for Unicode characters, so Perl behaved as if you meant

```
    pack("c", $x & 255);
```

If you actually want to pack Unicode codepoints, use the `"U"` format instead.

close() on unopened filehandle %s

(W unopened) You tried to close a filehandle that was never opened.

Code missing after '/'

(F) You had a (sub-)template that ends with a '/'. There must be another template code following the slash. See pack in *perlfunc*.

%s: Command not found

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

Compilation failed in require

(F) Perl could not compile a file specified in a `require` statement. Perl uses this generic message when none of the errors that it encountered were severe enough to halt compilation immediately.

Complex regular subexpression recursion limit (%d) exceeded

(W regexp) The regular expression engine uses recursion in complex situations where back-tracking is required. Recursion depth is limited to 32766, or perhaps less in architectures where the stack cannot grow arbitrarily. ("Simple" and "medium" situations are handled without recursion and are not subject to a limit.) Try shortening the string under examination; looping in Perl code (e.g. with `while`) rather than in the regular expression engine; or rewriting the regular expression so that it is simpler or backtracks less. (See *perlfaq2* for information on *Mastering Regular Expressions*.)

cond_broadcast() called on unlocked variable

(W threads) Within a thread-enabled program, you tried to call cond_broadcast() on a variable which wasn't locked. The cond_broadcast() function is used to wake up another thread that is waiting in a cond_wait(). To ensure that the signal isn't sent before the other thread has a chance to enter the wait, it is usual for the signaling thread to first wait for a lock on variable. This lock attempt will only succeed after the other thread has entered cond_wait() and thus relinquished the lock.

cond_signal() called on unlocked variable

(W threads) Within a thread-enabled program, you tried to call cond_signal() on a variable which wasn't locked. The cond_signal() function is used to wake up another thread that is waiting in a cond_wait(). To ensure that the signal isn't sent before the other thread has a chance to enter the wait, it is usual for the signaling thread to first wait for a lock on variable. This lock attempt will only succeed after the other thread has entered cond_wait() and thus relinquished the lock.

connect() on closed socket %s

(W closed) You tried to do a connect on a closed socket. Did you forget to check the return value of your socket() call? See connect in *perlfunc*.

Constant(%s)%s: %s

(F) The parser found inconsistencies either while attempting to define an overloaded constant, or when trying to find the character name specified in the `\N{...}` escape. Perhaps you forgot to load the corresponding `overload` or `charnames` pragma? See *charnames* and *overload*.

Constant is not %s reference

(F) A constant value (perhaps declared using the `use constant` pragma) is being dereferenced, but it amounts to the wrong type of reference. The message indicates the type of reference that was expected. This usually indicates a syntax error in dereferencing the constant value. See Constant Functions in *perlsub* and *constant*.

Constant subroutine %s redefined

(S) You redefined a subroutine which had previously been eligible for inlining. See Constant Functions in *perlsub* for commentary and workarounds.

Constant subroutine %s undefined

(W misc) You undefined a subroutine which had previously been eligible for inlining. See Constant Functions in *perlsub* for commentary and workarounds.

Copy method did not return a reference

(F) The method which overloads "=" is buggy. See Copy Constructor in *overload*.

CORE::%s is not a keyword

(F) The CORE:: namespace is reserved for Perl keywords.

corrupted regexp pointers

(P) The regular expression engine got confused by what the regular expression compiler gave it.

corrupted regexp program

(P) The regular expression engine got passed a regexp program without a valid magic number.

Corrupt malloc ptr 0x%lx at 0x%lx

(P) The malloc package that comes with Perl had an internal failure.

Count after length/code in unpack

(F) You had an unpack template indicating a counted-length string, but you have also specified an explicit size for the string. See pack in *perlfunc*.

Deep recursion on subroutine "%s"

(W recursion) This subroutine has called itself (directly or indirectly) 100 times more than it has returned. This probably indicates an infinite recursion, unless you're writing strange benchmark programs, in which case it indicates something else.

defined(@array) is deprecated

(D deprecated) defined() is not usually useful on arrays because it checks for an undefined *scalar* value. If you want to see if the array is empty, just use `if (@array) { # not empty }` for example.

defined(%hash) is deprecated

(D deprecated) defined() is not usually useful on hashes because it checks for an undefined *scalar* value. If you want to see if the hash is empty, just use `if (%hash) { # not empty }` for example.

%s defines neither package nor VERSION–version check failed

(F) You said something like "use Module 42" but in the Module file there are neither package declarations nor a `$VERSION`.

Delimiter for here document is too long

(F) In a here document construct like <<`FOO`, the label `FOO` is too long for Perl to handle. You have to be seriously twisted to write code that triggers this error.

DESTROY created new reference to dead object '%s'

(F) A DESTROY() method created a new reference to the object which is just being DESTROYed. Perl is confused, and prefers to abort rather than to create a dangling reference.

Did not produce a valid header

See Server error.

%s did not return a true value

(F) A required (or used) file must return a true value to indicate that it compiled correctly and ran its initialization code correctly. It's traditional to end such a file with a "1;", though any true value would do. See require in *perlfunc*.

(Did you mean &%s instead?)

(W) You probably referred to an imported subroutine &FOO as $FOO or some such.

(Did you mean "local" instead of "our"?)

(W misc) Remember that "our" does not localize the declared global variable. You have declared it again in the same lexical scope, which seems superfluous.

(Did you mean $ or @ instead of %?)

(W) You probably said %hash{$key} when you meant $hash{$key} or @hash{@keys}. On the other hand, maybe you just meant %hash and got carried away.

Died

(F) You passed die() an empty string (the equivalent of `die ""`) or you called it with no args and both `$@` and `$_` were empty.

Document contains no data

See Server error.

%s does not define %s::VERSION–version check failed

(F) You said something like "use Module 42" but the Module did not define a `$VERSION.`

'/' does not take a repeat count

(F) You cannot put a repeat count of any kind right after the '/' code. See pack in *perlfunc*.

Don't know how to handle magic of type '%s'

(P) The internal handling of magical variables has been cursed.

do_study: out of memory

(P) This should have been caught by safemalloc() instead.

(Do you need to predeclare %s?)

(S syntax) This is an educated guess made in conjunction with the message "%s found where operator expected". It often means a subroutine or module name is being referenced that hasn't been declared yet. This may be because of ordering problems in your file, or because of a missing "sub", "package", "require", or "use" statement. If you're referencing something that isn't defined yet, you don't actually have to define the subroutine or package before the current location. You can use an empty "sub foo;" or "package FOO;" to enter a "forward" declaration.

dump() better written as CORE::dump()

(W misc) You used the obsolescent `dump()` built-in function, without fully qualifying it as `CORE::dump()`. Maybe it's a typo. See dump in *perlfunc*.

Duplicate free() ignored

(S malloc) An internal routine called free() on something that had already been freed.

elseif should be elsif

(S syntax) There is no keyword "elseif" in Perl because Larry thinks it's ugly. Your code will be interpreted as an attempt to call a method named "elseif" for the class returned by the following block. This is unlikely to be what you want.

Empty %s

(F) `\p` and `\P` are used to introduce a named Unicode property, as described in *perlunicode* and *perlre*. You used `\p` or `\P` in a regular expression without specifying the property name.

entering effective %s failed

(F) While under the `use filetest` pragma, switching the real and effective uids or gids failed.

Error converting file specification %s

(F) An error peculiar to VMS. Because Perl may have to deal with file specifications in either VMS or Unix syntax, it converts them to a single form when it must operate on them directly. Either you've passed an invalid file specification to Perl, or you've found a case the conversion routines don't handle. Drat.

%s: Eval-group in insecure regular expression

(F) Perl detected tainted data when trying to compile a regular expression that contains the `(?{ ... })` zero-width assertion, which is unsafe. See (?{ code }) in *perlre*, and *perlsec*.

%s: Eval-group not allowed at run time

(F) Perl tried to compile a regular expression containing the `(?{ ... })` zero-width assertion at run time, as it would when the pattern contains interpolated values. Since that is a security risk, it is not allowed. If you insist, you may still do this by explicitly building the pattern from an interpolated string at run time and using that in an eval(). See (?{ code }) in *perlre*.

%s: Eval-group not allowed, use re 'eval'

(F) A regular expression contained the `(?{ ... })` zero-width assertion, but that construct is only allowed when the `use re 'eval'` pragma is in effect. See (?{ code }) in *perlre*.

Excessively long <> operator

(F) The contents of a <> operator may not exceed the maximum size of a Perl identifier. If you're just trying to glob a long list of filenames, try using the glob() operator, or put the filenames into a variable and glob that.

exec? I'm not *that* kind of operating system

(F) The `exec` function is not implemented in MacPerl. See *perlport*.

Execution of %s aborted due to compilation errors

(F) The final summary message when a Perl compilation fails.

Exiting eval via %s

(W exiting) You are exiting an eval by unconventional means, such as a goto, or a loop control statement.

Exiting format via %s

(W exiting) You are exiting a format by unconventional means, such as a goto, or a loop control statement.

Exiting pseudo-block via %s

(W exiting) You are exiting a rather special block construct (like a sort block or subroutine) by unconventional means, such as a goto, or a loop control statement. See sort in *perlfunc*.

Exiting subroutine via %s

(W exiting) You are exiting a subroutine by unconventional means, such as a goto, or a loop control statement.

Exiting substitution via %s

(W exiting) You are exiting a substitution by unconventional means, such as a return, a goto, or a loop control statement.

Explicit blessing to '' (assuming package main)

(W misc) You are blessing a reference to a zero length string. This has the effect of blessing the reference into the package main. This is usually not what you want. Consider providing a default target package, e.g. bless($ref, $p || 'MyPackage');

%s: Expression syntax

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

%s failed–call queue aborted

(F) An untrapped exception was raised while executing a CHECK, INIT, or END subroutine. Processing of the remainder of the queue of such routines has been prematurely ended.

False [range "%s" in regex; marked by] **<– HERE in m/%s/**

(W regexp) A character class range must start and end at a literal character, not another character class like `\d` or `[:alpha:]`. The "-" in your false range is interpreted as a literal "-". Consider quoting the "-", "\-". The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Fatal VMS error at %s, line %d

(P) An error peculiar to VMS. Something untoward happened in a VMS system service or RTL routine; Perl's exit status should provide more details. The filename in "at %s" and the line number in "line %d" tell you which section of the Perl source code is distressed.

fcntl is not implemented

(F) Your machine apparently doesn't implement fcntl(). What is this, a PDP-11 or something?

Filehandle %s opened only for input

(W io) You tried to write on a read-only filehandle. If you intended it to be a read-write filehandle, you needed to open it with "+<" or "+>" or "+>>" instead of with "<" or nothing. If you intended only to write the file, use ">" or ">>". See open in *perlfunc*.

Filehandle %s opened only for output

(W io) You tried to read from a filehandle opened only for writing, If you intended it to be a read/write filehandle, you needed to open it with "+<" or "+>" or "+>>" instead of with "<" or nothing. If you intended only to read from the file, use "<". See open in *perlfunc*. Another possibility is that you attempted to open filedescriptor 0 (also known as STDIN) for output (maybe you closed STDIN earlier?).

Filehandle %s reopened as %s only for input

(W io) You opened for reading a filehandle that got the same filehandle id as STDOUT or STDERR. This occured because you closed STDOUT or STDERR previously.

Filehandle STDIN reopened as %s only for output

(W io) You opened for writing a filehandle that got the same filehandle id as STDIN. This occured because you closed STDIN previously.

Final $ should be \$ or $ name

(F) You must now decide whether the final $ in a string was meant to be a literal dollar sign, or was meant to introduce a variable name that happens to be missing. So you have to put either the backslash or the name.

flock() on closed filehandle %s

(W closed) The filehandle you're attempting to flock() got itself closed some time before now. Check your control flow. flock() operates on filehandles. Are you attempting to call flock() on a dirhandle by the same name?

Format not terminated

(F) A format must be terminated by a line with a solitary dot. Perl got to the end of your file without finding such a line.

Format %s redefined

(W redefine) You redefined a format. To suppress this warning, say

```
        {
            no warnings 'redefine';
            eval "format NAME =...";
        }
```

Found = in conditional, should be ==

(W syntax) You said

```
    if ($foo = 123)
```

when you meant

```
    if ($foo == 123)
```

(or something like that).

%s found where operator expected

(S syntax) The Perl lexer knows whether to expect a term or an operator. If it sees what it knows to be a term when it was expecting to see an operator, it gives you this warning. Usually it indicates that an operator or delimiter was omitted, such as a semicolon.

gdbm store returned %d, errno %d, key "%s"

(S) A warning from the GDBM_File extension that a store failed.

gethostent not implemented

(F) Your C library apparently doesn't implement gethostent(), probably because if it did, it'd feel morally obligated to return every hostname on the Internet.

get%sname() on closed socket %s

(W closed) You tried to get a socket or peer socket name on a closed socket. Did you forget to check the return value of your socket() call?

getpwnam returned invalid UIC %#o for user "%s"

(S) A warning peculiar to VMS. The call to `sys$getuai` underlying the `getpwnam` operator returned an invalid UIC.

getsockopt() on closed socket %s

(W closed) You tried to get a socket option on a closed socket. Did you forget to check the return value of your socket() call? See getsockopt in *perlfunc*.

Global symbol "%s" requires explicit package name

(F) You've said "use strict vars", which indicates that all variables must either be lexically scoped (using "my"), declared beforehand using "our", or explicitly qualified to say which package the global variable is in (using "::").

glob failed (%s)

(W glob) Something went wrong with the external program(s) used for `glob` and `<*.c>`. Usually, this means that you supplied a `glob` pattern that caused the external program to fail and exit with a nonzero status. If the message indicates that the abnormal exit resulted in a coredump, this may also mean that your csh (C shell) is broken. If so, you should change all of the csh-related variables in config.sh: If you have tcsh, make the variables refer to it as if it were csh (e.g. `full_csh='/usr/bin/tcsh'`); otherwise, make them all empty (except that `d_csh` should be `'undef'`) so that Perl will think csh is missing. In either case, after editing config.sh, run `./Configure -S` and rebuild Perl.

Glob not terminated

(F) The lexer saw a left angle bracket in a place where it was expecting a term, so it's looking for the corresponding right angle bracket, and not finding it. Chances are you left some needed parentheses out earlier in the line, and you really meant a "less than".

Got an error from DosAllocMem

(P) An error peculiar to OS/2. Most probably you're using an obsolete version of Perl, and this should not happen anyway.

goto must have label

(F) Unlike with "next" or "last", you're not allowed to goto an unspecified destination. See `goto` in *perlfunc*.

()-group starts with a count

(F) A ()-group started with a count. A count is supposed to follow something: a template character or a ()-group. See `pack` in *perlfunc*.

%s had compilation errors

(F) The final summary message when a `perl -c` fails.

Had to create %s unexpectedly

(S internal) A routine asked for a symbol from a symbol table that ought to have existed already, but for some reason it didn't, and had to be created on an emergency basis to prevent a core dump.

Hash %%s missing the % in argument %d of %s()

(D deprecated) Really old Perl let you omit the % on hash names in some spots. This is now heavily deprecated.

%s has too many errors

(F) The parser has given up trying to parse the program after 10 errors. Further error messages would likely be uninformative.

Hexadecimal number > 0xffffffff non-portable

(W portable) The hexadecimal number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

Identifier too long

(F) Perl limits identifiers (names for variables, functions, etc.) to about 250 characters for simple names, and somewhat more for compound names (like `$A::B`). You've exceeded Perl's limits. Future versions of Perl are likely to eliminate these arbitrary limitations.

Illegal binary digit %s

(F) You used a digit other than 0 or 1 in a binary number.

Illegal binary digit %s ignored

(W digit) You may have tried to use a digit other than 0 or 1 in a binary number. Interpretation of the binary number stopped before the offending digit.

Illegal character %s (carriage return)

(F) Perl normally treats carriage returns in the program text as it would any other whitespace, which means you should never see this error when Perl was built using standard options. For some reason, your version of Perl appears to have been built without this support. Talk to your Perl administrator.

Illegal character in prototype for %s : %s

(W syntax) An illegal character was found in a prototype declaration. Legal characters in prototypes are $, @, %, *, ;, [,], &, and \.

Illegal declaration of anonymous subroutine

(F) When using the `sub` keyword to construct an anonymous subroutine, you must always specify a block of code. See *perlsub*.

Illegal declaration of subroutine %s

(F) A subroutine was not declared correctly. See *perlsub*.

Illegal division by zero

(F) You tried to divide a number by 0. Either something was wrong in your logic, or you need to put a conditional in to guard against meaningless input.

Illegal hexadecimal digit %s ignored

(W digit) You may have tried to use a character other than 0 - 9 or A - F, a - f in a hexadecimal number. Interpretation of the hexadecimal number stopped before the illegal character.

Illegal modulus zero

(F) You tried to divide a number by 0 to get the remainder. Most numbers don't take to this kindly.

Illegal number of bits in vec

(F) The number of bits in vec() (the third argument) must be a power of two from 1 to 32 (or 64, if your platform supports that).

Illegal octal digit %s

(F) You used an 8 or 9 in an octal number.

Illegal octal digit %s ignored

(W digit) You may have tried to use an 8 or 9 in an octal number. Interpretation of the octal number stopped before the 8 or 9.

Illegal switch in PERL5OPT: %s

(X) The PERL5OPT environment variable may only be used to set the following switches: **-[DIMUdmtw]**.

Ill-formed CRTL environ value "%s"

(W internal) A warning peculiar to VMS. Perl tried to read the CRTL's internal environ array, and encountered an element without the = delimiter used to separate keys from values. The element is ignored.

Ill-formed message in prime_env_iter: |%s|

(W internal) A warning peculiar to VMS. Perl tried to read a logical name or CLI symbol definition when preparing to iterate over %ENV, and didn't see the expected delimiter between key and value, so the line was ignored.

(in cleanup) %s

(W misc) This prefix usually indicates that a DESTROY() method raised the indicated exception. Since destructors are usually called by the system at arbitrary points during execution, and often a vast number of times, the warning is issued only once for any number of failures that would otherwise result in the same message being repeated.

Failure of user callbacks dispatched using the `G_KEEPERR` flag could also result in this warning. See G_KEEPERR in *perlcall*.

In EBCDIC the v-string components cannot exceed 2147483647

(F) An error peculiar to EBCDIC. Internally, v-strings are stored as Unicode code points, and encoded in EBCDIC as UTF-EBCDIC. The UTF-EBCDIC encoding is limited to code points no larger than 2147483647 (0x7FFFFFFF).

Insecure dependency in %s

(F) You tried to do something that the tainting mechanism didn't like. The tainting mechanism is turned on when you're running setuid or setgid, or when you specify **-T** to turn it on explicitly. The tainting mechanism labels all data that's derived directly or indirectly from the user, who is considered to be unworthy of your trust. If any such data is used in a "dangerous" operation, you get this error. See *perlsec* for more information.

Insecure directory in %s

(F) You can't use system(), exec(), or a piped open in a setuid or setgid script if `$ENV{PATH}` contains a directory that is writable by the world. See *perlsec*.

Insecure $ ENV{%s} while running %s

(F) You can't use system(), exec(), or a piped open in a setuid or setgid script if any of `$ENV{PATH}`, `$ENV{IFS}`, `$ENV{CDPATH}`, `$ENV{ENV}`, `$ENV{BASH_ENV}` or `$ENV{TERM}` are derived from data supplied (or potentially supplied) by the user. The script must set the path to a known value, using trustworthy data. See *perlsec*.

Integer overflow in %s number

(W overflow) The hexadecimal, octal or binary number you have specified either as a literal or as an argument to hex() or oct() is too big for your architecture, and has been converted to a floating point number. On a 32-bit architecture the largest hexadecimal, octal or binary number representable without overflow is 0xFFFFFFFF, 037777777777, or 0b11111111111111111111111111111111 respectively. Note that Perl transparently promotes all numbers to a floating point representation internally–subject to loss of precision errors in subsequent operations.

Internal disaster in regex; marked by <– HERE in m/%s/

(P) Something went badly wrong in the regular expression parser. The <– HERE shows in the regular expression about where the problem was discovered.

Internal inconsistency in tracking vforks

(S) A warning peculiar to VMS. Perl keeps track of the number of times you've called `fork` and `exec`, to determine whether the current call to `exec` should affect the current script or a subprocess (see exec LIST in *perlvms*). Somehow, this count has become scrambled, so Perl is making a guess and treating this `exec` as a request to terminate the Perl script and execute the specified command.

Internal urp in regex; marked by <– HERE in m/%s/

(P) Something went badly awry in the regular expression parser. The <– HERE shows in the regular expression about where the problem was discovered.

%s (...) interpreted as function

(W syntax) You've run afoul of the rule that says that any list operator followed by parentheses turns into a function, with all the list operators arguments found inside the parentheses. See Terms and List Operators (Leftward) in *perlop*.

Invalid %s attribute: %s

The indicated attribute for a subroutine or variable was not recognized by Perl or by a user-supplied handler. See *attributes*.

Invalid %s attributes: %s

The indicated attributes for a subroutine or variable were not recognized by Perl or by a user-supplied handler. See *attributes*.

Invalid conversion in %s: "%s"

(W printf) Perl does not understand the given format conversion. See sprintf in *perlfunc*.

Invalid [range "%s" in regex; marked] **by <– HERE in m/%s/**

(F) The range specified in a character class had a minimum character greater than the maximum character. One possibility is that you forgot the `{}` from your ending `\x{}` - `\x` without the curly braces can go only up to `ff`. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Invalid range "%s" in transliteration operator

(F) The range specified in the tr/// or y/// operator had a minimum character greater than the maximum character. See *perlop*.

Invalid separator character %s in attribute list

(F) Something other than a colon or whitespace was seen between the elements of an attribute list. If the previous attribute had a parenthesised parameter list, perhaps that list was terminated too soon. See *attributes*.

Invalid separator character %s in PerlIO layer specification %s

(W layer) When pushing layers onto the Perl I/O system, something other than a colon or whitespace was seen between the elements of a layer list. If the previous attribute had a parenthesised parameter list, perhaps that list was terminated too soon.

Invalid type '%s' in %s

(F) The given character is not a valid pack or unpack type. See pack in *perlfunc*. (W) The given character is not a valid pack or unpack type but used to be silently ignored.

ioctl is not implemented

(F) Your machine apparently doesn't implement ioctl(), which is pretty strange for a machine that supports C.

ioctl() on unopened %s

(W unopened) You tried ioctl() on a filehandle that was never opened. Check you control flow and number of arguments.

IO layers (like "%s") unavailable

(F) Your Perl has not been configured to have PerlIO, and therefore you cannot use IO layers. To have PerlIO Perl must be configured with 'useperlio'.

IO::Socket::atmark not implemented on this architecture

(F) Your machine doesn't implement the sockatmark() functionality, neither as a system call or an ioctl call (SIOCATMARK).

'%s' is not a code reference

(W overload) The second (fourth, sixth, ...) argument of overload::constant needs to be a code reference. Either an anonymous subroutine, or a reference to a subroutine.

'%s' is not an overloadable type

(W overload) You tried to overload a constant type the overload package is unaware of.

junk on end of regexp

(P) The regular expression parser is confused.

Label not found for "last %s"

(F) You named a loop to break out of, but you're not currently in a loop of that name, not even if you count where you were called from. See last in *perlfunc*.

Label not found for "next %s"

(F) You named a loop to continue, but you're not currently in a loop of that name, not even if you count where you were called from. See last in *perlfunc*.

Label not found for "redo %s"

(F) You named a loop to restart, but you're not currently in a loop of that name, not even if you count where you were called from. See last in *perlfunc*.

leaving effective %s failed

(F) While under the `use filetest` pragma, switching the real and effective uids or gids failed.

length/code after end of string in unpack

(F) While unpacking, the string buffer was alread used up when an unpack length/code combination tried to obtain more data. This results in an undefined value for the length. See pack in *perlfunc*.

listen() on closed socket %s

(W closed) You tried to do a listen on a closed socket. Did you forget to check the return value of your socket() call? See listen in *perlfunc*.

Lookbehind longer than %d not implemented in regex; marked by <– HERE in m/%s/

(F) There is currently a limit on the length of string which lookbehind can handle. This restriction may be eased in a future release. The <– HERE shows in the regular expression about where the problem was discovered.

lstat() on filehandle %s

(W io) You tried to do an lstat on a filehandle. What did you mean by that? lstat() makes sense only on filenames. (Perl did a fstat() instead on the filehandle.)

Lvalue subs returning %s not implemented yet

(F) Due to limitations in the current implementation, array and hash values cannot be returned in subroutines used in lvalue context. See Lvalue subroutines in *perlsub*.

Malformed integer in [in pack]

(F) Between the brackets enclosing a numeric repeat count only digits are permitted. See pack in *perlfunc*.

Malformed integer in [in unpack]

(F) Between the brackets enclosing a numeric repeat count only digits are permitted. See pack in *perlfunc*.

Malformed PERLLIB_PREFIX

(F) An error peculiar to OS/2. PERLLIB_PREFIX should be of the form

```
    prefix1;prefix2
```

or prefix1 prefix2

with nonempty prefix1 and prefix2. If `prefix1` is indeed a prefix of a builtin library search path, prefix2 is substituted. The error may appear if components are not found, or are too long. See "PERLLIB_PREFIX" in *perlos2*.

Malformed prototype for %s: %s

(F) You tried to use a function with a malformed prototype. The syntax of function prototypes is given a brief compile-time check for obvious errors like invalid characters. A more rigorous check is run when the function is called.

Malformed UTF-8 character (%s)

Perl detected something that didn't comply with UTF-8 encoding rules.

One possible cause is that you read in data that you thought to be in UTF-8 but it wasn't (it was for example legacy 8-bit data). Another possibility is careless use of utf8::upgrade().

Malformed UTF-16 surrogate

Perl thought it was reading UTF-16 encoded character data but while doing it Perl met a malformed Unicode surrogate.

%s matches null string many times in regex; marked by <– HERE in m/%s/

(W regexp) The pattern you've specified would be an infinite loop if the regular expression engine didn't specifically check for that. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

"%s" may clash with future reserved word

(W) This warning may be due to running a perl5 script through a perl4 interpreter, especially if the word that is being warned about is "use" or "my".

% may not be used in pack

(F) You can't pack a string by supplying a checksum, because the checksumming process loses information, and you can't go the other way. See unpack in *perlfunc*.

Method for operation %s not found in package %s during blessing

(F) An attempt was made to specify an entry in an overloading table that doesn't resolve to a valid subroutine. See *overload*.

Method %s not permitted

See Server error.

Might be a runaway multi-line %s string starting on line %d

(S) An advisory indicating that the previous error may have been caused by a missing delimiter on a string or pattern, because it eventually ended earlier on the current line.

Misplaced _ in number

(W syntax) An underscore (underbar) in a numeric constant did not separate two digits.

Missing %sbrace%s on \N{}

(F) Wrong syntax of character name literal `\N{charname}` within double-quotish context.

Missing comma after first argument to %s function

(F) While certain functions allow you to specify a filehandle or an "indirect object" before the argument list, this ain't one of them.

Missing command in piped open

(W pipe) You used the `open(FH, "| command")` or `open(FH, "command |")` construction, but the command was missing or blank.

Missing control char name in \c

(F) A double-quoted string ended with "\c", without the required control character name.

Missing name in "my sub"

(F) The reserved syntax for lexically scoped subroutines requires that they have a name with which they can be found.

Missing $ on loop variable

(F) Apparently you've been programming in **csh** too much. Variables are always mentioned with the $ in Perl, unlike in the shells, where it can vary from one line to the next.

(Missing operator before %s?)

(S syntax) This is an educated guess made in conjunction with the message "%s found where operator expected". Often the missing operator is a comma.

Missing right brace on %s

(F) Missing right brace in `\p{...}` or `\P{...}`.

Missing right curly or square bracket

(F) The lexer counted more opening curly or square brackets than closing ones. As a general rule, you'll find it's missing near the place you were last editing.

(Missing semicolon on previous line?)

(S syntax) This is an educated guess made in conjunction with the message "%s found where operator expected". Don't automatically put a semicolon on the previous line just because you saw this message.

Modification of a read-only value attempted

(F) You tried, directly or indirectly, to change the value of a constant. You didn't, of course, try "2 = 1", because the compiler catches that. But an easy way to do the same thing is:

```
    sub mod { $_[0] = 1 }
    mod(2);
```

Another way is to assign to a substr() that's off the end of the string.

Yet another way is to assign to a `foreach` loop *VAR* when *VAR* is aliased to a constant in the look *LIST*:

```
$x = 1;
foreach my $n ($x, 2) {
    $n *= 2; # modifies the $x, but fails on attempt to modify the 2
}
```

Modification of non-creatable array value attempted, %s

(F) You tried to make an array value spring into existence, and the subscript was probably negative, even counting from end of the array backwards.

Modification of non-creatable hash value attempted, %s

(P) You tried to make a hash value spring into existence, and it couldn't be created for some peculiar reason.

Module name must be constant

(F) Only a bare module name is allowed as the first argument to a "use".

Module name required with -%c option

(F) The `-M` or `-m` options say that Perl should load some module, but you omitted the name of the module. Consult *perlrun* for full details about `-M` and `-m`.

More than one argument to open

(F) The `open` function has been asked to open multiple files. This can happen if you are trying to open a pipe to a command that takes a list of arguments, but have forgotten to specify a piped open mode. See open in *perlfunc* for details.

msg%s not implemented

(F) You don't have System V message IPC on your system.

Multidimensional syntax %s not supported

(W syntax) Multidimensional arrays aren't written like `$foo[1,2,3]`. They're written like `$foo[1][2][3]`, as in C.

'/' must be followed by 'a*', 'A*' or 'Z*'

(F) You had a pack template indicating a counted-length string, Currently the only things that can have their length counted are a*, A* or Z*. See pack in *perlfunc*.

'/' must follow a numeric type in unpack

(F) You had an unpack template that contained a '/', but this did not follow some unpack specification producing a numeric value. See pack in *perlfunc*.

"my sub" not yet implemented

(F) Lexically scoped subroutines are not yet implemented. Don't try that yet.

"my" variable %s can't be in a package

(F) Lexically scoped variables aren't in a package, so it doesn't make sense to try to declare one with a package qualifier on the front. Use local() if you want to localize a package variable.

Name "%s::%s" used only once: possible typo

(W once) Typographical errors often show up as unique variable names. If you had a good reason for having a unique name, then just mention it again somehow to suppress the message. The `our` declaration is provided for this purpose.

NOTE: This warning detects symbols that have been used only once so $c, @c, %c, *c, &c, sub c{}, c(), and c (the filehandle or format) are considered the same; if a program uses $c only once but also uses any of the others it will not trigger this warning.

Negative '/' count in unpack

(F) The length count obtained from a length/code unpack operation was negative. See pack in *perlfunc*.

Negative length

(F) You tried to do a read/write/send/recv operation with a buffer length that is less than 0. This is difficult to imagine.

Negative offset to vec in lvalue context

(F) When `vec` is called in an lvalue context, the second argument must be greater than or equal to zero.

Nested quantifiers in regex; marked by <– HERE in m/%s/

(F) You can't quantify a quantifier without intervening parentheses. So things like ** or +* or ?* are illegal. The <– HERE shows in the regular expression about where the problem was discovered.

Note that the minimal matching quantifiers, `*?`, `+?`, and `??` appear to be nested quantifiers, but aren't. See *perlre*.

%s never introduced

(S internal) The symbol in question was declared but somehow went out of scope before it could possibly have been used.

Newline in left-justified string for %s

(W printf) There is a newline in a string to be left justified by `printf` or `sprintf`.

The padding spaces will appear after the newline, which is probably not what you wanted. Usually you should remove the newline from the string and put formatting characters in the `sprintf` format.

No %s allowed while running setuid

(F) Certain operations are deemed to be too insecure for a setuid or setgid script to even be allowed to attempt. Generally speaking there will be another way to do what you want that is, if not secure, at least securable. See *perlsec*.

No comma allowed after %s

(F) A list operator that has a filehandle or "indirect object" is not allowed to have a comma between that and the following arguments. Otherwise it'd be just another one of the arguments.

One possible cause for this is that you expected to have imported a constant to your name space with **use** or **import** while no such importing took place, it may for example be that your operating system does not support that particular constant. Hopefully you did use an explicit import list for the constants you expect to see, please see use in *perlfunc* and import in *perlfunc*. While an explicit import list would probably have caught this error earlier it naturally does not remedy the fact that your operating system still does not support that constant. Maybe you have a typo in the constants of the symbol import list of **use** or **import** or in the constant name at the line where this error was triggered?

No command into which to pipe on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a '|' at the end of the command line, so it doesn't know where you want to pipe the output from this command.

No DB::DB routine defined

(F) The currently executing code was compiled with the **-d** switch, but for some reason the perl5db.pl file (or some facsimile thereof) didn't define a routine to be called at the beginning of each statement. Which is odd, because the file should have been required automatically, and should have blown up the require if it didn't parse right.

No dbm on this machine

(P) This is counted as an internal error, because every machine should supply dbm nowadays, because Perl comes with SDBM. See SDBM_File.

No DBsub routine

(F) The currently executing code was compiled with the **-d** switch, but for some reason the perl5db.pl file (or some facsimile thereof) didn't define a DB::sub routine to be called at the beginning of each ordinary subroutine call.

No -e allowed in setuid scripts

(F) A setuid script can’t be specified by the user.

No error file after 2> or 2>> on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a ’2>’ or a ’2>>’ on the command line, but can’t find the name of the file to which to write data destined for stderr.

No group ending character ’%c’ found in template

(F) A pack or unpack template has an opening ’(’ or ’[’ without its matching counterpart. See pack in *perlfunc*.

No input file after < on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a ’<’ on the command line, but can’t find the name of the file from which to read data for stdin.

No #! line

(F) The setuid emulator requires that scripts have a well-formed #! line even on machines that don’t support the #! construct.

"no" not allowed in expression

(F) The "no" keyword is recognized and executed at compile time, and returns no useful value. See *perlmod*.

No output file after > on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a lone ’>’ at the end of the command line, so it doesn’t know where you wanted to redirect stdout.

No output file after > or >> on command line

(F) An error peculiar to VMS. Perl handles its own command line redirection, and found a ’>’ or a ’>>’ on the command line, but can’t find the name of the file to which to write data destined for stdout.

No package name allowed for variable %s in "our"

(F) Fully qualified variable names are not allowed in "our" declarations, because that doesn’t make much sense under existing semantics. Such syntax is reserved for future extensions.

No Perl script found in input

(F) You called `perl -x`, but no line was found in the file beginning with #! and containing the word "perl".

No setregid available

(F) Configure didn’t find anything resembling the setregid() call for your system.

No setreuid available

(F) Configure didn’t find anything resembling the setreuid() call for your system.

No space allowed after -%c

(F) The argument to the indicated command line switch must follow immediately after the switch, without intervening spaces.

No %s specified for -%c

(F) The indicated command line switch needs a mandatory argument, but you haven’t specified one.

No such class %s

(F) You provided a class qualifier in a "my" or "our" declaration, but this class doesn’t exist at this point in your program.

No such pipe open

(P) An error peculiar to VMS. The internal routine my_pclose() tried to close a pipe which hadn’t been opened. This should have been caught earlier as an attempt to close an unopened filehandle.

No such pseudo-hash field "%s"

(F) You tried to access an array as a hash, but the field name used is not defined. The hash at index 0 should map all valid field names to array indices for that to work.

No such pseudo-hash field "%s" in variable %s of type %s

(F) You tried to access a field of a typed variable where the type does not know about the field name. The field names are looked up in the %FIELDS hash in the type package at compile time. The %FIELDS hash is %usually set up with the 'fields' pragma.

No such signal: SIG%s

(W signal) You specified a signal name as a subscript to %SIG that was not recognized. Say `kill -l` in your shell to see the valid signal names on your system.

Not a CODE reference

(F) Perl was trying to evaluate a reference to a code value (that is, a subroutine), but found a reference to something else instead. You can use the ref() function to find out what kind of ref it really was. See also *perlref*.

Not a format reference

(F) I'm not sure how you managed to generate a reference to an anonymous format, but this indicates you did, and that it didn't exist.

Not a GLOB reference

(F) Perl was trying to evaluate a reference to a "typeglob" (that is, a symbol table entry that looks like `*foo`), but found a reference to something else instead. You can use the ref() function to find out what kind of ref it really was. See *perlref*.

Not a HASH reference

(F) Perl was trying to evaluate a reference to a hash value, but found a reference to something else instead. You can use the ref() function to find out what kind of ref it really was. See *perlref*.

Not an ARRAY reference

(F) Perl was trying to evaluate a reference to an array value, but found a reference to something else instead. You can use the ref() function to find out what kind of ref it really was. See *perlref*.

Not a perl script

(F) The setuid emulator requires that scripts have a well-formed #! line even on machines that don't support the #! construct. The line must mention perl.

Not a SCALAR reference

(F) Perl was trying to evaluate a reference to a scalar value, but found a reference to something else instead. You can use the ref() function to find out what kind of ref it really was. See *perlref*.

Not a subroutine reference

(F) Perl was trying to evaluate a reference to a code value (that is, a subroutine), but found a reference to something else instead. You can use the ref() function to find out what kind of ref it really was. See also *perlref*.

Not a subroutine reference in overload table

(F) An attempt was made to specify an entry in an overloading table that doesn't somehow point to a valid subroutine. See *overload*.

Not enough arguments for %s

(F) The function requires more arguments than you specified.

Not enough format arguments

(W syntax) A format specified more picture fields than the next line supplied. See *perlform*.

%s: not found

(A) You've accidentally run your script through the Bourne shell instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

no UTC offset information; assuming local time is UTC

(S) A warning peculiar to VMS. Perl was unable to find the local timezone offset, so it's assuming that local system time is equivalent to UTC. If it's not, define the logical name *SYS$ TIMEZONE_DIFFERENTIAL* to translate to the number of seconds which need to be added to UTC to get local time.

Null filename used

(F) You can't require the null filename, especially because on many machines that means the current directory! See require in *perlfunc*.

NULL OP IN RUN

(P debugging) Some internal routine called run() with a null opcode pointer.

Null picture in formline

(F) The first argument to formline must be a valid format picture specification. It was found to be empty, which probably means you supplied it an uninitialized value. See *perlform*.

Null realloc

(P) An attempt was made to realloc NULL.

NULL regexp argument

(P) The internal pattern matching routines blew it big time.

NULL regexp parameter

(P) The internal pattern matching routines are out of their gourd.

Number too long

(F) Perl limits the representation of decimal numbers in programs to about 250 characters. You've exceeded that length. Future versions of Perl are likely to eliminate this arbitrary limitation. In the meantime, try using scientific notation (e.g. "1e6" instead of "1_000_000").

Octal number in vector unsupported

(F) Numbers with a leading `0` are not currently allowed in vectors. The octal number interpretation of such numbers may be supported in a future version.

Octal number > 037777777777 non-portable

(W portable) The octal number you specified is larger than 2**32-1 (4294967295) and therefore non-portable between systems. See *perlport* for more on portability concerns.

See also *perlport* for writing portable code.

Odd number of arguments for overload::constant

(W overload) The call to overload::constant contained an odd number of arguments. The arguments should come in pairs.

Odd number of elements in anonymous hash

(W misc) You specified an odd number of elements to initialize a hash, which is odd, because hashes come in key/value pairs.

Odd number of elements in hash assignment

(W misc) You specified an odd number of elements to initialize a hash, which is odd, because hashes come in key/value pairs.

Offset outside string

(F) You tried to do a read/write/send/recv operation with an offset pointing outside the buffer. This is difficult to imagine. The sole exception to this is that `sysread()`ing past the buffer will extend the buffer and zero pad the new area.

%s() on unopened %s

(W unopened) An I/O operation was attempted on a filehandle that was never initialized. You need to do an open(), a sysopen(), or a socket() call, or call a constructor from the FileHandle package.

-%s on unopened filehandle %s

(W unopened) You tried to invoke a file test operator on a filehandle that isn't open. Check your control flow. See also -X in *perlfunc*.

oops: oopsAV

(S internal) An internal warning that the grammar is screwed up.

oops: oopsHV

(S internal) An internal warning that the grammar is screwed up.

Operation '%s': no method found, %s

(F) An attempt was made to perform an overloaded operation for which no handler was defined. While some handlers can be autogenerated in terms of other handlers, there is no default handler for any operation, unless `fallback` overloading key is specified to be true. See *overload*.

Operator or semicolon missing before %s

(S ambiguous) You used a variable or subroutine call where the parser was expecting an operator. The parser has assumed you really meant to use an operator, but this is highly likely to be incorrect. For example, if you say "*foo *foo" it will be interpreted as if you said "*foo * 'foo'".

"our" variable %s redeclared

(W misc) You seem to have already declared the same global once before in the current lexical scope.

Out of memory!

(X) The malloc() function returned 0, indicating there was insufficient remaining memory (or virtual memory) to satisfy the request. Perl has no option but to exit immediately.

At least in Unix you may be able to get past this by increasing your process datasize limits: in csh/tcsh use `limit` and `limit datasize n` (where `n` is the number of kilobytes) to check the current limits and change them, and in ksh/bash/zsh use `ulimit -a` and `ulimit -d n`, respectively.

Out of memory during "large" request for %s

(F) The malloc() function returned 0, indicating there was insufficient remaining memory (or virtual memory) to satisfy the request. However, the request was judged large enough (compile-time default is 64K), so a possibility to shut down by trapping this error is granted.

Out of memory during %s extend

(X) An attempt was made to extend an array, a list, or a string beyond the largest possible memory allocation.

Out of memory during request for %s

(X|F) The malloc() function returned 0, indicating there was insufficient remaining memory (or virtual memory) to satisfy the request.

The request was judged to be small, so the possibility to trap it depends on the way perl was compiled. By default it is not trappable. However, if compiled for this, Perl may use the contents of `$^M` as an emergency pool after die()ing with this message. In this case the error is trappable *once*, and the error message will include the line and file where the failed request happened.

Out of memory during ridiculously large request

(F) You can't allocate more than 2^31+"small amount" bytes. This error is most likely to be caused by a typo in the Perl program. e.g., `$arr[time]` instead of `$arr[$time]`.

Out of memory for yacc stack

(F) The yacc parser wanted to grow its stack so it could continue parsing, but realloc() wouldn't give it more memory, virtual or otherwise.

'@' outside of string in unpack

(F) You had a template that specified an absolute position outside the string being unpacked. See pack in *perlfunc*.

%s package attribute may clash with future reserved word: %s

(W reserved) A lowercase attribute name was used that had a package-specific handler. That name might have a meaning to Perl itself some day, even though it doesn't yet. Perhaps you should use a mixed-case attribute name, instead. See *attributes*.

pack/unpack repeat count overflow

(F) You can't specify a repeat count so large that it overflows your signed integers. See pack in *perlfunc*.

page overflow

(W io) A single call to write() produced more lines than can fit on a page. See *perlform*.

panic: %s

(P) An internal error.

panic: ck_grep

(P) Failed an internal consistency check trying to compile a grep.

panic: ck_split

(P) Failed an internal consistency check trying to compile a split.

panic: corrupt saved stack index

(P) The savestack was requested to restore more localized values than there are in the savestack.

panic: del_backref

(P) Failed an internal consistency check while trying to reset a weak reference.

panic: Devel::DProf inconsistent subroutine return

(P) Devel::DProf called a subroutine that exited using goto(LABEL), last(LABEL) or next(LABEL). Leaving that way a subroutine called from an XSUB will lead very probably to a crash of the interpreter. This is a bug that will hopefully one day get fixed.

panic: die %s

(P) We popped the context stack to an eval context, and then discovered it wasn't an eval context.

panic: do_subst

(P) The internal pp_subst() routine was called with invalid operational data.

panic: do_trans_%s

(P) The internal do_trans routines were called with invalid operational data.

panic: frexp

(P) The library function frexp() failed, making printf("%f") impossible.

panic: goto

(P) We popped the context stack to a context with the specified label, and then discovered it wasn't a context we know how to do a goto in.

panic: INTERPCASEMOD

(P) The lexer got into a bad state at a case modifier.

panic: INTERPCONCAT

(P) The lexer got into a bad state parsing a string with brackets.

panic: kid popen errno read

(F) forked child returned an incomprehensible message about its errno.

panic: last

(P) We popped the context stack to a block context, and then discovered it wasn't a block context.

panic: leave_scope clearsv

(P) A writable lexical variable became read-only somehow within the scope.

panic: leave_scope inconsistency

(P) The savestack probably got out of sync. At least, there was an invalid enum on the top of it.

panic: magic_killbackrefs

(P) Failed an internal consistency check while trying to reset all weak references to an object.

panic: malloc

(P) Something requested a negative number of bytes of malloc.

panic: mapstart

(P) The compiler is screwed up with respect to the map() function.

panic: memory wrap

(P) Something tried to allocate more memory than possible.

panic: null array

(P) One of the internal array routines was passed a null AV pointer.

panic: pad_alloc

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_free curpad

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_free po

(P) An invalid scratch pad offset was detected internally.

panic: pad_reset curpad

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_sv po

(P) An invalid scratch pad offset was detected internally.

panic: pad_swipe curpad

(P) The compiler got confused about which scratch pad it was allocating and freeing temporaries and lexicals from.

panic: pad_swipe po

(P) An invalid scratch pad offset was detected internally.

panic: pp_iter

(P) The foreach iterator got called in a non-loop context frame.

panic: pp_match%s

(P) The internal pp_match() routine was called with invalid operational data.

panic: pp_split

(P) Something terrible went wrong in setting up for the split.

panic: realloc

(P) Something requested a negative number of bytes of realloc.

panic: restartop

(P) Some internal routine requested a goto (or something like it), and didn't supply the destination.

panic: return

(P) We popped the context stack to a subroutine or eval context, and then discovered it wasn't a subroutine or eval context.

panic: scan_num

(P) scan_num() got called on something that wasn't a number.

panic: sv_insert

(P) The sv_insert() routine was told to remove more string than there was string.

panic: top_env

(P) The compiler attempted to do a goto, or something weird like that.

panic: utf16_to_utf8: odd bytelen

(P) Something tried to call utf16_to_utf8 with an odd (as opposed to even) byte length.

panic: yylex

(P) The lexer got into a bad state while processing a case modifier.

Parentheses missing around "%s" list

(W parenthesis) You said something like

```
my $foo, $bar = @_;
```

when you meant

```
my ($foo, $bar) = @_;
```

Remember that "my", "our", and "local" bind tighter than comma.

-p destination: %s

(F) An error occurred during the implicit output invoked by the `-p` command-line switch. (This output goes to STDOUT unless you've redirected it with select().)

(perhaps you forgot to load "%s"?)

(F) This is an educated guess made in conjunction with the message "Can't locate object method \"%s\" via package \"%s\"". It often means that a method requires a package that has not been loaded.

Perl %s required–this is only version %s, stopped

(F) The module in question uses features of a version of Perl more recent than the currently running version. How long has it been since you upgraded, anyway? See require in *perlfunc*.

PERL_SH_DIR too long

(F) An error peculiar to OS/2. PERL_SH_DIR is the directory to find the sh-shell in. See "PERL_SH_DIR" in *perlos2*.

PERL_SIGNALS illegal: "%s"

See PERL_SIGNALS in *perlrun* for legal values.

perl: warning: Setting locale failed.

(S) The whole warning message will look something like:

```
perl: warning: Setting locale failed.
perl: warning: Please check that your locale settings:
        LC_ALL = "En_US",
        LANG = (unset)
    are supported and installed on your system.
perl: warning: Falling back to the standard locale ("C").
```

Exactly what were the failed locale settings varies. In the above the settings were that the LC_ALL was "En_US" and the LANG had no value. This error means that Perl detected that you and/or your operating system supplier and/or system administrator have set up the so-called locale system but Perl could not use those settings. This was not dead serious, fortunately: there is a "default locale" called "C" that Perl can and will use, the script will be run. Before you really fix the problem, however, you will get the same error message each time you run Perl. How to really fix the problem can be found in *perllocale* section **LOCALE PROBLEMS**.

Permission denied

(F) The setuid emulator in suidperl decided you were up to no good.

pid %x not a child

(W exec) A warning peculiar to VMS. Waitpid() was asked to wait for a process which isn't a subprocess of the current process. While this is fine from VMS' perspective, it's probably not what you intended.

'P' must have an explicit size in unpack

(F) The unpack format P must have an explicit size, not "*".

-P not allowed for setuid/setgid script

(F) The script would have to be opened by the C preprocessor by name, which provides a race condition that breaks security.

POSIX class [:%s: unknown in regex; marked] **by <– HERE in m/%s/**

(F) The class in the character class [: :] syntax is unknown. The <– HERE shows in the regular expression about where the problem was discovered. Note that the POSIX character classes do **not** have the `is` prefix the corresponding C interfaces have: in other words, it's `[[:print:]]`, not `isprint`. See *perlre*.

POSIX getpgrp can't take an argument

(F) Your system has POSIX getpgrp(), which takes no argument, unlike the BSD version, which takes a pid.

POSIX syntax [%s belongs inside character] **classes in regex; marked by <– HERE in m/%s/**

(W regexp) The character class constructs [: :], [= =], and [. .] go *inside* character classes, the [] are part of the construct, for example: /[012[:alpha:]345]/. Note that [= =] and [. .] are not currently implemented; they are simply placeholders for future extensions and will cause fatal errors. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

POSIX syntax [. . is reserved for future] **extensions in regex; marked by <– HERE in m/%s/**

(F regexp) Within regular expression character classes ([]) the syntax beginning with "[." and ending with ".]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[." and ".\]". The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

POSIX syntax [= = is reserved for future] **extensions in regex; marked by <– HERE in m/%s/**

(F) Within regular expression character classes ([]) the syntax beginning with "[=" and ending with "=]" is reserved for future extensions. If you need to represent those character sequences inside a regular expression character class, just quote the square brackets with the backslash: "\[=" and "=\]". The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Possible attempt to put comments in qw() list

(W qw) qw() lists contain items separated by whitespace; as with literal strings, comment characters are not ignored, but are instead treated as literal data. (You may have used different delimiters than the parentheses shown here; braces are also frequently used.)

You probably wrote something like this:

```
@list = qw(
    a # a comment
    b # another comment
);
```

when you should have written this:

```
@list = qw(
    a
    b
);
```

If you really want comments, build your list the old-fashioned way, with quotes and commas:

```
@list = (
    'a',    # a comment
    'b',    # another comment
);
```

Possible attempt to separate words with commas

(W qw) qw() lists contain items separated by whitespace; therefore commas aren't needed to separate the items. (You may have used different delimiters than the parentheses shown here; braces are also frequently used.)

You probably wrote something like this:

```
qw! a, b, c !;
```

which puts literal commas into some of the list items. Write it without commas if you don't want them to appear in your data:

```
qw! a b c !;
```

Possible memory corruption: %s overflowed 3rd argument

(F) An ioctl() or fcntl() returned more than Perl was bargaining for. Perl guesses a reasonable buffer size, but puts a sentinel byte at the end of the buffer just in case. This sentinel byte got clobbered, and Perl assumes that memory is now corrupted. See ioctl in *perlfunc*.

Possible precedence problem on bitwise %c operator

(W precedence) Your program uses a bitwise logical operator in conjunction with a numeric comparison operator, like this :

```
if ($x & $y == 0) { ... }
```

This expression is actually equivalent to `$x & ($y == 0)`, due to the higher precedence of ==. This is probably not what you want. (If you really meant to write this, disable the warning, or, better, put the parentheses explicitly and write `$x & ($y == 0)`).

Possible unintended interpolation of %s in string

(W ambiguous) You said something like '@foo' in a double-quoted string but there was no array `@foo` in scope at the time. If you wanted a literal @foo, then write it as \@foo; otherwise find out what happened to the array you apparently lost track of.

Possible Y2K bug: %s

(W y2k) You are concatenating the number 19 with another number, which could be a potential Year 2000 problem.

pragma "attrs" is deprecated, use "sub NAME : ATTRS" instead

(D deprecated) You have written something like this:

```
sub doit
{
    use attrs qw(locked);
}
```

You should use the new declaration syntax instead.

```
sub doit : locked
{
    ...
```

The `use attrs` pragma is now obsolete, and is only provided for backward-compatibility. See Subroutine Attributes in *perlsub*.

Precedence problem: open %s should be open(%s)

(S precedence) The old irregular construct

```
open FOO || die;
```

is now misinterpreted as

```
open(FOO || die);
```

because of the strict regularization of Perl 5's grammar into unary and list operators. (The old open was a little of both.) You must put parentheses around the filehandle, or use the new "or" operator instead of "||".

Premature end of script headers

See Server error.

printf() on closed filehandle %s

(W closed) The filehandle you're writing to got itself closed sometime before now. Check your control flow.

print() on closed filehandle %s

(W closed) The filehandle you're printing on got itself closed sometime before now. Check your control flow.

Process terminated by SIG%s

(W) This is a standard message issued by OS/2 applications, while *nix applications die in silence. It is considered a feature of the OS/2 port. One can easily disable this by appropriate sighandlers, see Signals in *perlipc*. See also "Process terminated by SIGTERM/SIGINT" in *perlos2*.

Prototype mismatch: %s vs %s

(S prototype) The subroutine being declared or defined had previously been declared or defined with a different function prototype.

Prototype not terminated

(F) You've omitted the closing parenthesis in a function prototype definition.

Pseudo-hashes are deprecated

(D deprecated) Pseudo-hashes were deprecated in Perl 5.8.0 and they will be removed in Perl 5.10.0, see *perl58delta* for more details. You can continue to use the `fields` pragma.

Quantifier follows nothing in regex; marked by <– HERE in m/%s/

(F) You started a regular expression with a quantifier. Backslash it if you meant it literally. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Quantifier in {,} bigger than %d in regex; marked by <– HERE in m/%s/

(F) There is currently a limit to the size of the min and max values of the {min,max} construct. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Quantifier unexpected on zero-length expression; marked by <– HERE in m/%s/

(W regexp) You applied a regular expression quantifier in a place where it makes no sense, such as on a zero-width assertion. Try putting the quantifier inside the assertion instead. For example, the way to match "abc" provided that it is followed by three repetitions of "xyz" is `/abc(?=(?:xyz){3})/`, not `/abc(?=xyz){3}/`.

The <– HERE shows in the regular expression about where the problem was discovered.

Range iterator outside integer range

(F) One (or both) of the numeric arguments to the range operator ".." are outside the range which can be represented by integers internally. One possible workaround is to force Perl to use magical string increment by prepending "0" to your numbers.

readline() on closed filehandle %s

(W closed) The filehandle you're reading from got itself closed sometime before now. Check your control flow.

read() on closed filehandle %s

(W closed) You tried to read from a closed filehandle.

read() on unopened filehandle %s

(W unopened) You tried to read from a filehandle that was never opened.

Reallocation too large: %lx

(F) You can't allocate more than 64K on an MS-DOS machine.

realloc() of freed memory ignored

(S malloc) An internal routine called realloc() on something that had already been freed.

Recompile perl with -DDEBUGGING to use -D switch

(F debugging) You can't use the **-D** option unless the code to produce the desired output is compiled into Perl, which entails some overhead, which is why it's currently left out of your copy.

Recursive inheritance detected in package '%s'

(F) More than 100 levels of inheritance were used. Probably indicates an unintended loop in your inheritance hierarchy.

Recursive inheritance detected while looking for method %s

(F) More than 100 levels of inheritance were encountered while invoking a method. Probably indicates an unintended loop in your inheritance hierarchy.

Reference found where even-sized list expected

(W misc) You gave a single reference where Perl was expecting a list with an even number of elements (for assignment to a hash). This usually means that you used the anon hash constructor when you meant to use parens. In any case, a hash requires key/value **pairs**.

```
    %hash = { one => 1, two => 2, };    # WRONG
    %hash = [ qw/ an anon array / ];    # WRONG
    %hash = ( one => 1, two => 2, );    # right
    %hash = qw( one 1 two 2 );                  # also fine
```

Reference is already weak

(W misc) You have attempted to weaken a reference that is already weak. Doing so has no effect.

Reference miscount in sv_replace()

(W internal) The internal sv_replace() function was handed a new SV with a reference count of other than 1.

Reference to nonexistent group in regex; marked by <– HERE in m/%s/

(F) You used something like `\7` in your regular expression, but there are not at least seven sets of capturing parentheses in the expression. If you wanted to have the character with value 7 inserted into the regular expression, prepend a zero to make the number at least two digits: `\07`

The <– HERE shows in the regular expression about where the problem was discovered.

regexp memory corruption

(P) The regular expression engine got confused by what the regular expression compiler gave it.

Regexp out of space

(P) A "can't happen" error, because safemalloc() should have caught it earlier.

Repeated format line will never terminate (~~ and @# incompatible)

(F) Your format containes the ~~ repeat-until-blank sequence and a numeric field that will never go blank so that the repetition never terminates. You might use ^# instead. See *perlform*.

Reversed %s= operator

(W syntax) You wrote your assignment operator backwards. The = must always comes last, to avoid ambiguity with subsequent unary operators.

Runaway format

(F) Your format contained the ~~ repeat-until-blank sequence, but it produced 200 lines at once, and the 200th line looked exactly like the 199th line. Apparently you didn't arrange for the arguments to exhaust themselves, either by using ^ instead of @ (for scalar variables), or by shifting or popping (for array variables). See *perlform*.

Scalars leaked: %d

(P) Something went wrong in Perl's internal bookkeeping of scalars: not all scalar variables were deallocated by the time Perl exited. What this usually indicates is a memory leak, which is of course bad, especially if the Perl program is intended to be long-running.

Scalar value @%s[%s better written as] **$ %s[%s]**

(W syntax) You've used an array slice (indicated by @) to select a single element of an array. Generally it's better to ask for a scalar value (indicated by $). The difference is that `$foo[&bar]` always behaves like a scalar, both when assigning to it and when evaluating its argument, while `@foo[&bar]` behaves like a list when you assign to it, and provides a list context to its subscript, which can do weird things if you're expecting only one subscript.

On the other hand, if you were actually hoping to treat the array element as a list, you need to look into how references work, because Perl will not magically convert between scalars and lists for you. See *perlref*.

Scalar value @%s{%s} better written as $ %s{%s}

(W syntax) You've used a hash slice (indicated by @) to select a single element of a hash. Generally it's better to ask for a scalar value (indicated by $). The difference is that `$foo{&bar}` always behaves like a scalar, both when assigning to it and when evaluating its argument, while `@foo{&bar}` behaves like a list when you assign to it, and provides a list context to its subscript, which can do weird things if you're expecting only one subscript.

On the other hand, if you were actually hoping to treat the hash element as a list, you need to look into how references work, because Perl will not magically convert between scalars and lists for you. See *perlref*.

Script is not setuid/setgid in suidperl

(F) Oddly, the suidperl program was invoked on a script without a setuid or setgid bit set. This doesn't make much sense.

Search pattern not terminated

(F) The lexer couldn't find the final delimiter of a // or m{} construct. Remember that bracketing delimiters count nesting level. Missing the leading `$` from a variable `$m` may cause this error.

Note that since Perl 5.9.0 a // can also be the *defined-or* construct, not just the empty search pattern. Therefore code written in Perl 5.9.0 or later that uses the // as the *defined-or* can be misparsed by pre-5.9.0 Perls as a non-terminated search pattern.

%sseek() on unopened filehandle

(W unopened) You tried to use the seek() or sysseek() function on a filehandle that was either never opened or has since been closed.

select not implemented

(F) This machine doesn't implement the select() system call.

Self-ties of arrays and hashes are not supported

(F) Self-ties are of arrays and hashes are not supported in the current implementation.

Semicolon seems to be missing

(W semicolon) A nearby syntax error was probably caused by a missing semicolon, or possibly some other missing operator, such as a comma.

semi-panic: attempt to dup freed string

(S internal) The internal newSVsv() routine was called to duplicate a scalar that had previously been marked as free.

sem%s not implemented

(F) You don't have System V semaphore IPC on your system.

send() on closed socket %s

(W closed) The socket you're sending to got itself closed sometime before now. Check your control flow.

Sequence (? incomplete in regex; marked by <– HERE in m/%s/

(F) A regular expression ended with an incomplete extension (?. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Sequence (?%s...) not implemented in regex; marked by <– HERE in m/%s/

(F) A proposed regular expression extension has the character reserved but has not yet been written. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Sequence (?%s...) not recognized in regex; marked by <– HERE in m/%s/

(F) You used a regular expression extension that doesn't make sense. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Sequence (?#... not terminated in regex; marked by <– HERE in m/%s/

(F) A regular expression comment must be terminated by a closing parenthesis. Embedded parentheses aren't allowed. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Sequence (?{...}) not terminated or not {}-balanced in regex; marked by <– HERE in m/%s/

(F) If the contents of a (?{...}) clause contains braces, they must balance for Perl to properly detect the end of the clause. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

500 Server error

See Server error.

Server error

This is the error message generally seen in a browser window when trying to run a CGI program (including SSI) over the web. The actual error text varies widely from server to server. The most frequently-seen variants are "500 Server error", "Method (something) not permitted", "Document contains no data", "Premature end of script headers", and "Did not produce a valid header".

This is a CGI error, not a Perl error.

You need to make sure your script is executable, is accessible by the user CGI is running the script under (which is probably not the user account you tested it under), does not rely on any environment variables (like PATH) from the user it isn't running under, and isn't in a location where the CGI server can't find it, basically, more or less. Please see the following for more information:

```
        http://www.perl.org/CGI_MetaFAQ.html
        http://www.htmlhelp.org/faq/cgifaq.html
        http://www.w3.org/Security/Faq/
```

You should also look at *perlfaq9*.

setegid() not implemented

(F) You tried to assign to `$)`, and your operating system doesn't support the setegid() system call (or equivalent), or at least Configure didn't think so.

seteuid() not implemented

(F) You tried to assign to `$>`, and your operating system doesn't support the seteuid() system call (or equivalent), or at least Configure didn't think so.

setpgrp can't take arguments

(F) Your system has the setpgrp() from BSD 4.2, which takes no arguments, unlike POSIX setpgid(), which takes a process ID and process group ID.

setrgid() not implemented

(F) You tried to assign to `$(`, and your operating system doesn't support the setrgid() system call (or equivalent), or at least Configure didn't think so.

setruid() not implemented

(F) You tried to assign to `$<`, and your operating system doesn't support the setruid() system call (or equivalent), or at least Configure didn't think so.

setsockopt() on closed socket %s

(W closed) You tried to set a socket option on a closed socket. Did you forget to check the return value of your socket() call? See setsockopt in *perlfunc*.

Setuid/gid script is writable by world

(F) The setuid emulator won't run a script that is writable by the world, because the world might have written on it already.

shm%s not implemented

(F) You don't have System V shared memory IPC on your system.

<> should be quotes

(F) You wrote `require <file>` when you should have written `require 'file'`.

/%s/ should probably be written as "%s"

(W syntax) You have used a pattern where Perl expected to find a string, as in the first argument to `join`. Perl will treat the true or false result of matching the pattern against $_ as the string, which is probably not what you had in mind.

shutdown() on closed socket %s

(W closed) You tried to do a shutdown on a closed socket. Seems a bit superfluous.

SIG%s handler "%s" not defined

(W signal) The signal handler named in %SIG doesn't, in fact, exist. Perhaps you put it into the wrong package?

sort is now a reserved word

(F) An ancient error message that almost nobody ever runs into anymore. But before sort was a keyword, people sometimes used it as a filehandle.

Sort subroutine didn't return a numeric value

(F) A sort comparison routine must return a number. You probably blew it by not using <=> or `cmp`, or by not using them correctly. See sort in *perlfunc*.

Sort subroutine didn't return single value

(F) A sort comparison subroutine may not return a list value with more or less than one element. See sort in *perlfunc*.

splice() offset past end of array

(W misc) You attempted to specify an offset that was past the end of the array passed to splice(). Splicing will instead commence at the end of the array, rather than past it. If this isn't what you want, try explicitly pre-extending the array by assigning $#array = $offset. See splice in *perlfunc*.

Split loop

(P) The split was looping infinitely. (Obviously, a split shouldn't iterate more times than there are characters of input, which is what happened.) See split in *perlfunc*.

Statement unlikely to be reached

(W exec) You did an exec() with some statement after it other than a die(). This is almost always an error, because exec() never returns unless there was a failure. You probably wanted to use system() instead, which does return. To suppress this warning, put the exec() in a block by itself.

stat() on unopened filehandle %s

(W unopened) You tried to use the stat() function on a filehandle that was either never opened or has since been closed.

Stub found while resolving method '%s' overloading %s

(P) Overloading resolution over @ISA tree may be broken by importation stubs. Stubs should never be implicitly created, but explicit calls to `can` may break this.

Subroutine %s redefined

(W redefine) You redefined a subroutine. To suppress this warning, say

```
        {
            no warnings 'redefine';
            eval "sub name { ... }";
        }
```

Substitution loop

(P) The substitution was looping infinitely. (Obviously, a substitution shouldn't iterate more times than there are characters of input, which is what happened.) See the discussion of substitution in Quote and Quote-like Operators in *perlop*.

Substitution pattern not terminated

(F) The lexer couldn't find the interior delimiter of an s/// or s{}{} construct. Remember that bracketing delimiters count nesting level. Missing the leading `$` from variable `$s` may cause this error.

Substitution replacement not terminated

(F) The lexer couldn't find the final delimiter of an s/// or s{}{} construct. Remember that bracketing delimiters count nesting level. Missing the leading `$` from variable `$s` may cause this error.

substr outside of string

(W substr),(F) You tried to reference a substr() that pointed outside of a string. That is, the absolute value of the offset was larger than the length of the string. See substr in *perlfunc*. This warning is fatal if substr is used in an lvalue context (as the left hand side of an assignment or as a subroutine argument for example).

suidperl is no longer needed since %s

(F) Your Perl was compiled with **-D**SETUID_SCRIPTS_ARE_SECURE_NOW, but a version of the setuid emulator somehow got run anyway.

Switch (?(condition)... contains too many branches in regex; marked by <– HERE in m/%s/

(F) A (?(condition)if-clause|else-clause) construct can have at most two branches (the if-clause and the else-clause). If you want one or both to contain alternation, such as using `this|that|other`, enclose it in clustering parentheses:

```
    (?(condition)(?:this|that|other)|else-clause)
```

The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Switch condition not recognized in regex; marked by <– HERE in m/%s/

(F) If the argument to the (?(...)if-clause|else-clause) construct is a number, it can be only a number. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

switching effective %s is not implemented

(F) While under the `use filetest` pragma, we cannot switch the real and effective uids or gids.

%s syntax

(F) The final summary message when a `perl -c` succeeds.

syntax error

(F) Probably means you had a syntax error. Common reasons include:

```
    A keyword is misspelled.
    A semicolon is missing.
    A comma is missing.
    An opening or closing parenthesis is missing.
    An opening or closing brace is missing.
    A closing quote is missing.
```

Often there will be another error message associated with the syntax error giving more information. (Sometimes it helps to turn on **-w**.) The error message itself often tells you where it was in the line when it decided to give up. Sometimes the actual error is several tokens before this, because Perl is good at understanding random input. Occasionally the line number may be misleading, and once in a blue moon the only way to figure out what's triggering the error is to call `perl -c` repeatedly, chopping away half the program each time to see if the error went away. Sort of the cybernetic version of 20 questions.

syntax error at line %d: '%s' unexpected

(A) You've accidentally run your script through the Bourne shell instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

syntax error in file %s at line %d, next 2 tokens "%s"

(F) This error is likely to occur if you run a perl5 script through a perl4 interpreter, especially if the next 2 tokens are "use strict" or "my $var" or "our $var".

sysread() on closed filehandle %s

(W closed) You tried to read from a closed filehandle.

sysread() on unopened filehandle %s

(W unopened) You tried to read from a filehandle that was never opened.

System V %s is not implemented on this machine

(F) You tried to do something with a function beginning with "sem", "shm", or "msg" but that System V IPC is not implemented in your machine. In some machines the functionality can exist but be unconfigured. Consult your system support.

syswrite() on closed filehandle %s

(W closed) The filehandle you're writing to got itself closed sometime before now. Check your control flow.

`-T` and `-B` not implemented on filehandles

(F) Perl can't peek at the stdio buffer of filehandles when it doesn't know about your kind of stdio. You'll have to use a filename instead.

Target of goto is too deeply nested

(F) You tried to use `goto` to reach a label that was too deeply nested for Perl to reach. Perl is doing you a favor by refusing.

tell() on unopened filehandle

(W unopened) You tried to use the tell() function on a filehandle that was either never opened or has since been closed.

That use of $ [is unsupported

(F) Assignment to `$[` is now strictly circumscribed, and interpreted as a compiler directive. You may say only one of

```
    $[ = 0;
    $[ = 1;
    ...
    local $[ = 0;
    local $[ = 1;
    ...
```

This is to prevent the problem of one module changing the array base out from under another module inadvertently. See $[in *perlvar*.

The crypt() function is unimplemented due to excessive paranoia

(F) Configure couldn't find the crypt() function on your machine, probably because your vendor didn't supply it, probably because they think the U.S. Government thinks it's a secret, or at least that they will continue to pretend that it is. And if you quote me on that, I will deny it.

The `%s` function is unimplemented

The function indicated isn't implemented on this architecture, according to the probings of Configure.

The stat preceding `%s` wasn't an lstat

(F) It makes no sense to test the current stat buffer for symbolic linkhood if the last stat that wrote to the stat buffer already went past the symlink to get to the real file. Use an actual filename instead.

The 'unique' attribute may only be applied to 'our' variables

(F) Currently this attribute is not supported on `my` or `sub` declarations. See our in *perlfunc*.

This Perl can't reset CRTL environ elements (`%s`)

This Perl can't set CRTL environ elements (`%s=%s`)

(W internal) Warnings peculiar to VMS. You tried to change or delete an element of the CRTL's internal environ array, but your copy of Perl wasn't built with a CRTL that contained the setenv() function. You'll need to rebuild Perl with a CRTL that does, or redefine *PERL_ENV_TABLES* (see *perlvms*) so that the environ array isn't the target of the change to %ENV which produced the warning.

thread failed to start: `%s`

(F) The entry point function of threads->create() failed for some reason.

5.005 threads are deprecated

(D deprecated) The 5.005-style threads (activated by `use Thread;`) are deprecated and one should use the new ithreads instead, see *perl58delta* for more details.

Tied variable freed while still in use

(F) An access method for a tied variable (e.g. FETCH) did something to free the variable. Since continuing the current operation is likely to result in a coredump, Perl is bailing out instead.

times not implemented

(F) Your version of the C library apparently doesn't do times(). I suspect you're not running on Unix.

To`%s`: illegal mapping '`%s`'

(F) You tried to define a customized To-mapping for lc(), lcfirst, uc(), or ucfirst() (or their string-inlined versions), but you specified an illegal mapping. See User-Defined Character Properties in *perlunicode*.

Too deeply nested ()-groups

(F) Your template contains ()-groups with a ridiculously deep nesting level.

Too few args to syscall

(F) There has to be at least one argument to syscall() to specify the system call to call, silly dilly.

Too late for "-`%s`" option

(X) The #! line (or local equivalent) in a Perl script contains the **-M** or **-m** option. This is an error because **-M** and **-m** options are not intended for use inside scripts. Use the `use` pragma instead.

Too late for "-T" option

(X) The #! line (or local equivalent) in a Perl script contains the **-T** option, but Perl was not invoked with **-T** in its command line. This is an error because, by the time Perl discovers a **-T** in a script, it's too late to properly taint everything from the environment. So Perl gives up.

If the Perl script is being executed as a command using the #! mechanism (or its local equivalent), this error can usually be fixed by editing the #! line so that the **-T** option is a part of Perl's first argument: e.g. change `perl -n -T` to `perl -T -n`.

If the Perl script is being executed as `perl scriptname`, then the **-T** option must appear on the command line: `perl -T scriptname`.

Too late to run %s block

(W void) A CHECK or INIT block is being defined during run time proper, when the opportunity to run them has already passed. Perhaps you are loading a file with `require` or `do` when you should be using `use` instead. Or perhaps you should put the `require` or `do` inside a BEGIN block.

Too many args to syscall

(F) Perl supports a maximum of only 14 args to syscall().

Too many arguments for %s

(F) The function requires fewer arguments than you specified.

Too many)'s

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

Too many ('s

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

Trailing \ in regex m/%s/

(F) The regular expression ends with an unbackslashed backslash. Backslash it. See *perlre*.

Transliteration pattern not terminated

(F) The lexer couldn't find the interior delimiter of a tr/// or tr[][] or y/// or y[][] construct. Missing the leading `$` from variables `$tr` or `$y` may cause this error.

Transliteration replacement not terminated

(F) The lexer couldn't find the final delimiter of a tr///, tr[][], y/// or y[][] construct.

'%s' trapped by operation mask

(F) You tried to use an operator from a Safe compartment in which it's disallowed. See *Safe*.

truncate not implemented

(F) Your machine doesn't implement a file truncation mechanism that Configure knows about.

Type of arg %d to %s must be %s (not %s)

(F) This function requires the argument in that position to be of a certain type. Arrays must be @NAME or `@{EXPR}`. Hashes must be %NAME or `%{EXPR}`. No implicit dereferencing is allowed–use the {EXPR} forms as an explicit dereference. See *perlref*.

umask not implemented

(F) Your machine doesn't implement the umask function and you tried to use it to restrict permissions for yourself (EXPR & 0700).

Unable to create sub named "%s"

(F) You attempted to create or access a subroutine with an illegal name.

Unbalanced context: %d more PUSHes than POPs

(W internal) The exit code detected an internal inconsistency in how many execution contexts were entered and left.

Unbalanced saves: %d more saves than restores

(W internal) The exit code detected an internal inconsistency in how many values were temporarily localized.

Unbalanced scopes: %d more ENTERs than LEAVEs

(W internal) The exit code detected an internal inconsistency in how many blocks were entered and left.

Unbalanced tmps: %d more allocs than frees

(W internal) The exit code detected an internal inconsistency in how many mortal scalars were allocated and freed.

Undefined format "%s" called

(F) The format indicated doesn't seem to exist. Perhaps it's really in another package? See *perlform*.

Undefined sort subroutine "%s" called

(F) The sort comparison routine specified doesn't seem to exist. Perhaps it's in a different package? See sort in *perlfunc*.

Undefined subroutine &%s called

(F) The subroutine indicated hasn't been defined, or if it was, it has since been undefined.

Undefined subroutine called

(F) The anonymous subroutine you're trying to call hasn't been defined, or if it was, it has since been undefined.

Undefined subroutine in sort

(F) The sort comparison routine specified is declared but doesn't seem to have been defined yet. See sort in *perlfunc*.

Undefined top format "%s" called

(F) The format indicated doesn't seem to exist. Perhaps it's really in another package? See *perlform*.

Undefined value assigned to typeglob

(W misc) An undefined value was assigned to a typeglob, a la `*foo = undef`. This does nothing. It's possible that you really mean `undef *foo`.

%s: Undefined variable

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

unexec of %s into %s failed!

(F) The unexec() routine failed for some reason. See your local FSF representative, who probably put it there in the first place.

Unicode character %s is illegal

(W utf8) Certain Unicode characters have been designated off-limits by the Unicode standard and should not be generated. If you really know what you are doing you can turn off this warning by `no warnings 'utf8';`.

Unknown BYTEORDER

(F) There are no byte-swapping functions for a machine with this byte order.

Unknown open() mode '%s'

(F) The second argument of 3-argument open() is not among the list of valid modes: <, >, >>, +<, +>, +>>, -|, |-, <&, >&.

Unknown PerlIO layer "%s"

(W layer) An attempt was made to push an unknown layer onto the Perl I/O system. (Layers take care of transforming data between external and internal representations.) Note that some layers, such as `mmap`, are not supported in all environments. If your program didn't explicitly request the failing operation, it may be the result of the value of the environment variable PERLIO.

Unknown process %x sent message to prime_env_iter: %s

(P) An error peculiar to VMS. Perl was reading values for %ENV before iterating over it, and someone else stuck a message in the stream of data Perl expected. Someone's very confused, or perhaps trying to subvert Perl's population of %ENV for nefarious purposes.

Unknown "re" subpragma '%s' (known ones are: %s)

You tried to use an unknown subpragma of the "re" pragma.

Unknown switch condition (?(%.2s in regex; marked by <– HERE in m/%s/

(F) The condition part of a (?(condition)if-clause|else-clause) construct is not known. The condition may be lookahead or lookbehind (the condition is true if the lookahead or lookbehind is true), a (?{...}) construct (the condition is true if the code evaluates to a true value), or a number (the condition is true if the set of capturing parentheses named by the number matched).

The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Unknown Unicode option letter '%c'

You specified an unknown Unicode option. See *perlrun* documentation of the `-C` switch for the list of known options.

Unknown Unicode option value %x

You specified an unknown Unicode option. See *perlrun* documentation of the `-C` switch for the list of known options.

Unknown warnings category '%s'

(F) An error issued by the `warnings` pragma. You specified a warnings category that is unknown to perl at this point.

Note that if you want to enable a warnings category registered by a module (e.g. `use warnings 'File::Find'`), you must have imported this module first.

unmatched [in regex; marked by <– HERE in m/%s/

(F) The brackets around a character class must match. If you wish to include a closing bracket in a character class, backslash it or put it first. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

unmatched (in regex; marked by <– HERE in m/%s/

(F) Unbackslashed parentheses must always be balanced in regular expressions. If you're a vi user, the % key is valuable for finding the matching parenthesis. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Unmatched right %s bracket

(F) The lexer counted more closing curly or square brackets than opening ones, so you're probably missing a matching opening bracket. As a general rule, you'll find the missing one (so to speak) near the place you were last editing.

Unquoted string "%s" may clash with future reserved word

(W reserved) You used a bareword that might someday be claimed as a reserved word. It's best to put such a word in quotes, or capitalize it somehow, or insert an underbar into it. You might also declare it as a subroutine.

Unrecognized character %s

(F) The Perl parser has no idea what to do with the specified character in your Perl script (or eval). Perhaps you tried to run a compressed script, a binary program, or a directory as a Perl program.

/%s/: Unrecognized escape \\%c in character class passed through

(W regexp) You used a backslash-character combination which is not recognized by Perl inside character classes. The character was understood literally.

Unrecognized escape \\%c passed through

(W misc) You used a backslash-character combination which is not recognized by Perl.

Unrecognized escape \\%c passed through in regex; marked by <– HERE in m/%s/

(W regexp) You used a backslash-character combination which is not recognized by Perl. This combination appears in an interpolated variable or a `'`-delimited regular expression. The character was understood literally. The <– HERE shows in the regular expression about where the escape was discovered.

Unrecognized signal name "%s"

(F) You specified a signal name to the kill() function that was not recognized. Say `kill -l` in your shell to see the valid signal names on your system.

Unrecognized switch: -%s (-h will show valid options)

(F) You specified an illegal option to Perl. Don't do that. (If you think you didn't do that, check the #! line to see if it's supplying the bad switch on your behalf.)

Unsuccessful %s on filename containing newline

(W newline) A file operation was attempted on a filename, and that operation failed, PROBABLY because the filename contained a newline, PROBABLY because you forgot to chomp() it off. See chomp in *perlfunc*.

Unsupported directory function "%s" called

(F) Your machine doesn't support opendir() and readdir().

Unsupported function %s

(F) This machine doesn't implement the indicated function, apparently. At least, Configure doesn't think so.

Unsupported function fork

(F) Your version of executable does not support forking.

Note that under some systems, like OS/2, there may be different flavors of Perl executables, some of which may support fork, some not. Try changing the name you call Perl by to `perl_`, `perl__`, and so on.

Unsupported script encoding %s

(F) Your program file begins with a Unicode Byte Order Mark (BOM) which declares it to be in a Unicode encoding that Perl cannot read.

Unsupported socket function "%s" called

(F) Your machine doesn't support the Berkeley socket mechanism, or at least that's what Configure thought.

Unterminated attribute list

(F) The lexer found something other than a simple identifier at the start of an attribute, and it wasn't a semicolon or the start of a block. Perhaps you terminated the parameter list of the previous attribute too soon. See *attributes*.

Unterminated attribute parameter in attribute list

(F) The lexer saw an opening (left) parenthesis character while parsing an attribute list, but the matching closing (right) parenthesis character was not found. You may need to add (or remove) a backslash character to get your parentheses to balance. See *attributes*.

Unterminated compressed integer

(F) An argument to unpack("w",...) was incompatible with the BER compressed integer format and could not be converted to an integer. See pack in *perlfunc*.

Unterminated <> operator

(F) The lexer saw a left angle bracket in a place where it was expecting a term, so it's looking for the corresponding right angle bracket, and not finding it. Chances are you left some needed parentheses out earlier in the line, and you really meant a "less than".

untie attempted while %d inner references still exist

(W untie) A copy of the object returned from `tie` (or `tied`) was still valid when `untie` was called.

Usage: POSIX::%s(%s)

(F) You called a POSIX function with incorrect arguments. See FUNCTIONS in *POSIX* for more information.

Usage: Win32::%s(%s)

(F) You called a Win32 function with incorrect arguments. See *Win32* for more information.

Useless (?-%s) - don't use /%s modifier in regex; marked by <– HERE in m/%s/

(W regexp) You have used an internal modifier such as (?-o) that has no meaning unless removed from the entire regexp:

```
    if ($string =~ /(?-o)$pattern/o) { ... }
```

must be written as

```
    if ($string =~ /$pattern/) { ... }
```

The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Useless (?%s) - use /%s modifier in regex; marked by <– HERE in m/%s/

(W regexp) You have used an internal modifier such as (?o) that has no meaning unless applied to the entire regexp:

```
    if ($string =~ /(?o)$pattern/) { ... }
```

must be written as

```
    if ($string =~ /$pattern/o) { ... }
```

The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

Useless use of %s in void context

(W void) You did something without a side effect in a context that does nothing with the return value, such as a statement that doesn't return a value from a block, or the left side of a scalar comma operator. Very often this points not to stupidity on your part, but a failure of Perl to parse your program the way you thought it would. For example, you'd get this if you mixed up your C precedence with Python precedence and said

```
    $one, $two = 1, 2;
```

when you meant to say

```
    ($one, $two) = (1, 2);
```

Another common error is to use ordinary parentheses to construct a list reference when you should be using square or curly brackets, for example, if you say

```
    $array = (1,2);
```

when you should have said

```
    $array = [1,2];
```

The square brackets explicitly turn a list value into a scalar value, while parentheses do not. So when a parenthesized list is evaluated in a scalar context, the comma is treated like C's comma operator, which throws away the left argument, which is not what you want. See *perlref* for more on this.

This warning will not be issued for numerical constants equal to 0 or 1 since they are often used in statements like

```
1 while sub_with_side_effects() ;
```

String constants that would normally evaluate to 0 or 1 are warned about.

Useless use of "re" pragma

(W) You did `use re;` without any arguments. That isn't very useful.

Useless use of sort in scalar context

(W void) You used sort in scalar context, as in :

```
my $x = sort @y;
```

This is not very useful, and perl currently optimizes this away.

Useless use of %s with no values

(W syntax) You used the push() or unshift() function with no arguments apart from the array, like `push(@x)` or `unshift(@foo)`. That won't usually have any effect on the array, so is completely useless. It's possible in principle that push(@tied_array) could have some effect if the array is tied to a class which implements a PUSH method. If so, you can write it as `push(@tied_array,())` to avoid this warning.

"use" not allowed in expression

(F) The "use" keyword is recognized and executed at compile time, and returns no useful value. See *perlmod*.

Use of bare << to mean <<"" is deprecated

(D deprecated) You are now encouraged to use the explicitly quoted form if you wish to use an empty line as the terminator of the here-document.

Use of chdir(") or chdir(undef) as chdir() deprecated

(D deprecated) chdir() with no arguments is documented to change to $ENV{HOME} or $ENV{LOGDIR}. chdir(undef) and chdir(") share this behavior, but that has been deprecated. In future versions they will simply fail.

Be careful to check that what you pass to chdir() is defined and not blank, else you might find yourself in your home directory.

Use of /c modifier is meaningless in s///

(W regexp) You used the /c modifier in a substitution. The /c modifier is not presently meaningful in substitutions.

Use of /c modifier is meaningless without /g

(W regexp) You used the /c modifier with a regex operand, but didn't use the /g modifier. Currently, /c is meaningful only when /g is used. (This may change in the future.)

Use of freed value in iteration

(F) Perhaps you modified the iterated array within the loop? This error is typically caused by code like the following:

```
@a = (3,4);
@a = () for (1,2,@a);
```

You are not supposed to modify arrays while they are being iterated over. For speed and efficiency reasons, Perl internally does not do full reference-counting of iterated items, hence deleting such an item in the middle of an iteration causes Perl to see a freed value.

Use of *glob{FILEHANDLE} is deprecated

(D deprecated) You are now encouraged to use the shorter *glob{IO} form to access the filehandle slot within a typeglob.

Use of /g modifier is meaningless in split

(W regexp) You used the /g modifier on the pattern for a `split` operator. Since `split` always tries to match the pattern repeatedly, the `/g` has no effect.

Use of implicit split to @_ is deprecated

(D deprecated) It makes a lot of work for the compiler when you clobber a subroutine's argument list, so it's better if you assign the results of a split() explicitly to an array (or list).

Use of inherited AUTOLOAD for non-method %s() is deprecated

(D deprecated) As an (ahem) accidental feature, `AUTOLOAD` subroutines are looked up as methods (using the `@ISA` hierarchy) even when the subroutines to be autoloaded were called as plain functions (e.g. `Foo::bar()`), not as methods (e.g. `Foo->bar()` or `$obj->bar()`).

This bug will be rectified in future by using method lookup only for methods' `AUTOLOAD`s. However, there is a significant base of existing code that may be using the old behavior. So, as an interim step, Perl currently issues an optional warning when non-methods use inherited `AUTOLOAD`s.

The simple rule is: Inheritance will not work when autoloading non-methods. The simple fix for old code is: In any module that used to depend on inheriting `AUTOLOAD` for non-methods from a base class named `BaseClass`, execute `*AUTOLOAD = \&BaseClass::AUTOLOAD` during startup.

In code that currently says `use AutoLoader; @ISA = qw(AutoLoader);` you should remove AutoLoader from @ISA and change `use AutoLoader;` to `use AutoLoader 'AUTOLOAD';`.

Use of %s in printf format not supported

(F) You attempted to use a feature of printf that is accessible from only C. This usually means there's a better way to do it in Perl.

Use of $ * is deprecated

(D deprecated) This variable magically turned on multi-line pattern matching, both for you and for any luckless subroutine that you happen to call. You should use the new `//m` and `//s` modifiers now to do that without the dangerous action-at-a-distance effects of `$*`.

Use of $ # is deprecated

(D deprecated) This was an ill-advised attempt to emulate a poorly defined **awk** feature. Use an explicit printf() or sprintf() instead.

Use of %s is deprecated

(D deprecated) The construct indicated is no longer recommended for use, generally because there's a better way to do it, and also because the old way has bad side effects.

Use of -l on filehandle %s

(W io) A filehandle represents an opened file, and when you opened the file it already went past any symlink you are presumably trying to look for. The operation returned `undef`. Use a filename instead.

Use of "package" with no arguments is deprecated

(D deprecated) You used the `package` keyword without specifying a package name. So no namespace is current at all. Using this can cause many otherwise reasonable constructs to fail in baffling ways. `use strict;` instead.

Use of reference "%s" as array index

(W misc) You tried to use a reference as an array index; this probably isn't what you mean, because references in numerical context tend to be huge numbers, and so usually indicates programmer error.

If you really do mean it, explicitly numify your reference, like so: `$array[0+$ref]`. This warning is not given for overloaded objects, either, because you can overload the numification and stringification operators and then you assumedly know what you are doing.

Use of reserved word "%s" is deprecated

(D deprecated) The indicated bareword is a reserved word. Future versions of perl may use it as a keyword, so you're better off either explicitly quoting the word in a manner appropriate for its context of use, or using a different name altogether. The warning can be suppressed for subroutine names by either adding a `&` prefix, or using a package qualifier, e.g. `&our()`, or `Foo::our()`.

Use of tainted arguments in %s is deprecated

(W taint, deprecated) You have supplied `system()` or `exec()` with multiple arguments and at least one of them is tainted. This used to be allowed but will become a fatal error in a future version of perl. Untaint your arguments. See *perlsec*.

Use of uninitialized value%s

(W uninitialized) An undefined value was used as if it were already defined. It was interpreted as a "" or a 0, but maybe it was a mistake. To suppress this warning assign a defined value to your variables.

To help you figure out what was undefined, perl tells you what operation you used the undefined value in. Note, however, that perl optimizes your program and the operation displayed in the warning may not necessarily appear literally in your program. For example, `"that $foo"` is usually optimized into `"that " . $foo`, and the warning will refer to the `concatenation (.)` operator, even though there is no `.` in your program.

Using a hash as a reference is deprecated

(D deprecated) You tried to use a hash as a reference, as in `%foo->{"bar"}` or `%$ref->{"hello"}`. Versions of perl <= 5.6.1 used to allow this syntax, but shouldn't have. It is now deprecated, and will be removed in a future version.

Using an array as a reference is deprecated

(D deprecated) You tried to use an array as a reference, as in `@foo->[23]` or `@$ref->[99]`. Versions of perl <= 5.6.1 used to allow this syntax, but shouldn't have. It is now deprecated, and will be removed in a future version.

UTF-16 surrogate %s

(W utf8) You tried to generate half of an UTF-16 surrogate by requesting a Unicode character between the code points 0xD800 and 0xDFFF (inclusive). That range is reserved exclusively for the use of UTF-16 encoding (by having two 16-bit UCS-2 characters); but Perl encodes its characters in UTF-8, so what you got is a very illegal character. If you really know what you are doing you can turn off this warning by `no warnings 'utf8';`.

Value of %s can be "0"; test with defined()

(W misc) In a conditional expression, you used <HANDLE>, <*> (glob), `each()`, or `readdir()` as a boolean value. Each of these constructs can return a value of "0"; that would make the conditional expression false, which is probably not what you intended. When using these constructs in conditional expressions, test their values with the `defined` operator.

Value of CLI symbol "%s" too long

(W misc) A warning peculiar to VMS. Perl tried to read the value of an %ENV element from a CLI symbol table, and found a resultant string longer than 1024 characters. The return value has been truncated to 1024 characters.

Variable "%s" is not imported%s

(F) While "use strict" in effect, you referred to a global variable that you apparently thought was imported from another module, because something else of the same name (usually a subroutine) is exported by that module. It usually means you put the wrong funny character on the front of your variable.

Variable length lookbehind not implemented in regex; marked by <– HERE in m/%s/

(F) Lookbehind is allowed only for subexpressions whose length is fixed and known at compile time. The <– HERE shows in the regular expression about where the problem was discovered. See *perlre*.

"%s" variable %s masks earlier declaration in same %s

(W misc) A "my" or "our" variable has been redeclared in the current scope or statement, effectively eliminating all access to the previous instance. This is almost always a typographical error. Note that the earlier variable will still exist until the end of the scope or until all closure referents to it are destroyed.

Variable "%s" may be unavailable

(W closure) An inner (nested) *anonymous* subroutine is inside a *named* subroutine, and outside that is another subroutine; and the anonymous (innermost) subroutine is referencing a lexical variable defined in the outermost subroutine. For example:

```
sub outermost { my $a; sub middle { sub { $a } } }
```

If the anonymous subroutine is called or referenced (directly or indirectly) from the outermost subroutine, it will share the variable as you would expect. But if the anonymous subroutine is called or referenced when the outermost subroutine is not active, it will see the value of the shared variable as it was before and during the *first* call to the outermost subroutine, which is probably not what you want.

In these circumstances, it is usually best to make the middle subroutine anonymous, using the `sub {}` syntax. Perl has specific support for shared variables in nested anonymous subroutines; a named subroutine in between interferes with this feature.

Variable syntax

(A) You've accidentally run your script through **csh** instead of Perl. Check the #! line, or manually feed your script into Perl yourself.

Variable "%s" will not stay shared

(W closure) An inner (nested) *named* subroutine is referencing a lexical variable defined in an outer subroutine.

When the inner subroutine is called, it will probably see the value of the outer subroutine's variable as it was before and during the *first* call to the outer subroutine; in this case, after the first call to the outer subroutine is complete, the inner and outer subroutines will no longer share a common value for the variable. In other words, the variable will no longer be shared.

Furthermore, if the outer subroutine is anonymous and references a lexical variable outside itself, then the outer and inner subroutines will *never* share the given variable.

This problem can usually be solved by making the inner subroutine anonymous, using the `sub {}` syntax. When inner anonymous subs that reference variables in outer subroutines are called or referenced, they are automatically rebound to the current values of such variables.

Version number must be a constant number

(P) The attempt to translate a `use Module n.n LIST` statement into its equivalent `BEGIN` block found an internal inconsistency with the version number.

Warning: something's wrong

(W) You passed warn() an empty string (the equivalent of `warn ""`) or you called it with no args and `$_` was empty.

Warning: unable to close filehandle %s properly

(S) The implicit close() done by an open() got an error indication on the close(). This usually indicates your file system ran out of disk space.

Warning: Use of "%s" without parentheses is ambiguous

(S ambiguous) You wrote a unary operator followed by something that looks like a binary operator that could also have been interpreted as a term or unary operator. For instance, if you know that the rand function has a default argument of 1.0, and you write

```
rand + 5;
```

you may THINK you wrote the same thing as

```
rand() + 5;
```

but in actual fact, you got

```
    rand(+5);
```

So put in parentheses to say what you really mean.

Wide character in %s

(W utf8) Perl met a wide character (>255) when it wasn't expecting one. This warning is by default on for I/O (like print). The easiest way to quiet this warning is simply to add the `:utf8` layer to the output, e.g. `binmode STDOUT, ':utf8'`. Another way to turn off the warning is to add `no warnings 'utf8';` but that is often closer to cheating. In general, you are supposed to explicitly mark the filehandle with an encoding, see *open* and binmode in *perlfunc*.

Within [-length '%c' not allowed]

(F) The count in the (un)pack template may be replaced by `[TEMPLATE]` only if `TEMPLATE` always matches the same amount of packed bytes that can be determined from the template alone. This is not possible if it contains an of the codes @, /, U, u, w or a *-length. Redesign the template.

write() on closed filehandle %s

(W closed) The filehandle you're writing to got itself closed sometime before now. Check your control flow.

%s "\x%s" does not map to Unicode

When reading in different encodings Perl tries to map everything into Unicode characters. The bytes you read in are not legal in this encoding, for example

```
    utf8 "\xE4" does not map to Unicode
```

if you try to read in the a-diaereses Latin-1 as UTF-8.

'X' outside of string

(F) You had a (un)pack template that specified a relative position before the beginning of the string being (un)packed. See pack in *perlfunc*.

'x' outside of string in unpack

(F) You had a pack template that specified a relative position after the end of the string being unpacked. See pack in *perlfunc*.

Xsub "%s" called in sort

(F) The use of an external subroutine as a sort comparison is not yet supported.

Xsub called in sort

(F) The use of an external subroutine as a sort comparison is not yet supported.

YOU HAVEN'T DISABLED SET-ID SCRIPTS IN THE KERNEL YET!

(F) And you probably never will, because you probably don't have the sources to your kernel, and your vendor probably doesn't give a rip about what you want. Your best bet is to put a setuid C wrapper around your script.

You need to quote "%s"

(W syntax) You assigned a bareword as a signal handler name. Unfortunately, you already have a subroutine of that name declared, which means that Perl 5 will try to call the subroutine when the assignment is executed, which is probably not what you want. (If it IS what you want, put an & in front.)

Your random numbers are not that random

(F) When trying to initialise the random seed for hashes, Perl could not get any randomness out of your system. This usually indicates Something Very Wrong.

Chapter 37

perllexwarn

Perl Lexical Warnings

37.1 DESCRIPTION

The `use warnings` pragma is a replacement for both the command line flag **-w** and the equivalent Perl variable, `$^W`.

The pragma works just like the existing "strict" pragma. This means that the scope of the warning pragma is limited to the enclosing block. It also means that the pragma setting will not leak across files (via `use`, `require` or `do`). This allows authors to independently define the degree of warning checks that will be applied to their module.

By default, optional warnings are disabled, so any legacy code that doesn't attempt to control the warnings will work unchanged.

All warnings are enabled in a block by either of these:

```
    use warnings ;
    use warnings 'all' ;
```

Similarly all warnings are disabled in a block by either of these:

```
    no warnings ;
    no warnings 'all' ;
```

For example, consider the code below:

```
    use warnings ;
    my @a ;
    {
        no warnings ;
        my $b = @a[0] ;
    }
    my $c = @a[0];
```

The code in the enclosing block has warnings enabled, but the inner block has them disabled. In this case that means the assignment to the scalar `$c` will trip the `"Scalar value @a[0] better written as $a[0]"` warning, but the assignment to the scalar `$b` will not.

37.1.1 Default Warnings and Optional Warnings

Before the introduction of lexical warnings, Perl had two classes of warnings: mandatory and optional.

As its name suggests, if your code tripped a mandatory warning, you would get a warning whether you wanted it or not. For example, the code below would always produce an `"isn't numeric"` warning about the "2:".

```
my $a = "2:" + 3;
```

With the introduction of lexical warnings, mandatory warnings now become *default* warnings. The difference is that although the previously mandatory warnings are still enabled by default, they can then be subsequently enabled or disabled with the lexical warning pragma. For example, in the code below, an `"isn't numeric"` warning will only be reported for the `$a` variable.

```
my $a = "2:" + 3;
no warnings ;
my $b = "2:" + 3;
```

Note that neither the **-w** flag or the `$^W` can be used to disable/enable default warnings. They are still mandatory in this case.

37.1.2 What's wrong with -w and `$^W`

Although very useful, the big problem with using **-w** on the command line to enable warnings is that it is all or nothing. Take the typical scenario when you are writing a Perl program. Parts of the code you will write yourself, but it's very likely that you will make use of pre-written Perl modules. If you use the **-w** flag in this case, you end up enabling warnings in pieces of code that you haven't written.

Similarly, using `$^W` to either disable or enable blocks of code is fundamentally flawed. For a start, say you want to disable warnings in a block of code. You might expect this to be enough to do the trick:

```
 {
     local ($^W) = 0 ;
     my $a =+ 2 ;
     my $b ; chop $b ;
 }
```

When this code is run with the **-w** flag, a warning will be produced for the `$a` line – `"Reversed += operator"`.

The problem is that Perl has both compile-time and run-time warnings. To disable compile-time warnings you need to rewrite the code like this:

```
 {
     BEGIN { $^W = 0 }
     my $a =+ 2 ;
     my $b ; chop $b ;
 }
```

The other big problem with `$^W` is the way you can inadvertently change the warning setting in unexpected places in your code. For example, when the code below is run (without the **-w** flag), the second call to `doit` will trip a `"Use of uninitialized value"` warning, whereas the first will not.

```
sub doit
{
    my $b ; chop $b ;
}
```

```
    doit() ;

    {
        local ($^W) = 1 ;
        doit()
    }
```

This is a side-effect of `$^W` being dynamically scoped.

Lexical warnings get around these limitations by allowing finer control over where warnings can or can't be tripped.

37.1.3 Controlling Warnings from the Command Line

There are three Command Line flags that can be used to control when warnings are (or aren't) produced:

-w

This is the existing flag. If the lexical warnings pragma is **not** used in any of you code, or any of the modules that you use, this flag will enable warnings everywhere. See Backward Compatibility for details of how this flag interacts with lexical warnings.

-W

If the **-W** flag is used on the command line, it will enable all warnings throughout the program regardless of whether warnings were disabled locally using `no warnings` or `$^W =0`. This includes all files that get included via `use`, `require` or `do`. Think of it as the Perl equivalent of the "lint" command.

-X

Does the exact opposite to the **-W** flag, i.e. it disables all warnings.

37.1.4 Backward Compatibility

If you are used with working with a version of Perl prior to the introduction of lexically scoped warnings, or have code that uses both lexical warnings and `$^W`, this section will describe how they interact.

How Lexical Warnings interact with **-w**/`$^W`:

1. If none of the three command line flags (**-w**, **-W** or **-X**) that control warnings is used and neither `$^W` or the `warnings` pragma are used, then default warnings will be enabled and optional warnings disabled. This means that legacy code that doesn't attempt to control the warnings will work unchanged.

2. The **-w** flag just sets the global `$^W` variable as in 5.005 – this means that any legacy code that currently relies on manipulating `$^W` to control warning behavior will still work as is.

3. Apart from now being a boolean, the `$^W` variable operates in exactly the same horrible uncontrolled global way, except that it cannot disable/enable default warnings.

4. If a piece of code is under the control of the `warnings` pragma, both the `$^W` variable and the **-w** flag will be ignored for the scope of the lexical warning.

5. The only way to override a lexical warnings setting is with the **-W** or **-X** command line flags.

The combined effect of 3 & 4 is that it will allow code which uses the `warnings` pragma to control the warning behavior of $^W-type code (using a `local $^W=0`) if it really wants to, but not vice-versa.

37.1.5 Category Hierarchy

A hierarchy of "categories" have been defined to allow groups of warnings to be enabled/disabled in isolation.

The current hierarchy is:

```
all -+
     |
     +- closure
     |
     +- deprecated
     |
     +- exiting
     |
     +- glob
     |
     +- io -----------+
     |                |
     |                +- closed
     |                |
     |                +- exec
     |                |
     |                +- layer
     |                |
     |                +- newline
     |                |
     |                +- pipe
     |                |
     |                +- unopened
     |
     +- misc
     |
     +- numeric
     |
     +- once
     |
     +- overflow
     |
     +- pack
     |
     +- portable
     |
     +- recursion
     |
     +- redefine
     |
     +- regexp
     |
     +- severe -------+
     |                |
     |                +- debugging
     |                |
     |                +- inplace
     |                |
     |                +- internal
     |                |
     |                +- malloc
```

```
       |
       +- signal
       |
       +- substr
       |
       +- syntax -------+
       |                |
       |                +- ambiguous
       |                |
       |                +- bareword
       |                |
       |                +- digit
       |                |
       |                +- parenthesis
       |                |
       |                +- precedence
       |                |
       |                +- printf
       |                |
       |                +- prototype
       |                |
       |                +- qw
       |                |
       |                +- reserved
       |                |
       |                +- semicolon
       |
       +- taint
       |
       +- threads
       |
       +- uninitialized
       |
       +- unpack
       |
       +- untie
       |
       +- utf8
       |
       +- void
       |
       +- y2k
```

Just like the "strict" pragma any of these categories can be combined

```
    use warnings qw(void redefine) ;
    no warnings qw(io syntax untie) ;
```

Also like the "strict" pragma, if there is more than one instance of the `warnings` pragma in a given scope the cumulative effect is additive.

```
    use warnings qw(void) ; # only "void" warnings enabled
    ...
    use warnings qw(io) ;   # only "void" & "io" warnings enabled
    ...
    no warnings qw(void) ;  # only "io" warnings enabled
```

To determine which category a specific warning has been assigned to see *perldiag*.

Note: In Perl 5.6.1, the lexical warnings category "deprecated" was a sub-category of the "syntax" category. It is now a top-level category in its own right.

37.1.6 Fatal Warnings

The presence of the word "FATAL" in the category list will escalate any warnings detected from the categories specified in the lexical scope into fatal errors. In the code below, the use of `time`, `length` and `join` can all produce a `"Useless use of xxx in void context"` warning.

```
    use warnings ;

    time ;

    {
        use warnings FATAL => qw(void) ;
        length "abc" ;
    }

    join "", 1,2,3 ;

    print "done\n" ;
```

When run it produces this output

```
    Useless use of time in void context at fatal line 3.
    Useless use of length in void context at fatal line 7.
```

The scope where `length` is used has escalated the `void` warnings category into a fatal error, so the program terminates immediately it encounters the warning.

To explicitly turn off a "FATAL" warning you just disable the warning it is associated with. So, for example, to disable the "void" warning in the example above, either of these will do the trick:

```
    no warnings qw(void);
    no warnings FATAL => qw(void);
```

If you want to downgrade a warning that has been escalated into a fatal error back to a normal warning, you can use the "NONFATAL" keyword. For example, the code below will promote all warnings into fatal errors, except for those in the "syntax" category.

```
    use warnings FATAL => 'all', NONFATAL => 'syntax';
```

37.1.7 Reporting Warnings from a Module

The `warnings` pragma provides a number of functions that are useful for module authors. These are used when you want to report a module-specific warning to a calling module has enabled warnings via the `warnings` pragma.

Consider the module `MyMod::Abc` below.

```
    package MyMod::Abc;

    use warnings::register;
    sub open {
        my $path = shift ;
        if ($path !~ m#^/#) {
            warnings::warn("changing relative path to /var/abc")
                if warnings::enabled();
            $path = "/var/abc/$path";
        }
    }

    1 ;
```

The call to `warnings::register` will create a new warnings category called "MyMod::abc", i.e. the new category name matches the current package name. The `open` function in the module will display a warning message if it gets given a relative path as a parameter. This warnings will only be displayed if the code that uses `MyMod::Abc` has actually enabled them with the `warnings` pragma like below.

```
    use MyMod::Abc;
    use warnings 'MyMod::Abc';
    ...
    abc::open("../fred.txt");
```

It is also possible to test whether the pre-defined warnings categories are set in the calling module with the `warnings::enabled` function. Consider this snippet of code:

```
    package MyMod::Abc;

    sub open {
        warnings::warnif("deprecated",
                         "open is deprecated, use new instead") ;
        new(@_) ;
    }

    sub new
    ...
    1 ;
```

The function `open` has been deprecated, so code has been included to display a warning message whenever the calling module has (at least) the "deprecated" warnings category enabled. Something like this, say.

```
    use warnings 'deprecated';
    use MyMod::Abc;
    ...
    MyMod::Abc::open($filename) ;
```

Either the `warnings::warn` or `warnings::warnif` function should be used to actually display the warnings message. This is because they can make use of the feature that allows warnings to be escalated into fatal errors. So in this case

```
    use MyMod::Abc;
    use warnings FATAL => 'MyMod::Abc';
    ...
    MyMod::Abc::open('../fred.txt');
```

the `warnings::warnif` function will detect this and die after displaying the warning message.

The three warnings functions, `warnings::warn`, `warnings::warnif` and `warnings::enabled` can optionally take an object reference in place of a category name. In this case the functions will use the class name of the object as the warnings category.

Consider this example:

```
    package Original ;

    no warnings ;
    use warnings::register ;

    sub new
    {
        my $class = shift ;
        bless [], $class ;
    }

    sub check
    {
        my $self = shift ;
        my $value = shift ;

        if ($value % 2 && warnings::enabled($self))
          { warnings::warn($self, "Odd numbers are unsafe") }
    }

    sub doit
    {
        my $self = shift ;
        my $value = shift ;
        $self->check($value) ;
        # ...
    }

    1 ;

    package Derived ;

    use warnings::register ;
    use Original ;
    our @ISA = qw( Original ) ;
    sub new
    {
        my $class = shift ;
        bless [], $class ;
    }

    1 ;
```

The code below makes use of both modules, but it only enables warnings from `Derived`.

```
    use Original ;
    use Derived ;
    use warnings 'Derived';
    my $a = new Original ;
    $a->doit(1) ;
    my $b = new Derived ;
    $a->doit(1) ;
```

When this code is run only the `Derived` object, `$b`, will generate a warning.

```
    Odd numbers are unsafe at main.pl line 7
```

Notice also that the warning is reported at the line where the object is first used.

37.2 TODO

```
  perl5db.pl
    The debugger saves and restores C<$^W> at runtime. I haven't checked
    whether the debugger will still work with the lexical warnings
    patch applied.

  diagnostics.pm
    I *think* I've got diagnostics to work with the lexical warnings
    patch, but there were design decisions made in diagnostics to work
    around the limitations of C<$^W>. Now that those limitations are gone,
    the module should be revisited.

  document calling the warnings::* functions from XS
```

perldebug

Perl debugging

38.1 DESCRIPTION

First of all, have you tried using the **-w** switch?

If you're new to the Perl debugger, you may prefer to read *perldebtut*, which is a tutorial introduction to the debugger .

38.2 The Perl Debugger

If you invoke Perl with the **-d** switch, your script runs under the Perl source debugger. This works like an interactive Perl environment, prompting for debugger commands that let you examine source code, set breakpoints, get stack backtraces, change the values of variables, etc. This is so convenient that you often fire up the debugger all by itself just to test out Perl constructs interactively to see what they do. For example:

```
    $ perl -d -e 42
```

In Perl, the debugger is not a separate program the way it usually is in the typical compiled environment. Instead, the **-d** flag tells the compiler to insert source information into the parse trees it's about to hand off to the interpreter. That means your code must first compile correctly for the debugger to work on it. Then when the interpreter starts up, it preloads a special Perl library file containing the debugger.

The program will halt *right before* the first run-time executable statement (but see below regarding compile-time statements) and ask you to enter a debugger command. Contrary to popular expectations, whenever the debugger halts and shows you a line of code, it always displays the line it's *about* to execute, rather than the one it has just executed.

Any command not recognized by the debugger is directly executed (`eval`'d) as Perl code in the current package. (The debugger uses the DB package for keeping its own state information.)

Note that the said `eval` is bound by an implicit scope. As a result any newly introduced lexical variable or any modified capture buffer content is lost after the eval. The debugger is a nice environment to learn Perl, but if you interactively experiment using material which should be in the same scope, stuff it in one line.

For any text entered at the debugger prompt, leading and trailing whitespace is first stripped before further processing. If a debugger command coincides with some function in your own program, merely precede the function with something that doesn't look like a debugger command, such as a leading `;` or perhaps a `+`, or by wrapping it with parentheses or braces.

38.2.1 Debugger Commands

The debugger understands the following commands:

h

Prints out a summary help message

h [command]

Prints out a help message for the given debugger command.

h h

The special argument of `h h` produces the entire help page, which is quite long.

If the output of the `h h` command (or any command, for that matter) scrolls past your screen, precede the command with a leading pipe symbol so that it's run through your pager, as in

```
    DB> |h h
```

You may change the pager which is used via `o pager=...` command.

p expr

Same as `print {$DB::OUT} expr` in the current package. In particular, because this is just Perl's own `print` function, this means that nested data structures and objects are not dumped, unlike with the `x` command.

The `DB::OUT` filehandle is opened to */dev/tty*, regardless of where STDOUT may be redirected to.

x [maxdepth expr]

Evaluates its expression in list context and dumps out the result in a pretty-printed fashion. Nested data structures are printed out recursively, unlike the real `print` function in Perl. When dumping hashes, you'll probably prefer 'x \%h' rather than 'x %h'. See *Dumpvalue* if you'd like to do this yourself.

The output format is governed by multiple options described under §38.2.2.

If the `maxdepth` is included, it must be a numeral *N*; the value is dumped only *N* levels deep, as if the `dumpDepth` option had been temporarily set to *N*.

V [pkg [vars]]

Display all (or some) variables in package (defaulting to `main`) using a data pretty-printer (hashes show their keys and values so you see what's what, control characters are made printable, etc.). Make sure you don't put the type specifier (like `$`) there, just the symbol names, like this:

```
    V DB filename line
```

Use `~pattern` and `!pattern` for positive and negative regexes.

This is similar to calling the `x` command on each applicable var.

X [vars]

Same as `V currentpackage [vars]`.

y [level [vars]]

Display all (or some) lexical variables (mnemonic: `mY` variables) in the current scope or *level* scopes higher. You can limit the variables that you see with *vars* which works exactly as it does for the `V` and `X` commands. Requires the `PadWalker` module version 0.08 or higher; will warn if this isn't installed. Output is pretty-printed in the same style as for `V` and the format is controlled by the same options.

T

Produce a stack backtrace. See below for details on its output.

s [expr]

Single step. Executes until the beginning of another statement, descending into subroutine calls. If an expression is supplied that includes function calls, it too will be single-stepped.

n [expr]

Next. Executes over subroutine calls, until the beginning of the next statement. If an expression is supplied that includes function calls, those functions will be executed with stops before each statement.

r

Continue until the return from the current subroutine. Dump the return value if the `PrintRet` option is set (default).

<CR>

Repeat last `n` or `s` command.

c [line|sub]

Continue, optionally inserting a one-time-only breakpoint at the specified line or subroutine.

l

List next window of lines.

l min+incr

List `incr+1` lines starting at `min`.

l min-max

List lines `min` through `max`. `l -` is synonymous to `-`.

l line

List a single line.

l subname

List first window of lines from subroutine. *subname* may be a variable that contains a code reference.

-

List previous window of lines.

v [line]

View a few lines of code around the current line.

.

Return the internal debugger pointer to the line last executed, and print out that line.

f filename

Switch to viewing a different file or `eval` statement. If *filename* is not a full pathname found in the values of %INC, it is considered a regex.

`eval`ed strings (when accessible) are considered to be filenames: `f (eval 7)` and `f eval 7\b` access the body of the 7th `eval`ed string (in the order of execution). The bodies of the currently executed `eval` and of `eval`ed strings that define subroutines are saved and thus accessible.

/pattern/

Search forwards for pattern (a Perl regex); final / is optional. The search is case-insensitive by default.

?pattern?

Search backwards for pattern; final ? is optional. The search is case-insensitive by default.

L [abw]

List (default all) actions, breakpoints and watch expressions

**S [[! ** regex]]

List subroutine names [not] matching the regex.

t

Toggle trace mode (see also the `AutoTrace` option).

t expr

Trace through execution of `expr`. See Frame Listing Output Examples in *perldebguts* for examples.

b

Sets breakpoint on current line

**b [line ** [condition]]

Set a breakpoint before the given line. If a condition is specified, it's evaluated each time the statement is reached: a breakpoint is taken only if the condition is true. Breakpoints may only be set on lines that begin an executable statement. Conditions don't use `if`:

```
b 237 $x > 30
b 237 ++$count237 < 11
b 33 /pattern/i
```

b subname [condition]

Set a breakpoint before the first line of the named subroutine. *subname* may be a variable containing a code reference (in this case *condition* is not supported).

b postpone subname [condition]

Set a breakpoint at first line of subroutine after it is compiled.

b load filename

Set a breakpoint before the first executed line of the *filename*, which should be a full pathname found amongst the %INC values.

b compile subname

Sets a breakpoint before the first statement executed after the specified subroutine is compiled.

B line

Delete a breakpoint from the specified *line*.

B *

Delete all installed breakpoints.

**a [line ** command]

Set an action to be done before the line is executed. If *line* is omitted, set an action on the line about to be executed. The sequence of steps taken by the debugger is

```
  1. check for a breakpoint at this line
  2. print the line if necessary (tracing)
  3. do any actions associated with that line
  4. prompt user if at a breakpoint or in single-step
  5. evaluate line
```

For example, this will print out $foo every time line 53 is passed:

```
    a 53 print "DB FOUND $foo\n"
```

A line

Delete an action from the specified line.

A *

Delete all installed actions.

w expr

Add a global watch-expression. We hope you know what one of these is, because they're supposed to be obvious.

W expr

Delete watch-expression

W *

Delete all watch-expressions.

o

Display all options

o booloption ...

Set each listed Boolean option to the value 1.

o anyoption? ...

Print out the value of one or more options.

o option=value ...

Set the value of one or more options. If the value has internal whitespace, it should be quoted. For example, you could set `o pager="less -MQeicsNfr"` to call **less** with those specific options. You may use either single or double quotes, but if you do, you must escape any embedded instances of same sort of quote you began with, as well as any escaping any escapes that immediately precede that quote but which are not meant to escape the quote itself. In other words, you follow single-quoting rules irrespective of the quote; eg: `o option='this isn\'t bad'` or `o option="She said, \"Isn't it?\""`.

For historical reasons, the `=value` is optional, but defaults to 1 only where it is safe to do so–that is, mostly for Boolean options. It is always better to assign a specific value using `=`. The `option` can be abbreviated, but for clarity probably should not be. Several options can be set together. See §38.2.2 for a list of these.

< **?**

List out all pre-prompt Perl command actions.

< **[command**]

Set an action (Perl command) to happen before every debugger prompt. A multi-line command may be entered by backslashing the newlines.

< *****

Delete all pre-prompt Perl command actions.

<< **command**

Add an action (Perl command) to happen before every debugger prompt. A multi-line command may be entered by backwhacking the newlines.

> **?**

List out post-prompt Perl command actions.

> **command**

Set an action (Perl command) to happen after the prompt when you've just given a command to return to executing the script. A multi-line command may be entered by backslashing the newlines (we bet you couldn't've guessed this by now).

> *

Delete all post-prompt Perl command actions.

>> **command**

Adds an action (Perl command) to happen after the prompt when you've just given a command to return to executing the script. A multi-line command may be entered by backslashing the newlines.

{ ?

List out pre-prompt debugger commands.

{ [command]

Set an action (debugger command) to happen before every debugger prompt. A multi-line command may be entered in the customary fashion.

Because this command is in some senses new, a warning is issued if you appear to have accidentally entered a block instead. If that's what you mean to do, write it as with `;{ ... }` or even `do { ... }`.

{ *

Delete all pre-prompt debugger commands.

{{ command

Add an action (debugger command) to happen before every debugger prompt. A multi-line command may be entered, if you can guess how: see above.

! number

Redo a previous command (defaults to the previous command).

! -number

Redo number'th previous command.

! pattern

Redo last command that started with pattern. See `o recallCommand`, too.

!! cmd

Run cmd in a subprocess (reads from DB::IN, writes to DB::OUT) See `o shellBang`, also. Note that the user's current shell (well, their `$ENV{SHELL}` variable) will be used, which can interfere with proper interpretation of exit status or signal and coredump information.

source file

Read and execute debugger commands from *file*. *file* may itself contain `source` commands.

H -number

Display last n commands. Only commands longer than one character are listed. If *number* is omitted, list them all.

q or ˆD

Quit. ("quit" doesn't work for this, unless you've made an alias) This is the only supported way to exit the debugger, though typing `exit` twice might work.

Set the `inhibit_exit` option to 0 if you want to be able to step off the end the script. You may also need to set $finished to 0 if you want to step through global destruction.

R

Restart the debugger by `exec()`ing a new session. We try to maintain your history across this, but internal settings and command-line options may be lost.

The following setting are currently preserved: history, breakpoints, actions, debugger options, and the Perl command-line options **-w**, **-I**, and **-e**.

|dbcmd

Run the debugger command, piping DB::OUT into your current pager.

||dbcmd

Same as `|dbcmd` but DB::OUT is temporarily `select`ed as well.

= [alias value]

Define a command alias, like

```
= quit q
```

or list current aliases.

command

Execute command as a Perl statement. A trailing semicolon will be supplied. If the Perl statement would otherwise be confused for a Perl debugger, use a leading semicolon, too.

m expr

List which methods may be called on the result of the evaluated expression. The expression may evaluated to a reference to a blessed object, or to a package name.

M

Displays all loaded modules and their versions

man [manpage]

Despite its name, this calls your system's default documentation viewer on the given page, or on the viewer itself if *manpage* is omitted. If that viewer is **man**, the current `Config` information is used to invoke **man** using the proper MANPATH or **-M** *manpath* option. Failed lookups of the form `XXX` that match known manpages of the form *perlXXX* will be retried. This lets you type `man debug` or `man op` from the debugger.

On systems traditionally bereft of a usable **man** command, the debugger invokes **perldoc**. Occasionally this determination is incorrect due to recalcitrant vendors or rather more felicitously, to enterprising users. If you fall into either category, just manually set the $DB::doccmd variable to whatever viewer to view the Perl documentation on your system. This may be set in an rc file, or through direct assignment. We're still waiting for a working example of something along the lines of:

```
$DB::doccmd = 'netscape -remote http://something.here/';
```

38.2.2 Configurable Options

The debugger has numerous options settable using the `o` command, either interactively or from the environment or an rc file. (./.perldb or ˜/.perldb under Unix.)

`recallCommand`, `ShellBang`

The characters used to recall command or spawn shell. By default, both are set to `!`, which is unfortunate.

`pager`

Program to use for output of pager-piped commands (those beginning with a | character.) By default, `$ENV{PAGER}` will be used. Because the debugger uses your current terminal characteristics for bold and underlining, if the chosen pager does not pass escape sequences through unchanged, the output of some debugger commands will not be readable when sent through the pager.

`tkRunning`

Run Tk while prompting (with ReadLine).

`signalLevel`, `warnLevel`, `dieLevel`

Level of verbosity. By default, the debugger leaves your exceptions and warnings alone, because altering them can break correctly running programs. It will attempt to print a message when uncaught INT, BUS, or SEGV signals arrive. (But see the mention of signals in *BUGS* below.)

To disable this default safe mode, set these values to something higher than 0. At a level of 1, you get backtraces upon receiving any kind of warning (this is often annoying) or exception (this is often valuable). Unfortunately, the debugger cannot discern fatal exceptions from non-fatal ones. If `dieLevel` is even 1, then your non-fatal exceptions are also traced and unceremoniously altered if they came from `eval'd` strings or from any kind of `eval` within modules you're attempting to load. If `dieLevel` is 2, the debugger doesn't care where they came from: It usurps your exception handler and prints out a trace, then modifies all exceptions with its own embellishments. This may perhaps be useful for some tracing purposes, but tends to hopelessly destroy any program that takes its exception handling seriously.

`AutoTrace`

Trace mode (similar to `t` command, but can be put into `PERLDB_OPTS`).

`LineInfo`

File or pipe to print line number info to. If it is a pipe (say, `|visual_perl_db`), then a short message is used. This is the mechanism used to interact with a slave editor or visual debugger, such as the special `vi` or `emacs` hooks, or the `ddd` graphical debugger.

`inhibit_exit`

If 0, allows *stepping off* the end of the script.

`PrintRet`

Print return value after `r` command if set (default).

`ornaments`

Affects screen appearance of the command line (see *Term::ReadLine*). There is currently no way to disable these, which can render some output illegible on some displays, or with some pagers. This is considered a bug.

`frame`

Affects the printing of messages upon entry and exit from subroutines. If `frame & 2` is false, messages are printed on entry only. (Printing on exit might be useful if interspersed with other messages.)

If `frame & 4`, arguments to functions are printed, plus context and caller info. If `frame & 8`, overloaded `stringify` and `tied` `FETCH` is enabled on the printed arguments. If `frame & 16`, the return value from the subroutine is printed.

The length at which the argument list is truncated is governed by the next option:

`maxTraceLen`

Length to truncate the argument list when the `frame` option's bit 4 is set.

`windowSize`

Change the size of code list window (default is 10 lines).

The following options affect what happens with `V`, `X`, and `x` commands:

`arrayDepth`, `hashDepth`

Print only first N elements (" for all).

`dumpDepth`

Limit recursion depth to N levels when dumping structures. Negative values are interpreted as infinity. Default: infinity.

`compactDump`, `veryCompact`

Change the style of array and hash output. If `compactDump`, short array may be printed on one line.

`globPrint`

Whether to print contents of globs.

`DumpDBFiles`

Dump arrays holding debugged files.

`DumpPackages`

Dump symbol tables of packages.

`DumpReused`

Dump contents of "reused" addresses.

`quote`, `HighBit`, `undefPrint`

Change the style of string dump. The default value for `quote` is `auto`; one can enable double-quotish or single-quotish format by setting it to `"` or `'`, respectively. By default, characters with their high bit set are printed verbatim.

`UsageOnly`

Rudimentary per-package memory usage dump. Calculates total size of strings found in variables in the package. This does not include lexicals in a module's file scope, or lost in closures.

After the rc file is read, the debugger reads the `$ENV{PERLDB_OPTS}` environment variable and parses this as the remainder of a 'O ...' line as one might enter at the debugger prompt. You may place the initialization options `TTY`, `noTTY`, `ReadLine`, and `NonStop` there.

If your rc file contains:

```
  parse_options("NonStop=1 LineInfo=db.out AutoTrace");
```

then your script will run without human intervention, putting trace information into the file *db.out*. (If you interrupt it, you'd better reset `LineInfo` to */dev/tty* if you expect to see anything.)

`TTY`

The TTY to use for debugging I/O.

`noTTY`

If set, the debugger goes into `NonStop` mode and will not connect to a TTY. If interrupted (or if control goes to the debugger via explicit setting of $DB::signal or $DB::single from the Perl script), it connects to a TTY specified in the `TTY` option at startup, or to a tty found at runtime using the `Term::Rendezvous` module of your choice.

This module should implement a method named `new` that returns an object with two methods: `IN` and `OUT`. These should return filehandles to use for debugging input and output correspondingly. The `new` method should inspect an argument containing the value of `$ENV{PERLDB_NOTTY}` at startup, or `".perldbtty$$"` otherwise. This file is not inspected for proper ownership, so security hazards are theoretically possible.

`ReadLine`

If false, readline support in the debugger is disabled in order to debug applications that themselves use ReadLine.

`NonStop`

If set, the debugger goes into non-interactive mode until interrupted, or programmatically by setting $DB::signal or $DB::single.

Here's an example of using the `$ENV{PERLDB_OPTS}` variable:

```
    $ PERLDB_OPTS="NonStop frame=2" perl -d myprogram
```

That will run the script **myprogram** without human intervention, printing out the call tree with entry and exit points. Note that `NonStop=1 frame=2` is equivalent to `N f=2`, and that originally, options could be uniquely abbreviated by the first letter (modulo the `Dump*` options). It is nevertheless recommended that you always spell them out in full for legibility and future compatibility.

Other examples include

```
    $ PERLDB_OPTS="NonStop LineInfo=listing frame=2" perl -d myprogram
```

which runs script non-interactively, printing info on each entry into a subroutine and each executed line into the file named *listing*. (If you interrupt it, you would better reset `LineInfo` to something "interactive"!)

Other examples include (using standard shell syntax to show environment variable settings):

```
  $ ( PERLDB_OPTS="NonStop frame=1 AutoTrace LineInfo=tperl.out"
      perl -d myprogram )
```

which may be useful for debugging a program that uses `Term::ReadLine` itself. Do not forget to detach your shell from the TTY in the window that corresponds to */dev/ttyXX*, say, by issuing a command like

```
  $ sleep 1000000
```

See Debugger Internals in *perldebguts* for details.

38.2.3 Debugger input/output

Prompt

The debugger prompt is something like

```
    DB<8>
```

or even

```
    DB<<17>>
```

where that number is the command number, and which you'd use to access with the built-in **csh**-like history mechanism. For example, `!17` would repeat command number 17. The depth of the angle brackets indicates the nesting depth of the debugger. You could get more than one set of brackets, for example, if you'd already at a breakpoint and then printed the result of a function call that itself has a breakpoint, or you step into an expression via `s/n/t expression` command.

Multiline commands

If you want to enter a multi-line command, such as a subroutine definition with several statements or a format, escape the newline that would normally end the debugger command with a backslash. Here's an example:

```
      DB<1> for (1..4) {         \
      cont:     print "ok\n";   \
      cont: }
      ok
      ok
      ok
      ok
```

Note that this business of escaping a newline is specific to interactive commands typed into the debugger.

Stack backtrace

Here's an example of what a stack backtrace via `T` command might look like:

```
$ = main::infested called from file 'Ambulation.pm' line 10
@ = Ambulation::legs(1, 2, 3, 4) called from file 'camel_flea' line 7
$ = main::pests('bactrian', 4) called from file 'camel_flea' line 4
```

The left-hand character up there indicates the context in which the function was called, with `$` and `@` meaning scalar or list contexts respectively, and `.` meaning void context (which is actually a sort of scalar context). The display above says that you were in the function `main::infested` when you ran the stack dump, and that it was called in scalar context from line 10 of the file *Ambulation.pm*, but without any arguments at all, meaning it was called as `&infested`. The next stack frame shows that the function `Ambulation::legs` was called in list context from the *camel_flea* file with four arguments. The last stack frame shows that `main::pests` was called in scalar context, also from *camel_flea*, but from line 4.

If you execute the `T` command from inside an active `use` statement, the backtrace will contain both a `require` frame and an `eval`) frame.

Line Listing Format

This shows the sorts of output the `l` command can produce:

```
  DB<<13>> l
101:            @i{@i} = ();
102:b           @isa{@i,$pack} = ()
103                 if(exists $i{$prevpack} || exists $isa{$pack});
104         }
105
106         next
107==>           if(exists $isa{$pack});
108
109:a        if ($extra-- > 0) {
110:            %isa = ($pack,1);
```

Breakable lines are marked with `:`. Lines with breakpoints are marked by `b` and those with actions by `a`. The line that's about to be executed is marked by ==>.

Please be aware that code in debugger listings may not look the same as your original source code. Line directives and external source filters can alter the code before Perl sees it, causing code to move from its original positions or take on entirely different forms.

Frame listing

When the `frame` option is set, the debugger would print entered (and optionally exited) subroutines in different styles. See *perldebguts* for incredibly long examples of these.

38.2.4 Debugging compile-time statements

If you have compile-time executable statements (such as code within BEGIN and CHECK blocks or `use` statements), these will *not* be stopped by debugger, although `require`s and INIT blocks will, and compile-time statements can be traced with `AutoTrace` option set in `PERLDB_OPTS`). From your own Perl code, however, you can transfer control back to the debugger using the following statement, which is harmless if the debugger is not running:

```
$DB::single = 1;
```

If you set `$DB::single` to 2, it's equivalent to having just typed the `n` command, whereas a value of 1 means the `s` command. The `$DB::trace` variable should be set to 1 to simulate having typed the `t` command.

Another way to debug compile-time code is to start the debugger, set a breakpoint on the *load* of some module:

```
    DB<7> b load f:/perllib/lib/Carp.pm
  Will stop on load of 'f:/perllib/lib/Carp.pm'.
```

and then restart the debugger using the `R` command (if possible). One can use `b compile subname` for the same purpose.

38.2.5 Debugger Customization

The debugger probably contains enough configuration hooks that you won't ever have to modify it yourself. You may change the behaviour of debugger from within the debugger using its `o` command, from the command line via the `PERLDB_OPTS` environment variable, and from customization files.

You can do some customization by setting up a *.perldb* file, which contains initialization code. For instance, you could make aliases like these (the last one is one people expect to be there):

```
    $DB::alias{'len'}  = 's/^len(.*)/p length($1)/';
    $DB::alias{'stop'} = 's/^stop (at|in)/b/';
    $DB::alias{'ps'}   = 's/^ps\b/p scalar /';
    $DB::alias{'quit'} = 's/^quit(\s*)/exit/';
```

You can change options from *.perldb* by using calls like this one;

```
    parse_options("NonStop=1 LineInfo=db.out AutoTrace=1 frame=2");
```

The code is executed in the package `DB`. Note that *.perldb* is processed before processing `PERLDB_OPTS`. If *.perldb* defines the subroutine `afterinit`, that function is called after debugger initialization ends. *.perldb* may be contained in the current directory, or in the home directory. Because this file is sourced in by Perl and may contain arbitrary commands, for security reasons, it must be owned by the superuser or the current user, and writable by no one but its owner.

You can mock TTY input to debugger by adding arbitrary commands to @DB::typeahead. For example, your *.perldb* file might contain:

```
    sub afterinit { push @DB::typeahead, "b 4", "b 6"; }
```

Which would attempt to set breakpoints on lines 4 and 6 immediately after debugger initilization. Note that @DB::typeahead is not a supported interface and is subject to change in future releases.

If you want to modify the debugger, copy *perl5db.pl* from the Perl library to another name and hack it to your heart's content. You'll then want to set your `PERL5DB` environment variable to say something like this:

```
    BEGIN { require "myperl5db.pl" }
```

As a last resort, you could also use `PERL5DB` to customize the debugger by directly setting internal variables or calling debugger functions.

Note that any variables and functions that are not documented in this document (or in *perldebguts*) are considered for internal use only, and as such are subject to change without notice.

38.2.6 Readline Support

As shipped, the only command-line history supplied is a simplistic one that checks for leading exclamation points. However, if you install the Term::ReadKey and Term::ReadLine modules from CPAN, you will have full editing capabilities much like GNU *readline*(3) provides. Look for these in the *modules/by-module/Term* directory on CPAN. These do not support normal **vi** command-line editing, however.

A rudimentary command-line completion is also available. Unfortunately, the names of lexical variables are not available for completion.

38.2.7 Editor Support for Debugging

If you have the FSF's version of **emacs** installed on your system, it can interact with the Perl debugger to provide an integrated software development environment reminiscent of its interactions with C debuggers.

Perl comes with a start file for making **emacs** act like a syntax-directed editor that understands (some of) Perl's syntax. Look in the *emacs* directory of the Perl source distribution.

A similar setup by Tom Christiansen for interacting with any vendor-shipped **vi** and the X11 window system is also available. This works similarly to the integrated multiwindow support that **emacs** provides, where the debugger drives the editor. At the time of this writing, however, that tool's eventual location in the Perl distribution was uncertain.

Users of **vi** should also look into **vim** and **gvim**, the mousey and windy version, for coloring of Perl keywords.

Note that only perl can truly parse Perl, so all such CASE tools fall somewhat short of the mark, especially if you don't program your Perl as a C programmer might.

38.2.8 The Perl Profiler

If you wish to supply an alternative debugger for Perl to run, just invoke your script with a colon and a package argument given to the **-d** flag. The most popular alternative debuggers for Perl is the Perl profiler. Devel::DProf is now included with the standard Perl distribution. To profile your Perl program in the file *mycode.pl*, just type:

```
    $ perl -d:DProf mycode.pl
```

When the script terminates the profiler will dump the profile information to a file called *tmon.out*. A tool like **dprofpp**, also supplied with the standard Perl distribution, can be used to interpret the information in that profile.

38.3 Debugging regular expressions

`use re 'debug'` enables you to see the gory details of how the Perl regular expression engine works. In order to understand this typically voluminous output, one must not only have some idea about how regular expression matching works in general, but also know how Perl's regular expressions are internally compiled into an automaton. These matters are explored in some detail in Debugging regular expressions in *perldebguts*.

38.4 Debugging memory usage

Perl contains internal support for reporting its own memory usage, but this is a fairly advanced concept that requires some understanding of how memory allocation works. See Debugging Perl memory usage in *perldebguts* for the details.

38.5 SEE ALSO

You did try the **-w** switch, didn't you?

perldebtut, *perldebguts*, *re*, *DB*, *Devel::DProf*, *dprofpp*, *Dumpvalue*, and *perlrun*.

38.6 BUGS

You cannot get stack frame information or in any fashion debug functions that were not compiled by Perl, such as those from C or C++ extensions.

If you alter your @_ arguments in a subroutine (such as with `shift` or `pop`), the stack backtrace will not show the original values.

The debugger does not currently work in conjunction with the **-W** command-line switch, because it itself is not free of warnings.

If you're in a slow syscall (like `wait`ing, `accept`ing, or `read`ing from your keyboard or a socket) and haven't set up your own `$SIG{INT}` handler, then you won't be able to CTRL-C your way back to the debugger, because the debugger's own `$SIG{INT}` handler doesn't understand that it needs to raise an exception to longjmp(3) out of slow syscalls.

Chapter 39

perlvar

Perl predefined variables

39.1 DESCRIPTION

39.1.1 Predefined Names

The following names have special meaning to Perl. Most punctuation names have reasonable mnemonics, or analogs in the shells. Nevertheless, if you wish to use long variable names, you need only say

```
    use English;
```

at the top of your program. This aliases all the short names to the long names in the current package. Some even have medium names, generally borrowed from **awk**. In general, it's best to use the

```
    use English '-no_match_vars';
```

invocation if you don't need $PREMATCH, $MATCH, or $POSTMATCH, as it avoids a certain performance hit with the use of regular expressions. See *English*.

Variables that depend on the currently selected filehandle may be set by calling an appropriate object method on the IO::Handle object, although this is less efficient than using the regular built-in variables. (Summary lines below for this contain the word HANDLE.) First you must say

```
    use IO::Handle;
```

after which you may use either

```
    method HANDLE EXPR
```

or more safely,

```
    HANDLE->method(EXPR)
```

Each method returns the old value of the IO::Handle attribute. The methods each take an optional EXPR, which, if supplied, specifies the new value for the IO::Handle attribute in question. If not supplied, most methods do nothing to the current value–except for autoflush(), which will assume a 1 for you, just to be different.

Because loading in the IO::Handle class is an expensive operation, you should learn how to use the regular built-in variables.

A few of these variables are considered "read-only". This means that if you try to assign to this variable, either directly or indirectly through a reference, you'll raise a run-time exception.

You should be very careful when modifying the default values of most special variables described in this document. In most cases you want to localize these variables before changing them, since if you don't, the change may affect other modules which rely on the default values of the special variables that you have changed. This is one of the correct ways to read the whole file at once:

```
    open my $fh, "foo" or die $!;
    local $/; # enable localized slurp mode
    my $content = <$fh>;
    close $fh;
```

But the following code is quite bad:

```
    open my $fh, "foo" or die $!;
    undef $/; # enable slurp mode
    my $content = <$fh>;
    close $fh;
```

since some other module, may want to read data from some file in the default "line mode", so if the code we have just presented has been executed, the global value of `$/` is now changed for any other code running inside the same Perl interpreter.

Usually when a variable is localized you want to make sure that this change affects the shortest scope possible. So unless you are already inside some short `{}` block, you should create one yourself. For example:

```
    my $content = '';
    open my $fh, "foo" or die $!;
    {
        local $/;
        $content = <$fh>;
    }
    close $fh;
```

Here is an example of how your own code can go broken:

```
    for (1..5){
        nasty_break();
        print "$_ ";
    }
    sub nasty_break {
        $_ = 5;
        # do something with $_
    }
```

You probably expect this code to print:

```
    1 2 3 4 5
```

but instead you get:

```
    5 5 5 5 5
```

Why? Because nasty_break() modifies `$_` without localizing it first. The fix is to add local():

```
        local $_ = 5;
```

It's easy to notice the problem in such a short example, but in more complicated code you are looking for trouble if you don't localize changes to the special variables.

The following list is ordered by scalar variables first, then the arrays, then the hashes.

$ ARG

$ _

The default input and pattern-searching space. The following pairs are equivalent:

```
while (<>) {...}    # equivalent only in while!
while (defined($_ = <>)) {...}

/^Subject:/
$_ =~ /^Subject:/

tr/a-z/A-Z/
$_ =~ tr/a-z/A-Z/

chomp
chomp($_)
```

Here are the places where Perl will assume $_ even if you don't use it:

- Various unary functions, including functions like ord() and int(), as well as the all file tests (`-f`, `-d`) except for `-t`, which defaults to STDIN.
- Various list functions like print() and unlink().
- The pattern matching operations `m//`, `s///`, and `tr///` when used without an `=~` operator.
- The default iterator variable in a `foreach` loop if no other variable is supplied.
- The implicit iterator variable in the grep() and map() functions.
- The default place to put an input record when a `<FH>` operation's result is tested by itself as the sole criterion of a `while` test. Outside a `while` test, this will not happen.

(Mnemonic: underline is understood in certain operations.)

$ a

$ b

Special package variables when using sort(), see sort in *perlfunc*. Because of this specialness $a and $b don't need to be declared (using use vars, or our()) even when using the `strict 'vars'` pragma. Don't lexicalize them with `my $a` or `my $b` if you want to be able to use them in the sort() comparison block or function.

$ <*digits*>

Contains the subpattern from the corresponding set of capturing parentheses from the last pattern match, not counting patterns matched in nested blocks that have been exited already. (Mnemonic: like \digits.) These variables are all read-only and dynamically scoped to the current BLOCK.

$ MATCH

$ &

The string matched by the last successful pattern match (not counting any matches hidden within a BLOCK or eval() enclosed by the current BLOCK). (Mnemonic: like & in some editors.) This variable is read-only and dynamically scoped to the current BLOCK.

The use of this variable anywhere in a program imposes a considerable performance penalty on all regular expression matches. See BUGS.

$ PREMATCH

$ ‘

The string preceding whatever was matched by the last successful pattern match (not counting any matches hidden within a BLOCK or eval enclosed by the current BLOCK). (Mnemonic: ‘ often precedes a quoted string.) This variable is read-only.

The use of this variable anywhere in a program imposes a considerable performance penalty on all regular expression matches. See BUGS.

$ POSTMATCH

$ ’

The string following whatever was matched by the last successful pattern match (not counting any matches hidden within a BLOCK or eval() enclosed by the current BLOCK). (Mnemonic: ’ often follows a quoted string.) Example:

```
local $_ = 'abcdefghi';
/def/;
print "$`:$&:$'\n";         # prints abc:def:ghi
```

This variable is read-only and dynamically scoped to the current BLOCK.

The use of this variable anywhere in a program imposes a considerable performance penalty on all regular expression matches. See BUGS.

$ LAST_PAREN_MATCH

$ +

The text matched by the last bracket of the last successful search pattern. This is useful if you don’t know which one of a set of alternative patterns matched. For example:

```
/Version: (.*)|Revision: (.*)/ && ($rev = $+);
```

(Mnemonic: be positive and forward looking.) This variable is read-only and dynamically scoped to the current BLOCK.

$ ˆN

The text matched by the used group most-recently closed (i.e. the group with the rightmost closing parenthesis) of the last successful search pattern. (Mnemonic: the (possibly) Nested parenthesis that most recently closed.)

This is primarily used inside `(?{...})` blocks for examining text recently matched. For example, to effectively capture text to a variable (in addition to `$1`, `$2`, etc.), replace `(...)` with

```
 (?:(...)(?{ $var = $^N }))
```

By setting and then using `$var` in this way relieves you from having to worry about exactly which numbered set of parentheses they are.

This variable is dynamically scoped to the current BLOCK.

@LAST_MATCH_END

@+

This array holds the offsets of the ends of the last successful submatches in the currently active dynamic scope. `$+[0]` is the offset into the string of the end of the entire match. This is the same value as what the `pos` function returns when called on the variable that was matched against. The *n*th element of this array holds the offset of the *n*th submatch, so `$+[1]` is the offset past where $1 ends, `$+[2]` the offset past where $2 ends, and so on. You can use `$#+` to determine how many subgroups were in the last successful match. See the examples given for the `@-` variable.

$ *

Set to a non-zero integer value to do multi-line matching within a string, 0 (or undefined) to tell Perl that it can assume that strings contain a single line, for the purpose of optimizing pattern matches. Pattern matches on strings containing multiple newlines can produce confusing results when `$*` is 0 or undefined. Default is undefined. (Mnemonic: * matches multiple things.) This variable influences the interpretation of only ˆ and `$`. A literal newline can be searched for even when `$* == 0`.

Use of `$*` is deprecated in modern Perl, supplanted by the `/s` and `/m` modifiers on pattern matching.

Assigning a non-numerical value to `$*` triggers a warning (and makes `$*` act if `$* == 0`), while assigning a numerical value to `$*` makes that an implicit `int` is applied on the value.

HANDLE->input_line_number(EXPR)

$ INPUT_LINE_NUMBER

$ NR

$.

Current line number for the last filehandle accessed.

Each filehandle in Perl counts the number of lines that have been read from it. (Depending on the value of `$/`, Perl's idea of what constitutes a line may not match yours.) When a line is read from a filehandle (via readline() or <>), or when tell() or seek() is called on it, `$.` becomes an alias to the line counter for that filehandle.

You can adjust the counter by assigning to `$.`, but this will not actually move the seek pointer. *Localizing `$.` will not localize the filehandle's line count.* Instead, it will localize perl's notion of which filehandle `$.` is currently aliased to.

`$.` is reset when the filehandle is closed, but **not** when an open filehandle is reopened without an intervening close(). For more details, see I/O Operators in *perlop*. Because <> never does an explicit close, line numbers increase across ARGV files (but see examples in eof in *perlfunc*).

You can also use `HANDLE->input_line_number(EXPR)` to access the line counter for a given filehandle without having to worry about which handle you last accessed.

(Mnemonic: many programs use "." to mean the current line number.)

IO::Handle->input_record_separator(EXPR)

$ INPUT_RECORD_SEPARATOR

$ RS

$ /

The input record separator, newline by default. This influences Perl's idea of what a "line" is. Works like **awk**'s RS variable, including treating empty lines as a terminator if set to the null string. (An empty line cannot contain any spaces or tabs.) You may set it to a multi-character string to match a multi-character terminator, or to `undef` to read through the end of file. Setting it to `"\n\n"` means something slightly different than setting to `""`, if the file contains consecutive empty lines. Setting to `""` will treat two or more consecutive empty lines as a single empty line. Setting to `"\n\n"` will blindly assume that the next input character belongs to the next paragraph, even if it's a newline. (Mnemonic: / delimits line boundaries when quoting poetry.)

```
local $/;           # enable "slurp" mode
local $_ = <FH>;    # whole file now here
s/\n[ \t]+/ /g;
```

Remember: the value of `$/` is a string, not a regex. **awk** has to be better for something. :-)

Setting `$/` to a reference to an integer, scalar containing an integer, or scalar that's convertible to an integer will attempt to read records instead of lines, with the maximum record size being the referenced integer. So this:

```
    local $/ = \32768; # or \"32768", or \$var_containing_32768
    open my $fh, $myfile or die $!;
    local $_ = <$fh>;
```

will read a record of no more than 32768 bytes from FILE. If you're not reading from a record-oriented file (or your OS doesn't have record-oriented files), then you'll likely get a full chunk of data with every read. If a record is larger than the record size you've set, you'll get the record back in pieces.

On VMS, record reads are done with the equivalent of `sysread`, so it's best not to mix record and non-record reads on the same file. (This is unlikely to be a problem, because any file you'd want to read in record mode is probably unusable in line mode.) Non-VMS systems do normal I/O, so it's safe to mix record and non-record reads of a file.

See also Newlines in *perlport*. Also see `$.`.

HANDLE->autoflush(EXPR)

$ OUTPUT_AUTOFLUSH

$ |

If set to nonzero, forces a flush right away and after every write or print on the currently selected output channel. Default is 0 (regardless of whether the channel is really buffered by the system or not; $| tells you only whether you've asked Perl explicitly to flush after each write). STDOUT will typically be line buffered if output is to the terminal and block buffered otherwise. Setting this variable is useful primarily when you are outputting to a pipe or socket, such as when you are running a Perl program under **rsh** and want to see the output as it's happening. This has no effect on input buffering. See getc in *perlfunc* for that. (Mnemonic: when you want your pipes to be piping hot.)

IO::Handle->output_field_separator EXPR

$ OUTPUT_FIELD_SEPARATOR

$ OFS

$,

The output field separator for the print operator. Ordinarily the print operator simply prints out its arguments without further adornment. To get behavior more like **awk**, set this variable as you would set **awk**'s OFS variable to specify what is printed between fields. (Mnemonic: what is printed when there is a "," in your print statement.)

IO::Handle->output_record_separator EXPR

$ OUTPUT_RECORD_SEPARATOR

$ ORS

**$ **

The output record separator for the print operator. Ordinarily the print operator simply prints out its arguments as is, with no trailing newline or other end-of-record string added. To get behavior more like **awk**, set this variable as you would set **awk**'s ORS variable to specify what is printed at the end of the print. (Mnemonic: you set `$\` instead of adding "\n" at the end of the print. Also, it's just like `$/`, but it's what you get "back" from Perl.)

$ LIST_SEPARATOR

$ "

This is like `$,` except that it applies to array and slice values interpolated into a double-quoted string (or similar interpreted string). Default is a space. (Mnemonic: obvious, I think.)

$ SUBSCRIPT_SEPARATOR

$ SUBSEP

$;

The subscript separator for multidimensional array emulation. If you refer to a hash element as

```
    $foo{$a,$b,$c}
```

it really means

```
    $foo{join($;, $a, $b, $c)}
```

But don't put

```
    @foo{$a,$b,$c}      # a slice--note the @
```

which means

```
    ($foo{$a},$foo{$b},$foo{$c})
```

Default is "\034", the same as SUBSEP in **awk**. If your keys contain binary data there might not be any safe value for `$;`. (Mnemonic: comma (the syntactic subscript separator) is a semi-semicolon. Yeah, I know, it's pretty lame, but `$,` is already taken for something more important.)

Consider using "real" multidimensional arrays as described in *perllol*.

$ #

The output format for printed numbers. This variable is a half-hearted attempt to emulate **awk**'s OFMT variable. There are times, however, when **awk** and Perl have differing notions of what counts as numeric. The initial value is "%.*n*g", where *n* is the value of the macro DBL_DIG from your system's *float.h*. This is different from **awk**'s default OFMT setting of "%.6g", so you need to set `$#` explicitly to get **awk**'s value. (Mnemonic: # is the number sign.)

Use of `$#` is deprecated.

HANDLE->format_page_number(EXPR)

$ FORMAT_PAGE_NUMBER

$ %

The current page number of the currently selected output channel. Used with formats. (Mnemonic: % is page number in **nroff**.)

HANDLE->format_lines_per_page(EXPR)

$ FORMAT_LINES_PER_PAGE

$ =

The current page length (printable lines) of the currently selected output channel. Default is 60. Used with formats. (Mnemonic: = has horizontal lines.)

HANDLE->format_lines_left(EXPR)

$ FORMAT_LINES_LEFT

$ -

The number of lines left on the page of the currently selected output channel. Used with formats. (Mnemonic: lines_on_page - lines_printed.)

@LAST_MATCH_START

@-

$-[0] is the offset of the start of the last successful match. `$-[`*n*`]` is the offset of the start of the substring matched by *n*-th subpattern, or undef if the subpattern did not match.

Thus after a match against $_, $& coincides with `substr $_, $-[0], $+[0] - $-[0]`. Similarly, $*n* coincides with `substr $_, $-[`*n*`], $+[`*n*`] - $-[`*n*`]` if `$-[`*n*`]` is defined, and $+ coincides with `substr $_, $-[$#-], $+[$#-]`. One can use `$#-` to find the last matched subgroup in the last successful match. Contrast with `$#+`, the number of subgroups in the regular expression. Compare with `@+`.

This array holds the offsets of the beginnings of the last successful submatches in the currently active dynamic scope. `$-[0]` is the offset into the string of the beginning of the entire match. The *n*th element of this array holds the offset of the *n*th submatch, so `$-[1]` is the offset where $1 begins, `$-[2]` the offset where $2 begins, and so on.

After a match against some variable $var:

`$‘` is the same as `substr($var, 0, $-[0])`

`$&` is the same as `substr($var, $-[0], $+[0] - $-[0])`

`$’` is the same as `substr($var, $+[0])`

`$1` is the same as `substr($var, $-[1], $+[1] - $-[1])`

`$2` is the same as `substr($var, $-[2], $+[2] - $-[2])`

`$3` is the same as `substr $var, $-[3], $+[3] - $-[3])`

HANDLE->format_name(EXPR)

$ FORMAT_NAME

$ ˜

The name of the current report format for the currently selected output channel. Default is the name of the filehandle. (Mnemonic: brother to `$^`.)

HANDLE->format_top_name(EXPR)

$ FORMAT_TOP_NAME

$ ˆ

The name of the current top-of-page format for the currently selected output channel. Default is the name of the filehandle with _TOP appended. (Mnemonic: points to top of page.)

IO::Handle->format_line_break_characters EXPR

$ FORMAT_LINE_BREAK_CHARACTERS

$:

The current set of characters after which a string may be broken to fill continuation fields (starting with ˆ) in a format. Default is " \n-", to break on whitespace or hyphens. (Mnemonic: a "colon" in poetry is a part of a line.)

IO::Handle->format_formfeed EXPR

$ FORMAT_FORMFEED

$ ˆL

What formats output as a form feed. Default is \f.

$ ACCUMULATOR

$ ˆA

The current value of the write() accumulator for format() lines. A format contains formline() calls that put their result into `$^A`. After calling its format, write() prints out the contents of `$^A` and empties. So you never really see the contents of `$^A` unless you call formline() yourself and then look at it. See *perlform* and formline() in *perlfunc*.

$ CHILD_ERROR

$?

The status returned by the last pipe close, backtick (“) command, successful call to wait() or waitpid(), or from the system() operator. This is just the 16-bit status word returned by the wait() system call (or else is made up to look like it). Thus, the exit value of the subprocess is really (`$? >> 8`), and `$? & 127` gives which signal, if any, the process died from, and `$? & 128` reports whether there was a core dump. (Mnemonic: similar to **sh** and **ksh**.)

Additionally, if the `h_errno` variable is supported in C, its value is returned via $? if any `gethost*()` function fails.

If you have installed a signal handler for `SIGCHLD`, the value of `$?` will usually be wrong outside that handler.

Inside an `END` subroutine `$?` contains the value that is going to be given to `exit()`. You can modify `$?` in an `END` subroutine to change the exit status of your program. For example:

```
END {
    $? = 1 if $? == 255;  # die would make it 255
}
```

Under VMS, the pragma `use vmsish 'status'` makes `$?` reflect the actual VMS exit status, instead of the default emulation of POSIX status; see `$?` in *perlvms* for details.

Also see Error Indicators.

$ {^ENCODING}

The *object reference* to the Encode object that is used to convert the source code to Unicode. Thanks to this variable your perl script does not have to be written in UTF-8. Default is *undef*. The direct manipulation of this variable is highly discouraged. See *encoding* for more details.

$ OS_ERROR

$ ERRNO

$!

If used numerically, yields the current value of the C `errno` variable, or in other words, if a system or library call fails, it sets this variable. This means that the value of `$!` is meaningful only *immediately* after a **failure**:

```
if (open(FH, $filename)) {
    # Here $! is meaningless.
    ...
} else {
    # ONLY here is $! meaningful.
    ...
    # Already here $! might be meaningless.
}
# Since here we might have either success or failure,
# here $! is meaningless.
```

In the above *meaningless* stands for anything: zero, non-zero, `undef`. A successful system or library call does **not** set the variable to zero.

If used as a string, yields the corresponding system error string. You can assign a number to `$!` to set *errno* if, for instance, you want `"$!"` to return the string for error *n*, or you want to set the exit value for the die() operator. (Mnemonic: What just went bang?)

Also see Error Indicators.

%!

Each element of %! has a true value only if $! is set to that value. For example, $!{ENOENT} is true if and only if the current value of $! is ENOENT; that is, if the most recent error was "No such file or directory" (or its moral equivalent: not all operating systems give that exact error, and certainly not all languages). To check if a particular key is meaningful on your system, use `exists $!{the_key}`; for a list of legal keys, use `keys %!`. See *Errno* for more information, and also see above for the validity of $!.

$ EXTENDED_OS_ERROR

$ ˆE

Error information specific to the current operating system. At the moment, this differs from $! under only VMS, OS/2, and Win32 (and for MacPerl). On all other platforms, $ˆE is always just the same as $!.

Under VMS, $ˆE provides the VMS status value from the last system error. This is more specific information about the last system error than that provided by $!. This is particularly important when $! is set to **EVMSERR**.

Under OS/2, $ˆE is set to the error code of the last call to OS/2 API either via CRT, or directly from perl.

Under Win32, $ˆE always returns the last error information reported by the Win32 call `GetLastError()` which describes the last error from within the Win32 API. Most Win32-specific code will report errors via $ˆE. ANSI C and Unix-like calls set `errno` and so most portable Perl code will report errors via $!.

Caveats mentioned in the description of $! generally apply to $ˆE, also. (Mnemonic: Extra error explanation.)

Also see Error Indicators.

$ EVAL_ERROR

$ @

The Perl syntax error message from the last eval() operator. If $@ is the null string, the last eval() parsed and executed correctly (although the operations you invoked may have failed in the normal fashion). (Mnemonic: Where was the syntax error "at"?)

Warning messages are not collected in this variable. You can, however, set up a routine to process warnings by setting $SIG{__WARN__} as described below.

Also see Error Indicators.

$ PROCESS_ID

$ PID

$ $

The process number of the Perl running this script. You should consider this variable read-only, although it will be altered across fork() calls. (Mnemonic: same as shells.)

Note for Linux users: on Linux, the C functions `getpid()` and `getppid()` return different values from different threads. In order to be portable, this behavior is not reflected by $$, whose value remains consistent across threads. If you want to call the underlying `getpid()`, you may use the CPAN module `Linux::Pid`.

$ REAL_USER_ID

$ UID

$ <

The real uid of this process. (Mnemonic: it's the uid you came *from*, if you're running setuid.) You can change both the real uid and the effective uid at the same time by using POSIX::setuid().

$ EFFECTIVE_USER_ID

$ EUID

$ >

The effective uid of this process. Example:

```
    $< = $>;            # set real to effective uid
    ($<,$>) = ($>,$<);  # swap real and effective uid
```

You can change both the effective uid and the real uid at the same time by using POSIX::setuid().

(Mnemonic: it's the uid you went *to*, if you're running setuid.) `$<` and `$>` can be swapped only on machines supporting setreuid().

$ REAL_GROUP_ID

$ GID

$ (

The real gid of this process. If you are on a machine that supports membership in multiple groups simultaneously, gives a space separated list of groups you are in. The first number is the one returned by getgid(), and the subsequent ones by getgroups(), one of which may be the same as the first number.

However, a value assigned to `$(` must be a single number used to set the real gid. So the value given by `$(` should *not* be assigned back to `$(` without being forced numeric, such as by adding zero.

You can change both the real gid and the effective gid at the same time by using POSIX::setgid().

(Mnemonic: parentheses are used to *group* things. The real gid is the group you *left*, if you're running setgid.)

$ EFFECTIVE_GROUP_ID

$ EGID

$)

The effective gid of this process. If you are on a machine that supports membership in multiple groups simultaneously, gives a space separated list of groups you are in. The first number is the one returned by getegid(), and the subsequent ones by getgroups(), one of which may be the same as the first number.

Similarly, a value assigned to `$)` must also be a space-separated list of numbers. The first number sets the effective gid, and the rest (if any) are passed to setgroups(). To get the effect of an empty list for setgroups(), just repeat the new effective gid; that is, to force an effective gid of 5 and an effectively empty setgroups() list, say `$) = "5 5"` .

You can change both the effective gid and the real gid at the same time by using POSIX::setgid() (use only a single numeric argument).

(Mnemonic: parentheses are used to *group* things. The effective gid is the group that's *right* for you, if you're running setgid.)

`$<`, `$>`, `$(` and `$)` can be set only on machines that support the corresponding *set[re][ug]id()* routine. `$(` and `$)` can be swapped only on machines supporting setregid().

$ PROGRAM_NAME

$ 0

Contains the name of the program being executed.

On some (read: not all) operating systems assigning to `$0` modifies the argument area that the `ps` program sees. On some platforms you may have to use special `ps` options or a different `ps` to see the changes. Modifying the $0 is more useful as a way of indicating the current program state than it is for hiding the program you're running. (Mnemonic: same as **sh** and **ksh**.)

Note that there are platform specific limitations on the the maximum length of `$0`. In the most extreme case it may be limited to the space occupied by the original `$0`.

In some platforms there may be arbitrary amount of padding, for example space characters, after the modified name as shown by `ps`. In some platforms this padding may extend all the way to the original length of the argument area, no matter what you do (this is the case for example with Linux 2.2).

Note for BSD users: setting `$0` does not completely remove "perl" from the ps(1) output. For example, setting `$0` to `"foobar"` may result in `"perl:  foobar (perl)"` (whether both the `"perl:  "` prefix and the " (perl)" suffix are shown depends on your exact BSD variant and version). This is an operating system feature, Perl cannot help it.

In multithreaded scripts Perl coordinates the threads so that any thread may modify its copy of the `$0` and the change becomes visible to ps(1) (assuming the operating system plays along). Note that the the view of `$0` the other threads have will not change since they have their own copies of it.

$ [

The index of the first element in an array, and of the first character in a substring. Default is 0, but you could theoretically set it to 1 to make Perl behave more like **awk** (or Fortran) when subscripting and when evaluating the index() and substr() functions. (Mnemonic: [begins subscripts.)

As of release 5 of Perl, assignment to `$[` is treated as a compiler directive, and cannot influence the behavior of any other file. (That's why you can only assign compile-time constants to it.) Its use is highly discouraged.

Note that, unlike other compile-time directives (such as *strict*), assignment to $[can be seen from outer lexical scopes in the same file. However, you can use local() on it to strictly bound its value to a lexical block.

$]

The version + patchlevel / 1000 of the Perl interpreter. This variable can be used to determine whether the Perl interpreter executing a script is in the right range of versions. (Mnemonic: Is this version of perl in the right bracket?) Example:

```
warn "No checksumming!\n" if $] < 3.019;
```

See also the documentation of `use VERSION` and `require VERSION` for a convenient way to fail if the running Perl interpreter is too old.

When testing the variable, to steer clear of floating point inaccuracies you might want to prefer the inequality tests < and > to the tests containing equivalence: <=, ==, and >=.

The floating point representation can sometimes lead to inaccurate numeric comparisons. See `$^V` for a more modern representation of the Perl version that allows accurate string comparisons.

$ COMPILING

$ ^C

The current value of the flag associated with the **-c** switch. Mainly of use with **-MO=...** to allow code to alter its behavior when being compiled, such as for example to AUTOLOAD at compile time rather than normal, deferred loading. See *perlcc*. Setting `$^C = 1` is similar to calling `B::minus_c`.

$ DEBUGGING

$ ^D

The current value of the debugging flags. (Mnemonic: value of **-D** switch.) May be read or set. Like its command-line equivalent, you can use numeric or symbolic values, eg `$^D = 10` or `$^D = "st"`.

$ SYSTEM_FD_MAX

$ ^F

The maximum system file descriptor, ordinarily 2. System file descriptors are passed to exec()ed processes, while higher file descriptors are not. Also, during an open(), system file descriptors are preserved even if the open() fails. (Ordinary file descriptors are closed before the open() is attempted.) The close-on-exec status of a file descriptor will be decided according to the value of `$^F` when the corresponding file, pipe, or socket was opened, not the time of the exec().

$ ^H

WARNING: This variable is strictly for internal use only. Its availability, behavior, and contents are subject to change without notice.

This variable contains compile-time hints for the Perl interpreter. At the end of compilation of a BLOCK the value of this variable is restored to the value when the interpreter started to compile the BLOCK.

When perl begins to parse any block construct that provides a lexical scope (e.g., eval body, required file, subroutine body, loop body, or conditional block), the existing value of $ˆH is saved, but its value is left unchanged. When the compilation of the block is completed, it regains the saved value. Between the points where its value is saved and restored, code that executes within BEGIN blocks is free to change the value of $ˆH.

This behavior provides the semantic of lexical scoping, and is used in, for instance, the `use strict` pragma.

The contents should be an integer; different bits of it are used for different pragmatic flags. Here's an example:

```
sub add_100 { $^H |= 0x100 }

sub foo {
    BEGIN { add_100() }
    bar->baz($boon);
}
```

Consider what happens during execution of the BEGIN block. At this point the BEGIN block has already been compiled, but the body of foo() is still being compiled. The new value of $ˆH will therefore be visible only while the body of foo() is being compiled.

Substitution of the above BEGIN block with:

```
BEGIN { require strict; strict->import('vars') }
```

demonstrates how `use strict 'vars'` is implemented. Here's a conditional version of the same lexical pragma:

```
BEGIN { require strict; strict->import('vars') if $condition }
```

%ˆH

WARNING: This variable is strictly for internal use only. Its availability, behavior, and contents are subject to change without notice.

The %ˆH hash provides the same scoping semantic as $ˆH. This makes it useful for implementation of lexically scoped pragmas.

$ INPLACE_EDIT

$ ˆI

The current value of the inplace-edit extension. Use `undef` to disable inplace editing. (Mnemonic: value of **-i** switch.)

$ ˆM

By default, running out of memory is an untrappable, fatal error. However, if suitably built, Perl can use the contents of `$^M` as an emergency memory pool after die()ing. Suppose that your Perl were compiled with -DPERL_EMERGENCY_SBRK and used Perl's malloc. Then

```
$^M = 'a' x (1 << 16);
```

would allocate a 64K buffer for use in an emergency. See the *INSTALL* file in the Perl distribution for information on how to enable this option. To discourage casual use of this advanced feature, there is no English long name for this variable.

$ OSNAME

$ ˆO

The name of the operating system under which this copy of Perl was built, as determined during the configuration process. The value is identical to `$Config{'osname'}`. See also *Config* and the **-V** command-line switch documented in *perlrun*.

In Windows platforms, $ˆO is not very helpful: since it is always `MSWin32`, it doesn't tell the difference between 95/98/ME/NT/2000/XP/CE/.NET. Use Win32::GetOSName() or Win32::GetOSVersion() (see *Win32* and *perlport*) to distinguish between the variants.

$ {^OPEN}

An internal variable used by PerlIO. A string in two parts, separated by a `\0` byte, the first part describes the input layers, the second part describes the output layers.

$ PERLDB

$ ^P

The internal variable for debugging support. The meanings of the various bits are subject to change, but currently indicate:

1. x01
   Debug subroutine enter/exit.
2. x02
   Line-by-line debugging.
3. x04
   Switch off optimizations.
4. x08
   Preserve more data for future interactive inspections.
5. x10
   Keep info about source lines on which a subroutine is defined.
6. x20
   Start with single-step on.
7. x40
   Use subroutine address instead of name when reporting.
8. x80
   Report `goto &subroutine` as well.
9. x100
   Provide informative "file" names for evals based on the place they were compiled.
10. x200
    Provide informative names to anonymous subroutines based on the place they were compiled.
11. x400
    Debug assertion subroutines enter/exit.

Some bits may be relevant at compile-time only, some at run-time only. This is a new mechanism and the details may change.

$ LAST_REGEXP_CODE_RESULT

$ ^R

The result of evaluation of the last successful `(?{ code })` regular expression assertion (see *perlre*). May be written to.

$ EXCEPTIONS_BEING_CAUGHT

$ ^S

Current state of the interpreter.

```
$^S         State
---------   -------------------
undef       Parsing module/eval
true (1)    Executing an eval
false (0)   Otherwise
```

The first state may happen in $SIG{__DIE__} and $SIG{__WARN__} handlers.

$ BASETIME

$ ˆT

The time at which the program began running, in seconds since the epoch (beginning of 1970). The values returned by the **-M**, **-A**, and **-C** filetests are based on this value.

$ {ˆTAINT}

Reflects if taint mode is on or off. 1 for on (the program was run with **-T**), 0 for off, -1 when only taint warnings are enabled (i.e. with **-t** or **-TU**).

$ {ˆUNICODE}

Reflects certain Unicode settings of Perl. See *perlrun* documentation for the `-C` switch for more information about the possible values. This variable is set during Perl startup and is thereafter read-only.

$ PERL_VERSION

$ ˆV

The revision, version, and subversion of the Perl interpreter, represented as a string composed of characters with those ordinals. Thus in Perl v5.6.0 it equals `chr(5) . chr(6) . chr(0)` and will return true for `$ˆV eq v5.6.0`. Note that the characters in this string value can potentially be in Unicode range.

This can be used to determine whether the Perl interpreter executing a script is in the right range of versions. (Mnemonic: use ˆV for Version Control.) Example:

```
    warn "No \"our\" declarations!\n" if $^V and $^V lt v5.6.0;
```

To convert `$ˆV` into its string representation use sprintf()'s `"%vd"` conversion:

```
    printf "version is v%vd\n", $^V;  # Perl's version
```

See the documentation of `use VERSION` and `require VERSION` for a convenient way to fail if the running Perl interpreter is too old.

See also `$]` for an older representation of the Perl version.

$ WARNING

$ ˆW

The current value of the warning switch, initially true if **-w** was used, false otherwise, but directly modifiable. (Mnemonic: related to the **-w** switch.) See also *warnings*.

$ {ˆWARNING_BITS}

The current set of warning checks enabled by the `use warnings` pragma. See the documentation of `warnings` for more details.

$ EXECUTABLE_NAME

$ ˆX

The name used to execute the current copy of Perl, from C's `argv[0]`.

Depending on the host operating system, the value of $ˆX may be a relative or absolute pathname of the perl program file, or may be the string used to invoke perl but not the pathname of the perl program file. Also, most operating systems permit invoking programs that are not in the PATH environment variable, so there is no guarantee that the value of $ˆX is in PATH. For VMS, the value may or may not include a version number.

You usually can use the value of $ˆX to re-invoke an independent copy of the same perl that is currently running, e.g.,

```
@first_run = `$^X -le "print int rand 100 for 1..100"`;
```

But recall that not all operating systems support forking or capturing of the output of commands, so this complex statement may not be portable.

It is not safe to use the value of $ˆX as a path name of a file, as some operating systems that have a mandatory suffix on executable files do not require use of the suffix when invoking a command. To convert the value of $ˆX to a path name, use the following statements:

# Build up a set of file names (not command names). use Config; $this_perl = $ˆX; if ($ˆO ne 'VMS') {$this_perl .= $Config{_exe} unless $this_perl =˜ m/$Config{_exe}$/i;}

Because many operating systems permit anyone with read access to the Perl program file to make a copy of it, patch the copy, and then execute the copy, the security-conscious Perl programmer should take care to invoke the installed copy of perl, not the copy referenced by $ˆX. The following statements accomplish this goal, and produce a pathname that can be invoked as a command or referenced as a file.

```
use Config;
$secure_perl_path = $Config{perlpath};
if ($^O ne 'VMS')
   {$secure_perl_path .= $Config{_exe}
        unless $secure_perl_path =~ m/$Config{_exe}$/i;}
```

ARGV

The special filehandle that iterates over command-line filenames in `@ARGV`. Usually written as the null filehandle in the angle operator <>. Note that currently `ARGV` only has its magical effect within the <> operator; elsewhere it is just a plain filehandle corresponding to the last file opened by <>. In particular, passing `\*ARGV` as a parameter to a function that expects a filehandle may not cause your function to automatically read the contents of all the files in `@ARGV`.

$ ARGV

contains the name of the current file when reading from <>.

@ARGV

The array @ARGV contains the command-line arguments intended for the script. `$#ARGV` is generally the number of arguments minus one, because `$ARGV[0]` is the first argument, *not* the program's command name itself. See `$0` for the command name.

ARGVOUT

The special filehandle that points to the currently open output file when doing edit-in-place processing with **-i**. Useful when you have to do a lot of inserting and don't want to keep modifying $_. See *perlrun* for the **-i** switch.

@F

The array @F contains the fields of each line read in when autosplit mode is turned on. See *perlrun* for the **-a** switch. This array is package-specific, and must be declared or given a full package name if not in package main when running under `strict 'vars'`.

@INC

The array @INC contains the list of places that the `do EXPR`, `require`, or `use` constructs look for their library files. It initially consists of the arguments to any **-I** command-line switches, followed by the default Perl library, probably */usr/local/lib/perl*, followed by ".", to represent the current directory. ("." will not be appended if taint checks are enabled, either by `-T` or by `-t`.) If you need to modify this at runtime, you should use the `use lib` pragma to get the machine-dependent library properly loaded also:

```
use lib '/mypath/libdir/';
use SomeMod;
```

You can also insert hooks into the file inclusion system by putting Perl code directly into @INC. Those hooks may be subroutine references, array references or blessed objects. See require in *perlfunc* for details.

@_

Within a subroutine the array @_ contains the parameters passed to that subroutine. See *perlsub*.

%INC

The hash %INC contains entries for each filename included via the `do`, `require`, or `use` operators. The key is the filename you specified (with module names converted to pathnames), and the value is the location of the file found. The `require` operator uses this hash to determine whether a particular file has already been included.

If the file was loaded via a hook (e.g. a subroutine reference, see require in *perlfunc* for a description of these hooks), this hook is by default inserted into %INC in place of a filename. Note, however, that the hook may have set the %INC entry by itself to provide some more specific info.

%ENV

$ ENV{expr}

The hash %ENV contains your current environment. Setting a value in `ENV` changes the environment for any child processes you subsequently fork() off.

%SIG

$ SIG{expr}

The hash %SIG contains signal handlers for signals. For example:

```
sub handler {       # 1st argument is signal name
    my($sig) = @_;
    print "Caught a SIG$sig--shutting down\n";
    close(LOG);
    exit(0);
}

$SIG{'INT'}  = \&handler;
$SIG{'QUIT'} = \&handler;
...
$SIG{'INT'}  = 'DEFAULT';   # restore default action
$SIG{'QUIT'} = 'IGNORE';    # ignore SIGQUIT
```

Using a value of `'IGNORE'` usually has the effect of ignoring the signal, except for the `CHLD` signal. See *perlipc* for more about this special case.

Here are some other examples:

```
$SIG{"PIPE"} = "Plumber";   # assumes main::Plumber (not recommended)
$SIG{"PIPE"} = \&Plumber;   # just fine; assume current Plumber
$SIG{"PIPE"} = *Plumber;    # somewhat esoteric
$SIG{"PIPE"} = Plumber();   # oops, what did Plumber() return??
```

Be sure not to use a bareword as the name of a signal handler, lest you inadvertently call it.

If your system has the sigaction() function then signal handlers are installed using it. This means you get reliable signal handling.

The default delivery policy of signals changed in Perl 5.8.0 from immediate (also known as "unsafe") to deferred, also known as "safe signals". See *perlipc* for more information.

Certain internal hooks can be also set using the %SIG hash. The routine indicated by `$SIG{__WARN__}` is called when a warning message is about to be printed. The warning message is passed as the first argument. The presence of a __WARN__ hook causes the ordinary printing of warnings to STDERR to be suppressed. You can use this to save warnings in a variable, or turn warnings into fatal errors, like this:

```
    local $SIG{__WARN__} = sub { die $_[0] };
    eval $proggie;
```

The routine indicated by `$SIG{__DIE__}` is called when a fatal exception is about to be thrown. The error message is passed as the first argument. When a __DIE__ hook routine returns, the exception processing continues as it would have in the absence of the hook, unless the hook routine itself exits via a `goto`, a loop exit, or a die(). The `__DIE__` handler is explicitly disabled during the call, so that you can die from a `__DIE__` handler. Similarly for `__WARN__`.

Due to an implementation glitch, the `$SIG{__DIE__}` hook is called even inside an eval(). Do not use this to rewrite a pending exception in `$@`, or as a bizarre substitute for overriding CORE::GLOBAL::die(). This strange action at a distance may be fixed in a future release so that `$SIG{__DIE__}` is only called if your program is about to exit, as was the original intent. Any other use is deprecated.

`__DIE__`/`__WARN__` handlers are very special in one respect: they may be called to report (probable) errors found by the parser. In such a case the parser may be in inconsistent state, so any attempt to evaluate Perl code from such a handler will probably result in a segfault. This means that warnings or errors that result from parsing Perl should be used with extreme caution, like this:

```
    require Carp if defined $^S;
    Carp::confess("Something wrong") if defined &Carp::confess;
    die "Something wrong, but could not load Carp to give backtrace...
         To see backtrace try starting Perl with -MCarp switch";
```

Here the first line will load Carp *unless* it is the parser who called the handler. The second line will print backtrace and die if Carp was available. The third line will be executed only if Carp was not available.

See die in *perlfunc*, warn in *perlfunc*, eval in *perlfunc*, and *warnings* for additional information.

39.1.2 Error Indicators

The variables `$@`, `$!`, `$^E`, and `$?` contain information about different types of error conditions that may appear during execution of a Perl program. The variables are shown ordered by the "distance" between the subsystem which reported the error and the Perl process. They correspond to errors detected by the Perl interpreter, C library, operating system, or an external program, respectively.

To illustrate the differences between these variables, consider the following Perl expression, which uses a single-quoted string:

```
    eval q{
        open my $pipe, "/cdrom/install |" or die $!;
        my @res = <$pipe>;
        close $pipe or die "bad pipe: $?, $!";
    };
```

After execution of this statement all 4 variables may have been set.

`$@` is set if the string to be `eval`-ed did not compile (this may happen if `open` or `close` were imported with bad prototypes), or if Perl code executed during evaluation die()d . In these cases the value of $@ is the compile error, or the argument to `die` (which will interpolate `$!` and `$?`!). (See also *Fatal*, though.)

When the eval() expression above is executed, open(), `<PIPE>`, and `close` are translated to calls in the C run-time library and thence to the operating system kernel. `$!` is set to the C library's `errno` if one of these calls fails.

Under a few operating systems, `$^E` may contain a more verbose error indicator, such as in this case, "CDROM tray not closed." Systems that do not support extended error messages leave `$^E` the same as `$!`.

Finally, `$?` may be set to non-0 value if the external program */cdrom/install* fails. The upper eight bits reflect specific error conditions encountered by the program (the program's exit() value). The lower eight bits reflect mode of failure, like signal death and core dump information See wait(2) for details. In contrast to `$!` and `$^E`, which are set only if error condition is detected, the variable `$?` is set on each `wait` or pipe `close`, overwriting the old value. This is more like `$@`, which on every eval() is always set on failure and cleared on success.

For more details, see the individual descriptions at `$@`, `$!`, `$^E`, and `$?`.

39.1.3 Technical Note on the Syntax of Variable Names

Variable names in Perl can have several formats. Usually, they must begin with a letter or underscore, in which case they can be arbitrarily long (up to an internal limit of 251 characters) and may contain letters, digits, underscores, or the special sequence `::` or `'`. In this case, the part before the last `::` or `'` is taken to be a *package qualifier*; see *perlmod*.

Perl variable names may also be a sequence of digits or a single punctuation or control character. These names are all reserved for special uses by Perl; for example, the all-digits names are used to hold data captured by backreferences after a regular expression match. Perl has a special syntax for the single-control-character names: It understands `^X` (caret `X`) to mean the control-`X` character. For example, the notation `$^W` (dollar-sign caret `W`) is the scalar variable whose name is the single character control-`W`. This is better than typing a literal control-`W` into your program.

Finally, new in Perl 5.6, Perl variable names may be alphanumeric strings that begin with control characters (or better yet, a caret). These variables must be written in the form `${^Foo}`; the braces are not optional. `${^Foo}` denotes the scalar variable whose name is a control-`F` followed by two `o`'s. These variables are reserved for future special uses by Perl, except for the ones that begin with `^_` (control-underscore or caret-underscore). No control-character name that begins with `^_` will acquire a special meaning in any future version of Perl; such names may therefore be used safely in programs. `$^_` itself, however, *is* reserved.

Perl identifiers that begin with digits, control characters, or punctuation characters are exempt from the effects of the `package` declaration and are always forced to be in package `main`; they are also exempt from `strict 'vars'` errors. A few other names are also exempt in these ways:

```
ENV             STDIN
INC             STDOUT
ARGV            STDERR
ARGVOUT         _
SIG
```

In particular, the new special `${^_XYZ}` variables are always taken to be in package `main`, regardless of any `package` declarations presently in scope.

39.2 BUGS

Due to an unfortunate accident of Perl's implementation, `use English` imposes a considerable performance penalty on all regular expression matches in a program, regardless of whether they occur in the scope of `use English`. For that reason, saying `use English` in libraries is strongly discouraged. See the Devel::SawAmpersand module documentation from CPAN (http://www.cpan.org/modules/by-module/Devel/) for more information.

Having to even think about the `$^S` variable in your exception handlers is simply wrong. `$SIG{__DIE__}` as currently implemented invites grievous and difficult to track down errors. Avoid it and use an `END{}` or CORE::GLOBAL::die override instead.

Chapter 40

perlre

Perl regular expressions

40.1 DESCRIPTION

This page describes the syntax of regular expressions in Perl.

If you haven't used regular expressions before, a quick-start introduction is available in *perlrequick*, and a longer tutorial introduction is available in *perlretut*.

For reference on how regular expressions are used in matching operations, plus various examples of the same, see discussions of `m//`, `s///`, `qr//` and `??` in Regexp Quote-Like Operators in *perlop*.

Matching operations can have various modifiers. Modifiers that relate to the interpretation of the regular expression inside are listed below. Modifiers that alter the way a regular expression is used by Perl are detailed in Regexp Quote-Like Operators in *perlop* and Gory details of parsing quoted constructs in *perlop*.

i

Do case-insensitive pattern matching.

If `use locale` is in effect, the case map is taken from the current locale. See *perllocale*.

m

Treat string as multiple lines. That is, change "^" and "$" from matching the start or end of the string to matching the start or end of any line anywhere within the string.

s

Treat string as single line. That is, change "." to match any character whatsoever, even a newline, which normally it would not match.

The `/s` and `/m` modifiers both override the `$*` setting. That is, no matter what `$*` contains, `/s` without `/m` will force "^" to match only at the beginning of the string and "$" to match only at the end (or just before a newline at the end) of the string. Together, as /ms, they let the "." match any character whatsoever, while still allowing "^" and "$" to match, respectively, just after and just before newlines within the string.

x

Extend your pattern's legibility by permitting whitespace and comments.

These are usually written as "the `/x` modifier", even though the delimiter in question might not really be a slash. Any of these modifiers may also be embedded within the regular expression itself using the `(?...)` construct. See below.

The `/x` modifier itself needs a little more explanation. It tells the regular expression parser to ignore whitespace that is neither backslashed nor within a character class. You can use this to break up your regular expression into (slightly) more readable parts. The `#` character is also treated as a metacharacter introducing a comment, just as in ordinary Perl code. This also means that if you want real whitespace or `#` characters in the pattern (outside a character class, where they are unaffected by `/x`), that you'll either have to escape them or encode them using octal or hex escapes. Taken together, these features go a long way towards making Perl's regular expressions more readable. Note that you have to be careful not to include the pattern delimiter in the comment–perl has no way of knowing you did not intend to close the pattern early. See the C-comment deletion code in *perlop*.

40.1.1 Regular Expressions

The patterns used in Perl pattern matching derive from supplied in the Version 8 regex routines. (The routines are derived (distantly) from Henry Spencer's freely redistributable reimplementation of the V8 routines.) See Version 8 Regular Expressions for details.

In particular the following metacharacters have their standard *egrep*-ish meanings:

```
\   Quote the next metacharacter
^   Match the beginning of the line
.   Match any character (except newline)
$   Match the end of the line (or before newline at the end)
|   Alternation
()  Grouping
[]  Character class
```

By default, the "^" character is guaranteed to match only the beginning of the string, the "$" character only the end (or before the newline at the end), and Perl does certain optimizations with the assumption that the string contains only one line. Embedded newlines will not be matched by "^" or "$". You may, however, wish to treat a string as a multi-line buffer, such that the "^" will match after any newline within the string, and "$" will match before any newline. At the cost of a little more overhead, you can do this by using the /m modifier on the pattern match operator. (Older programs did this by setting `$*`, but this practice is now deprecated.)

To simplify multi-line substitutions, the "." character never matches a newline unless you use the `/s` modifier, which in effect tells Perl to pretend the string is a single line–even if it isn't. The `/s` modifier also overrides the setting of `$*`, in case you have some (badly behaved) older code that sets it in another module.

The following standard quantifiers are recognized:

```
*      Match 0 or more times
+      Match 1 or more times
?      Match 1 or 0 times
{n}    Match exactly n times
{n,}   Match at least n times
{n,m}  Match at least n but not more than m times
```

(If a curly bracket occurs in any other context, it is treated as a regular character. In particular, the lower bound is not optional.) The "*" modifier is equivalent to `{0,}`, the "+" modifier to `{1,}`, and the "?" modifier to `{0,1}`. n and m are limited to integral values less than a preset limit defined when perl is built. This is usually 32766 on the most common platforms. The actual limit can be seen in the error message generated by code such as this:

```
$_ **= $_ , / {$_} / for 2 .. 42;
```

By default, a quantified subpattern is "greedy", that is, it will match as many times as possible (given a particular starting location) while still allowing the rest of the pattern to match. If you want it to match the minimum number of times possible, follow the quantifier with a "?". Note that the meanings don't change, just the "greediness":

```
*?     Match 0 or more times
+?     Match 1 or more times
??     Match 0 or 1 time
{n}?   Match exactly n times
{n,}?  Match at least n times
{n,m}? Match at least n but not more than m times
```

Because patterns are processed as double quoted strings, the following also work:

```
    \t          tab                   (HT, TAB)
    \n          newline               (LF, NL)
    \r          return                (CR)
    \f          form feed             (FF)
    \a          alarm (bell)          (BEL)
    \e          escape (think troff)  (ESC)
    \033        octal char (think of a PDP-11)
    \x1B        hex char
    \x{263a}    wide hex char         (Unicode SMILEY)
    \c[         control char
    \N{name}    named char
    \l          lowercase next char (think vi)
    \u          uppercase next char (think vi)
    \L          lowercase till \E (think vi)
    \U          uppercase till \E (think vi)
    \E          end case modification (think vi)
    \Q          quote (disable) pattern metacharacters till \E
```

If `use locale` is in effect, the case map used by `\l`, `\L`, `\u` and `\U` is taken from the current locale. See *perllocale*. For documentation of `\N{name}`, see *charnames*.

You cannot include a literal `$` or `@` within a `\Q` sequence. An unescaped `$` or `@` interpolates the corresponding variable, while escaping will cause the literal string `\$` to be matched. You'll need to write something like `m/\Quser\E\@\Qhost/`.

In addition, Perl defines the following:

```
    \w  Match a "word" character (alphanumeric plus "_")
    \W  Match a non-"word" character
    \s  Match a whitespace character
    \S  Match a non-whitespace character
    \d  Match a digit character
    \D  Match a non-digit character
    \pP Match P, named property.  Use \p{Prop} for longer names.
    \PP Match non-P
    \X  Match eXtended Unicode "combining character sequence",
        equivalent to (?:\PM\pM*)
    \C  Match a single C char (octet) even under Unicode.
        NOTE: breaks up characters into their UTF-8 bytes,
        so you may end up with malformed pieces of UTF-8.
        Unsupported in lookbehind.
```

A `\w` matches a single alphanumeric character (an alphabetic character, or a decimal digit) or `_`, not a whole word. Use `\w+` to match a string of Perl-identifier characters (which isn't the same as matching an English word). If `use locale` is in effect, the list of alphabetic characters generated by `\w` is taken from the current locale. See *perllocale*. You may use `\w`, `\W`, `\s`, `\S`, `\d`, and `\D` within character classes, but if you try to use them as endpoints of a range, that's not a range, the "-" is understood literally. If Unicode is in effect, `\s` matches also "\x{85}", "\x{2028}, and "\x{2029}", see *perlunicode* for more details about `\pP`, `\PP`, and `\X`, and *perluniintro* about Unicode in general. You can define your own `\p` and `\P` propreties, see *perlunicode*.

The POSIX character class syntax

```
    [:class:]
```

is also available. The available classes and their backslash equivalents (if available) are as follows:

```
    alpha
    alnum
    ascii
    blank              [1]
    cntrl
    digit       \d
    graph
    lower
    print
    punct
    space       \s     [2]
    upper
    word        \w     [3]
    xdigit
```

[1]

A GNU extension equivalent to `[ \t]`, 'all horizontal whitespace'.

[2]

Not exactly equivalent to `\s` since the `[[:space:]]` includes also the (very rare) 'vertical tabulator', "\ck", chr(11).

[3]

A Perl extension, see above.

For example use `[:upper:]` to match all the uppercase characters. Note that the `[]` are part of the `[::]` construct, not part of the whole character class. For example:

```
    [01[:alpha:]%]
```

matches zero, one, any alphabetic character, and the percentage sign.

The following equivalences to Unicode \p{} constructs and equivalent backslash character classes (if available), will hold:

```
    [:...:]     \p{...}         backslash

    alpha       IsAlpha
    alnum       IsAlnum
    ascii       IsASCII
    blank       IsSpace
    cntrl       IsCntrl
    digit       IsDigit        \d
    graph       IsGraph
    lower       IsLower
    print       IsPrint
    punct       IsPunct
    space       IsSpace
                IsSpacePerl    \s
    upper       IsUpper
    word        IsWord
    xdigit      IsXDigit
```

For example `[:lower:]` and `\p{IsLower}` are equivalent.

If the `utf8` pragma is not used but the `locale` pragma is, the classes correlate with the usual isalpha(3) interface (except for 'word' and 'blank').

The assumedly non-obviously named classes are:

cntrl

Any control character. Usually characters that don't produce output as such but instead control the terminal somehow: for example newline and backspace are control characters. All characters with ord() less than 32 are most often classified as control characters (assuming ASCII, the ISO Latin character sets, and Unicode), as is the character with the ord() value of 127 (`DEL`).

graph

Any alphanumeric or punctuation (special) character.

print

Any alphanumeric or punctuation (special) character or the space character.

punct

Any punctuation (special) character.

xdigit

Any hexadecimal digit. Though this may feel silly ([0-9A-Fa-f] would work just fine) it is included for completeness.

You can negate the [::] character classes by prefixing the class name with a '^'. This is a Perl extension. For example:

```
    POSIX       traditional Unicode

    [:^digit:]      \D      \P{IsDigit}
    [:^space:]      \S      \P{IsSpace}
    [:^word:]       \W      \P{IsWord}
```

Perl respects the POSIX standard in that POSIX character classes are only supported within a character class. The POSIX character classes [.cc.] and [=cc=] are recognized but **not** supported and trying to use them will cause an error.

Perl defines the following zero-width assertions:

```
    \b  Match a word boundary
    \B  Match a non-(word boundary)
    \A  Match only at beginning of string
    \Z  Match only at end of string, or before newline at the end
    \z  Match only at end of string
    \G  Match only at pos() (e.g. at the end-of-match position
        of prior m//g)
```

A word boundary (`\b`) is a spot between two characters that has a `\w` on one side of it and a `\W` on the other side of it (in either order), counting the imaginary characters off the beginning and end of the string as matching a `\W`. (Within character classes `\b` represents backspace rather than a word boundary, just as it normally does in any double-quoted string.) The `\A` and `\Z` are just like "^" and "$", except that they won't match multiple times when the `/m` modifier is used, while "^" and "$" will match at every internal line boundary. To match the actual end of the string and not ignore an optional trailing newline, use `\z`.

The `\G` assertion can be used to chain global matches (using `m//g`), as described in Regexp Quote-Like Operators in *perlop*. It is also useful when writing `lex`-like scanners, when you have several patterns that you want to match against consequent substrings of your string, see the previous reference. The actual location where `\G` will match can also be influenced by using `pos()` as an lvalue: see pos in *perlfunc*. Currently `\G` is only fully supported when anchored to the start of the pattern; while it is permitted to use it elsewhere, as in `/(?<=\G..)./g`, some such uses (`/.\G/g`, for example) currently cause problems, and it is recommended that you avoid such usage for now.

The bracketing construct `( ... )` creates capture buffers. To refer to the digit'th buffer use \<digit> within the match. Outside the match use "$" instead of "\". (The \<digit> notation works in certain circumstances outside the match. See the warning below about \1 vs $1 for details.) Referring back to another part of the match is called a *backreference*.

There is no limit to the number of captured substrings that you may use. However Perl also uses \10, \11, etc. as aliases for \010, \011, etc. (Recall that 0 means octal, so \011 is the character at number 9 in your coded character set; which would be the 10th character, a horizontal tab under ASCII.) Perl resolves this ambiguity by interpreting \10 as a backreference only if at least 10 left parentheses have opened before it. Likewise \11 is a backreference only if at least 11 left parentheses have opened before it. And so on. \1 through \9 are always interpreted as backreferences.

Examples:

```
s/^([^ ]*) *([^ ]*)/$2 $1/;     # swap first two words

 if (/(.)\1/) {                 # find first doubled char
     print "'$1' is the first doubled character\n";
 }

if (/Time: (..):(..):(..)/) {   # parse out values
    $hours = $1;
    $minutes = $2;
    $seconds = $3;
}
```

Several special variables also refer back to portions of the previous match. `$+` returns whatever the last bracket match matched. `$&` returns the entire matched string. (At one point `$0` did also, but now it returns the name of the program.) `` $` `` returns everything before the matched string. `$'` returns everything after the matched string. And `$^N` contains whatever was matched by the most-recently closed group (submatch). `$^N` can be used in extended patterns (see below), for example to assign a submatch to a variable.

The numbered match variables ($1, $2, $3, etc.) and the related punctuation set (`$+`, `$&`, `` $` ``, `$'`, and `$^N`) are all dynamically scoped until the end of the enclosing block or until the next successful match, whichever comes first. (See Compound Statements in *perlsyn*.)

NOTE: failed matches in Perl do not reset the match variables, which makes easier to write code that tests for a series of more specific cases and remembers the best match.

WARNING: Once Perl sees that you need one of `$&`, `` $` ``, or `$'` anywhere in the program, it has to provide them for every pattern match. This may substantially slow your program. Perl uses the same mechanism to produce $1, $2, etc, so you also pay a price for each pattern that contains capturing parentheses. (To avoid this cost while retaining the grouping behaviour, use the extended regular expression `(?: ... )` instead.) But if you never use `$&`, `` $` `` or `$'`, then patterns *without* capturing parentheses will not be penalized. So avoid `$&`, `$'`, and `` $` `` if you can, but if you can't (and some algorithms really appreciate them), once you've used them once, use them at will, because you've already paid the price. As of 5.005, `$&` is not so costly as the other two.

Backslashed metacharacters in Perl are alphanumeric, such as `\b`, `\w`, `\n`. Unlike some other regular expression languages, there are no backslashed symbols that aren't alphanumeric. So anything that looks like \\, \(, \), \<, \>, \{, or \} is always interpreted as a literal character, not a metacharacter. This was once used in a common idiom to disable or quote the special meanings of regular expression metacharacters in a string that you want to use for a pattern. Simply quote all non-"word" characters:

```
$pattern =~ s/(\W)/\\$1/g;
```

(If `use locale` is set, then this depends on the current locale.) Today it is more common to use the quotemeta() function or the `\Q` metaquoting escape sequence to disable all metacharacters' special meanings like this:

```
/$unquoted\Q$quoted\E$unquoted/
```

Beware that if you put literal backslashes (those not inside interpolated variables) between `\Q` and `\E`, double-quotish backslash interpolation may lead to confusing results. If you *need* to use literal backslashes within `\Q...\E`, consult Gory details of parsing quoted constructs in *perlop*.

40.1.2 Extended Patterns

Perl also defines a consistent extension syntax for features not found in standard tools like **awk** and **lex**. The syntax is a pair of parentheses with a question mark as the first thing within the parentheses. The character after the question mark indicates the extension.

The stability of these extensions varies widely. Some have been part of the core language for many years. Others are experimental and may change without warning or be completely removed. Check the documentation on an individual feature to verify its current status.

A question mark was chosen for this and for the minimal-matching construct because 1) question marks are rare in older regular expressions, and 2) whenever you see one, you should stop and "question" exactly what is going on. That's psychology...

`(?#text)`

A comment. The text is ignored. If the `/x` modifier enables whitespace formatting, a simple `#` will suffice. Note that Perl closes the comment as soon as it sees a `)`, so there is no way to put a literal `)` in the comment.

`(?imsx-imsx)`

One or more embedded pattern-match modifiers, to be turned on (or turned off, if preceded by `-`) for the remainder of the pattern or the remainder of the enclosing pattern group (if any). This is particularly useful for dynamic patterns, such as those read in from a configuration file, read in as an argument, are specified in a table somewhere, etc. Consider the case that some of which want to be case sensitive and some do not. The case insensitive ones need to include merely `(?i)` at the front of the pattern. For example:

```
$pattern = "foobar";
if ( /$pattern/i ) { }

# more flexible:

$pattern = "(?i)foobar";
if ( /$pattern/ ) { }
```

These modifiers are restored at the end of the enclosing group. For example,

```
( (?i) blah ) \s+ \1
```

will match a repeated (*including the case*!) word `blah` in any case, assuming `x` modifier, and no `i` modifier outside this group.

`(?:pattern)`

`(?imsx-imsx:pattern)`

This is for clustering, not capturing; it groups subexpressions like "()", but doesn't make backreferences as "()" does. So

```
@fields = split(/\b(?:a|b|c)\b/)
```

is like

```
@fields = split(/\b(a|b|c)\b/)
```

but doesn't spit out extra fields. It's also cheaper not to capture characters if you don't need to.

Any letters between `?` and `:` act as flags modifiers as with `(?imsx-imsx)`. For example,

```
/(?s-i:more.*than).*million/i
```

is equivalent to the more verbose

```
/(?:(?s-i)more.*than).*million/i
```

(?=pattern)

A zero-width positive look-ahead assertion. For example, `/\w+(?=\t)/` matches a word followed by a tab, without including the tab in `$&`.

(?!pattern)

A zero-width negative look-ahead assertion. For example `/foo(?!bar)/` matches any occurrence of "foo" that isn't followed by "bar". Note however that look-ahead and look-behind are NOT the same thing. You cannot use this for look-behind.

If you are looking for a "bar" that isn't preceded by a "foo", `/(?!foo)bar/` will not do what you want. That's because the `(?!foo)` is just saying that the next thing cannot be "foo"–and it's not, it's a "bar", so "foobar" will match. You would have to do something like `/(?!foo)...bar/` for that. We say "like" because there's the case of your "bar" not having three characters before it. You could cover that this way: `/(?:(?!foo)...|^.{0,2})bar/`. Sometimes it's still easier just to say:

```
if (/bar/ && $` !~ /foo$/)
```

For look-behind see below.

(?<=pattern)

A zero-width positive look-behind assertion. For example, `/(?<=\t)\w+/` matches a word that follows a tab, without including the tab in `$&`. Works only for fixed-width look-behind.

(?<!pattern)

A zero-width negative look-behind assertion. For example `/(?<!bar)foo/` matches any occurrence of "foo" that does not follow "bar". Works only for fixed-width look-behind.

(?{ code })

WARNING: This extended regular expression feature is considered highly experimental, and may be changed or deleted without notice.

This zero-width assertion evaluates any embedded Perl code. It always succeeds, and its `code` is not interpolated. Currently, the rules to determine where the `code` ends are somewhat convoluted.

This feature can be used together with the special variable `$^N` to capture the results of submatches in variables without having to keep track of the number of nested parentheses. For example:

```
$_ = "The brown fox jumps over the lazy dog";
/the (\S+)(?{ $color = $^N }) (\S+)(?{ $animal = $^N })/i;
print "color = $color, animal = $animal\n";
```

Inside the `(?{...})` block, `$_` refers to the string the regular expression is matching against. You can also use `pos()` to know what is the current position of matching withing this string.

The `code` is properly scoped in the following sense: If the assertion is backtracked (compare §40.1.3), all changes introduced after `local`ization are undone, so that

```
$_ = 'a' x 8;
m<
   (?{ $cnt = 0 })                   # Initialize $cnt.
   (
     a
     (?{
         local $cnt = $cnt + 1;      # Update $cnt, backtracking-safe.
```

```
        })
       )*
       aaaa
       (?{ $res = $cnt })                # On success copy to non-localized
                                         # location.
     >x;
```

will set `$res = 4`. Note that after the match, $cnt returns to the globally introduced value, because the scopes that restrict `local` operators are unwound.

This assertion may be used as a `(?(condition)yes-pattern|no-pattern)` switch. If *not* used in this way, the result of evaluation of `code` is put into the special variable `$^R`. This happens immediately, so `$^R` can be used from other `(?{ code })` assertions inside the same regular expression.

The assignment to `$^R` above is properly localized, so the old value of `$^R` is restored if the assertion is backtracked; compare §40.1.3.

For reasons of security, this construct is forbidden if the regular expression involves run-time interpolation of variables, unless the perilous `use re 'eval'` pragma has been used (see *re*), or the variables contain results of `qr//` operator (see qr/STRING/imosx in *perlop*).

This restriction is because of the wide-spread and remarkably convenient custom of using run-time determined strings as patterns. For example:

```
    $re = <>;
    chomp $re;
    $string =~ /$re/;
```

Before Perl knew how to execute interpolated code within a pattern, this operation was completely safe from a security point of view, although it could raise an exception from an illegal pattern. If you turn on the `use re 'eval'`, though, it is no longer secure, so you should only do so if you are also using taint checking. Better yet, use the carefully constrained evaluation within a Safe compartment. See *perlsec* for details about both these mechanisms.

`(??{ code })`

WARNING: This extended regular expression feature is considered highly experimental, and may be changed or deleted without notice. A simplified version of the syntax may be introduced for commonly used idioms.

This is a "postponed" regular subexpression. The `code` is evaluated at run time, at the moment this subexpression may match. The result of evaluation is considered as a regular expression and matched as if it were inserted instead of this construct.

The `code` is not interpolated. As before, the rules to determine where the `code` ends are currently somewhat convoluted.

The following pattern matches a parenthesized group:

```
  $re = qr{
             \(
             (?:
                (?> [^()]+ )    # Non-parens without backtracking
              |
                (??{ $re })     # Group with matching parens
             )*
             \)
          }x;
```

`(?>pattern)`

WARNING: This extended regular expression feature is considered highly experimental, and may be changed or deleted without notice.

An "independent" subexpression, one which matches the substring that a *standalone* `pattern` would match if anchored at the given position, and it matches *nothing other than this substring*. This construct is useful for optimizations of what would otherwise be "eternal" matches, because it will not backtrack (see §40.1.3). It may also be useful in places where the "grab all you can, and do not give anything back" semantic is desirable.

For example: `^(?>a*)ab` will never match, since `(?>a*)` (anchored at the beginning of string, as above) will match *all* characters `a` at the beginning of string, leaving no `a` for `ab` to match. In contrast, `a*ab` will match the same as `a+b`, since the match of the subgroup `a*` is influenced by the following group `ab` (see §40.1.3). In particular, `a*` inside `a*ab` will match fewer characters than a standalone `a*`, since this makes the tail match.

An effect similar to `(?>pattern)` may be achieved by writing `(?=(pattern))\1`. This matches the same substring as a standalone `a+`, and the following `\1` eats the matched string; it therefore makes a zero-length assertion into an analogue of `(?>...)`. (The difference between these two constructs is that the second one uses a capturing group, thus shifting ordinals of backreferences in the rest of a regular expression.)

Consider this pattern:

```
    m{ \(
          (
            [^()]+              # x+
          |
            \( [^()]* \)
          )+
       \)
     }x
```

That will efficiently match a nonempty group with matching parentheses two levels deep or less. However, if there is no such group, it will take virtually forever on a long string. That's because there are so many different ways to split a long string into several substrings. This is what `(.+)+` is doing, and `(.+)+` is similar to a subpattern of the above pattern. Consider how the pattern above detects no-match on `((()aaaaaaaaaaaaaaaaaa` in several seconds, but that each extra letter doubles this time. This exponential performance will make it appear that your program has hung. However, a tiny change to this pattern

```
    m{ \(
          (
            (?> [^()]+ )        # change x+ above to (?> x+ )
          |
            \( [^()]* \)
          )+
       \)
     }x
```

which uses `(?>...)` matches exactly when the one above does (verifying this yourself would be a productive exercise), but finishes in a fourth the time when used on a similar string with 1000000 `a`s. Be aware, however, that this pattern currently triggers a warning message under the `use warnings` pragma or **-w** switch saying it `"matches null string many times in regex"`.

On simple groups, such as the pattern `(?> [^()]+ )`, a comparable effect may be achieved by negative look-ahead, as in `[^()]+ (?! [^()] )`. This was only 4 times slower on a string with 1000000 `a`s.

The "grab all you can, and do not give anything back" semantic is desirable in many situations where on the first sight a simple `()*` looks like the correct solution. Suppose we parse text with comments being delimited by `#` followed by some optional (horizontal) whitespace. Contrary to its appearance, `#[ \t]*` *is not* the correct subexpression to match the comment delimiter, because it may "give up" some whitespace if the remainder of the pattern can be made to match that way. The correct answer is either one of these:

```
    (?>#[ \t]*)
    #[ \t]*(?![ \t])
```

For example, to grab non-empty comments into $1, one should use either one of these:

```
        / (?> \# [ \t]* ) (        .+ ) /x;
        /     \# [ \t]*   ( [^ \t] .* ) /x;
```

Which one you pick depends on which of these expressions better reflects the above specification of comments.

(?(condition)yes-pattern|no-pattern)

(?(condition)yes-pattern)

WARNING: This extended regular expression feature is considered highly experimental, and may be changed or deleted without notice.

Conditional expression. `(condition)` should be either an integer in parentheses (which is valid if the corresponding pair of parentheses matched), or look-ahead/look-behind/evaluate zero-width assertion.

For example:

```
        m{ ( \( )?
           [^()]+
           (?(1) \) )
         }x
```

matches a chunk of non-parentheses, possibly included in parentheses themselves.

40.1.3 Backtracking

NOTE: This section presents an abstract approximation of regular expression behavior. For a more rigorous (and complicated) view of the rules involved in selecting a match among possible alternatives, see Combining pieces together.

A fundamental feature of regular expression matching involves the notion called *backtracking*, which is currently used (when needed) by all regular expression quantifiers, namely `*`, `*?`, `+`, `+?`, `{n,m}`, and `{n,m}?`. Backtracking is often optimized internally, but the general principle outlined here is valid.

For a regular expression to match, the *entire* regular expression must match, not just part of it. So if the beginning of a pattern containing a quantifier succeeds in a way that causes later parts in the pattern to fail, the matching engine backs up and recalculates the beginning part–that's why it's called backtracking.

Here is an example of backtracking: Let's say you want to find the word following "foo" in the string "Food is on the foo table.":

```
    $_ = "Food is on the foo table.";
    if ( /\b(foo)\s+(\w+)/i ) {
        print "$2 follows $1.\n";
    }
```

When the match runs, the first part of the regular expression (`\b(foo)`) finds a possible match right at the beginning of the string, and loads up $1 with "Foo". However, as soon as the matching engine sees that there's no whitespace following the "Foo" that it had saved in $1, it realizes its mistake and starts over again one character after where it had the tentative match. This time it goes all the way until the next occurrence of "foo". The complete regular expression matches this time, and you get the expected output of "table follows foo."

Sometimes minimal matching can help a lot. Imagine you'd like to match everything between "foo" and "bar". Initially, you write something like this:

```
    $_ =  "The food is under the bar in the barn.";
    if ( /foo(.*)bar/ ) {
        print "got <$1>\n";
    }
```

Which perhaps unexpectedly yields:

```
  got <d is under the bar in the >
```

That's because `.*` was greedy, so you get everything between the *first* "foo" and the *last* "bar". Here it's more effective to use minimal matching to make sure you get the text between a "foo" and the first "bar" thereafter.

```
    if ( /foo(.*?)bar/ ) { print "got <$1>\n" }
  got <d is under the >
```

Here's another example: let's say you'd like to match a number at the end of a string, and you also want to keep the preceding part of the match. So you write this:

```
    $_ = "I have 2 numbers: 53147";
    if ( /(.*)(\d*)/ ) {                                # Wrong!
        print "Beginning is <$1>, number is <$2>.\n";
    }
```

That won't work at all, because `.*` was greedy and gobbled up the whole string. As `\d*` can match on an empty string the complete regular expression matched successfully.

```
    Beginning is <I have 2 numbers: 53147>, number is <>.
```

Here are some variants, most of which don't work:

```
    $_ = "I have 2 numbers: 53147";
    @pats = qw{
        (.*)(\d*)
        (.*)(\d+)
        (.*?)(\d*)
        (.*?)(\d+)
        (.*)(\d+)$
        (.*?)(\d+)$
        (.*)\b(\d+)$
        (.*\D)(\d+)$
    };

    for $pat (@pats) {
        printf "%-12s ", $pat;
        if ( /$pat/ ) {
            print "<$1> <$2>\n";
        } else {
            print "FAIL\n";
        }
    }
```

That will print out:

```
    (.*)(\d*)    <I have 2 numbers: 53147> <>
    (.*)(\d+)    <I have 2 numbers: 5314> <7>
    (.*?)(\d*)   <> <>
    (.*?)(\d+)   <I have > <2>
    (.*)(\d+)$   <I have 2 numbers: 5314> <7>
    (.*?)(\d+)$  <I have 2 numbers: > <53147>
    (.*)\b(\d+)$ <I have 2 numbers: > <53147>
    (.*\D)(\d+)$ <I have 2 numbers: > <53147>
```

As you see, this can be a bit tricky. It's important to realize that a regular expression is merely a set of assertions that gives a definition of success. There may be 0, 1, or several different ways that the definition might succeed against a particular string. And if there are multiple ways it might succeed, you need to understand backtracking to know which variety of success you will achieve.

When using look-ahead assertions and negations, this can all get even trickier. Imagine you'd like to find a sequence of non-digits not followed by "123". You might try to write that as

```
    $_ = "ABC123";
    if ( /^\D*(?!123)/ ) {              # Wrong!
        print "Yup, no 123 in $_\n";
    }
```

But that isn't going to match; at least, not the way you're hoping. It claims that there is no 123 in the string. Here's a clearer picture of why that pattern matches, contrary to popular expectations:

```
    $x = 'ABC123' ;
    $y = 'ABC445' ;

    print "1: got $1\n" if $x =~ /^(ABC)(?!123)/ ;
    print "2: got $1\n" if $y =~ /^(ABC)(?!123)/ ;

    print "3: got $1\n" if $x =~ /^(\D*)(?!123)/ ;
    print "4: got $1\n" if $y =~ /^(\D*)(?!123)/ ;
```

This prints

```
    2: got ABC
    3: got AB
    4: got ABC
```

You might have expected test 3 to fail because it seems to a more general purpose version of test 1. The important difference between them is that test 3 contains a quantifier (`\D*`) and so can use backtracking, whereas test 1 will not. What's happening is that you've asked "Is it true that at the start of $x, following 0 or more non-digits, you have something that's not 123?" If the pattern matcher had let `\D*` expand to "ABC", this would have caused the whole pattern to fail.

The search engine will initially match `\D*` with "ABC". Then it will try to match `(?!123` with "123", which fails. But because a quantifier (`\D*`) has been used in the regular expression, the search engine can backtrack and retry the match differently in the hope of matching the complete regular expression.

The pattern really, *really* wants to succeed, so it uses the standard pattern back-off-and-retry and lets `\D*` expand to just "AB" this time. Now there's indeed something following "AB" that is not "123". It's "C123", which suffices.

We can deal with this by using both an assertion and a negation. We'll say that the first part in $1 must be followed both by a digit and by something that's not "123". Remember that the look-aheads are zero-width expressions–they only look, but don't consume any of the string in their match. So rewriting this way produces what you'd expect; that is, case 5 will fail, but case 6 succeeds:

```
    print "5: got $1\n" if $x =~ /^(\D*)(?=\d)(?!123)/ ;
    print "6: got $1\n" if $y =~ /^(\D*)(?=\d)(?!123)/ ;

    6: got ABC
```

In other words, the two zero-width assertions next to each other work as though they're ANDed together, just as you'd use any built-in assertions: `/^$/` matches only if you're at the beginning of the line AND the end of the line simultaneously. The deeper underlying truth is that juxtaposition in regular expressions always means AND, except when you write an explicit OR using the vertical bar. `/ab/` means match "a" AND (then) match "b", although the attempted matches are made at different positions because "a" is not a zero-width assertion, but a one-width assertion.

WARNING: particularly complicated regular expressions can take exponential time to solve because of the immense number of possible ways they can use backtracking to try match. For example, without internal optimizations done by the regular expression engine, this will take a painfully long time to run:

```
    'aaaaaaaaaaaa' =~ /((a{0,5}){0,5})*[c]/
```

And if you used *'s in the internal groups instead of limiting them to 0 through 5 matches, then it would take forever–or until you ran out of stack space. Moreover, these internal optimizations are not always applicable. For example, if you put `{0,5}` instead of `*` on the external group, no current optimization is applicable, and the match takes a long time to finish.

A powerful tool for optimizing such beasts is what is known as an "independent group", which does not backtrack (see (?pattern)>). Note also that zero-length look-ahead/look-behind assertions will not backtrack to make the tail match, since they are in "logical" context: only whether they match is considered relevant. For an example where side-effects of look-ahead *might* have influenced the following match, see (?pattern)>.

40.1.4 Version 8 Regular Expressions

In case you're not familiar with the "regular" Version 8 regex routines, here are the pattern-matching rules not described above.

Any single character matches itself, unless it is a *metacharacter* with a special meaning described here or above. You can cause characters that normally function as metacharacters to be interpreted literally by prefixing them with a "\" (e.g., "\." matches a ".", not any character; "\\" matches a "\"). A series of characters matches that series of characters in the target string, so the pattern `blurfl` would match "blurfl" in the target string.

You can specify a character class, by enclosing a list of characters in `[]`, which will match any one character from the list. If the first character after the "[" is "^", the class matches any character not in the list. Within a list, the "-" character specifies a range, so that `a-z` represents all characters between "a" and "z", inclusive. If you want either "-" or "]" itself to be a member of a class, put it at the start of the list (possibly after a "^"), or escape it with a backslash. "-" is also taken literally when it is at the end of the list, just before the closing "]". (The following all specify the same class of three characters: `[-az]`, `[az-]`, and `[a\-z]`. All are different from `[a-z]`, which specifies a class containing twenty-six characters, even on EBCDIC based coded character sets.) Also, if you try to use the character classes `\w`, `\W`, `\s`, `\S`, `\d`, or `\D` as endpoints of a range, that's not a range, the "-" is understood literally.

Note also that the whole range idea is rather unportable between character sets–and even within character sets they may cause results you probably didn't expect. A sound principle is to use only ranges that begin from and end at either alphabets of equal case ([a-e], [A-E]), or digits ([0-9]). Anything else is unsafe. If in doubt, spell out the character sets in full.

Characters may be specified using a metacharacter syntax much like that used in C: "\n" matches a newline, "\t" a tab, "\r" a carriage return, "\f" a form feed, etc. More generally, *nnn*, where *nnn* is a string of octal digits, matches the character whose coded character set value is *nnn*. Similarly, \x*nn*, where *nn* are hexadecimal digits, matches the character whose numeric value is *nn*. The expression \c*x* matches the character control-*x*. Finally, the "." metacharacter matches any character except "\n" (unless you use `/s`).

You can specify a series of alternatives for a pattern using "|" to separate them, so that `fee|fie|foe` will match any of "fee", "fie", or "foe" in the target string (as would `f(e|i|o)e`). The first alternative includes everything from the last pattern delimiter ("(", "[", or the beginning of the pattern) up to the first "|", and the last alternative contains everything from the last "|" to the next pattern delimiter. That's why it's common practice to include alternatives in parentheses: to minimize confusion about where they start and end.

Alternatives are tried from left to right, so the first alternative found for which the entire expression matches, is the one that is chosen. This means that alternatives are not necessarily greedy. For example: when matching `foo|foot` against "barefoot", only the "foo" part will match, as that is the first alternative tried, and it successfully matches the target string. (This might not seem important, but it is important when you are capturing matched text using parentheses.)

Also remember that "|" is interpreted as a literal within square brackets, so if you write `[fee|fie|foe]` you're really only matching `[feio|]`.

Within a pattern, you may designate subpatterns for later reference by enclosing them in parentheses, and you may refer back to the *n*th subpattern later in the pattern using the metacharacter *n*. Subpatterns are numbered based on the left to right order of their opening parenthesis. A backreference matches whatever actually matched the subpattern in the string being examined, not the rules for that subpattern. Therefore, `(0|0x)\d*\s\1\d*` will match "0x1234 0x4321", but not "0x1234 01234", because subpattern 1 matched "0x", even though the rule `0|0x` could potentially match the leading 0 in the second number.

40.1.5 Warning on \1 vs $ 1

Some people get too used to writing things like:

```
    $pattern =~ s/(\W)/\\\1/g;
```

This is grandfathered for the RHS of a substitute to avoid shocking the **sed** addicts, but it's a dirty habit to get into. That's because in PerlThink, the righthand side of an `s///` is a double-quoted string. `\1` in the usual double-quoted string means a control-A. The customary Unix meaning of `\1` is kludged in for `s///`. However, if you get into the habit of doing that, you get yourself into trouble if you then add an `/e` modifier.

```
    s/(\d+)/ \1 + 1 /eg;        # causes warning under -w
```

Or if you try to do

```
    s/(\d+)/\1000/;
```

You can't disambiguate that by saying `\{1}000`, whereas you can fix it with `${1}000`. The operation of interpolation should not be confused with the operation of matching a backreference. Certainly they mean two different things on the *left* side of the `s///`.

40.1.6 Repeated patterns matching zero-length substring

WARNING: Difficult material (and prose) ahead. This section needs a rewrite.

Regular expressions provide a terse and powerful programming language. As with most other power tools, power comes together with the ability to wreak havoc.

A common abuse of this power stems from the ability to make infinite loops using regular expressions, with something as innocuous as:

```
    'foo' =~ m{ ( o? )* }x;
```

The `o?` can match at the beginning of `'foo'`, and since the position in the string is not moved by the match, `o?` would match again and again because of the * modifier. Another common way to create a similar cycle is with the looping modifier `//g`:

```
    @matches = ( 'foo' =~ m{ o? }xg );
```

or

```
    print "match: <$&>\n" while 'foo' =~ m{ o? }xg;
```

or the loop implied by split().

However, long experience has shown that many programming tasks may be significantly simplified by using repeated subexpressions that may match zero-length substrings. Here's a simple example being:

```
    @chars = split //, $string;           # // is not magic in split
    ($whitewashed = $string) =~ s/()/ /g; # parens avoid magic s// /
```

Thus Perl allows such constructs, by *forcefully breaking the infinite loop*. The rules for this are different for lower-level loops given by the greedy modifiers `*+{}`, and for higher-level ones like the `/g` modifier or split() operator.

The lower-level loops are *interrupted* (that is, the loop is broken) when Perl detects that a repeated expression matched a zero-length substring. Thus

```
   m{ (?: NON_ZERO_LENGTH | ZERO_LENGTH )* }x;
```

is made equivalent to

```
   m{   (?: NON_ZERO_LENGTH )*
      |
        (?: ZERO_LENGTH )?
    }x;
```

The higher level-loops preserve an additional state between iterations: whether the last match was zero-length. To break the loop, the following match after a zero-length match is prohibited to have a length of zero. This prohibition interacts with backtracking (see §40.1.3), and so the *second best* match is chosen if the *best* match is of zero length.

For example:

```
    $_ = 'bar';
    s/\w??/<$&>/g;
```

results in <><b><><a><><r><>. At each position of the string the best match given by non-greedy ?? is the zero-length match, and the *second best* match is what is matched by \w. Thus zero-length matches alternate with one-character-long matches.

Similarly, for repeated m/()/g the second-best match is the match at the position one notch further in the string.

The additional state of being *matched with zero-length* is associated with the matched string, and is reset by each assignment to pos(). Zero-length matches at the end of the previous match are ignored during split.

40.1.7 Combining pieces together

Each of the elementary pieces of regular expressions which were described before (such as ab or \Z) could match at most one substring at the given position of the input string. However, in a typical regular expression these elementary pieces are combined into more complicated patterns using combining operators ST, S|T, S* etc (in these examples S and T are regular subexpressions).

Such combinations can include alternatives, leading to a problem of choice: if we match a regular expression a|ab against "abc", will it match substring "a" or "ab"? One way to describe which substring is actually matched is the concept of backtracking (see §40.1.3). However, this description is too low-level and makes you think in terms of a particular implementation.

Another description starts with notions of "better"/"worse". All the substrings which may be matched by the given regular expression can be sorted from the "best" match to the "worst" match, and it is the "best" match which is chosen. This substitutes the question of "what is chosen?" by the question of "which matches are better, and which are worse?".

Again, for elementary pieces there is no such question, since at most one match at a given position is possible. This section describes the notion of better/worse for combining operators. In the description below S and T are regular subexpressions.

ST

Consider two possible matches, AB and A'B', A and A' are substrings which can be matched by S, B and B' are substrings which can be matched by T.

If A is better match for S than A', AB is a better match than A'B'.

If A and A' coincide: AB is a better match than AB' if B is better match for T than B'.

S|T

When S can match, it is a better match than when only T can match.

Ordering of two matches for S is the same as for S. Similar for two matches for T.

S{REPEAT_COUNT}

Matches as SSS...S (repeated as many times as necessary).

S{min,max}

Matches as S{max}|S{max-1}|...|S{min+1}|S{min}.

S{min,max}?

Matches as S{min}|S{min+1}|...|S{max-1}|S{max}.

S?, S*, S+

Same as S{0,1}, S{0,BIG_NUMBER}, S{1,BIG_NUMBER} respectively.

S??, S*?, S+?

Same as S{0,1}?, S{0,BIG_NUMBER}?, S{1,BIG_NUMBER}? respectively.

(?>S)

Matches the best match for S and only that.

(?=S), (?<=S)

Only the best match for S is considered. (This is important only if S has capturing parentheses, and backreferences are used somewhere else in the whole regular expression.)

(?!S), (?<!S)

For this grouping operator there is no need to describe the ordering, since only whether or not S can match is important.

(??{ EXPR })

The ordering is the same as for the regular expression which is the result of EXPR.

(?(condition)yes-pattern|no-pattern)

Recall that which of yes-pattern or no-pattern actually matches is already determined. The ordering of the matches is the same as for the chosen subexpression.

The above recipes describe the ordering of matches *at a given position*. One more rule is needed to understand how a match is determined for the whole regular expression: a match at an earlier position is always better than a match at a later position.

40.1.8 Creating custom RE engines

Overloaded constants (see *overload*) provide a simple way to extend the functionality of the RE engine.

Suppose that we want to enable a new RE escape-sequence \Y| which matches at boundary between white-space characters and non-whitespace characters. Note that (?=\S)(?<!\S)|(?!\S)(?<=\S) matches exactly at these positions, so we want to have each \Y| in the place of the more complicated version. We can create a module customre to do this:

```
package customre;
use overload;

sub import {
  shift;
  die "No argument to customre::import allowed" if @_;
  overload::constant 'qr' => \&convert;
}

sub invalid { die "/$_[0]/: invalid escape '\\$_[1]'"}
```

```
    my %rules = ( '\\' => '\\',
                  'Y|' => qr/(?=\S)(?<!\S)|(?!\S)(?<=\S)/ );
    sub convert {
      my $re = shift;
      $re =~ s{
                \\ ( \\ | Y . )
              }
              { $rules{$1} or invalid($re,$1) }sgex;
      return $re;
    }
```

Now `use customre` enables the new escape in constant regular expressions, i.e., those without any runtime variable interpolations. As documented in *overload*, this conversion will work only over literal parts of regular expressions. For `\Y|$re\Y|` the variable part of this regular expression needs to be converted explicitly (but only if the special meaning of `\Y|` should be enabled inside $re):

```
    use customre;
    $re = <>;
    chomp $re;
    $re = customre::convert $re;
    /\Y|$re\Y|/;
```

40.2 BUGS

This document varies from difficult to understand to completely and utterly opaque. The wandering prose riddled with jargon is hard to fathom in several places.

This document needs a rewrite that separates the tutorial content from the reference content.

Perl Regular Expressions Reference

41.1 DESCRIPTION

This is a quick reference to Perl's regular expressions. For full information see *perlre* and *perlop*, as well as the §41.3 section in this document.

41.1.1 OPERATORS

```
=~ determines to which variable the regex is applied.
   In its absence, $_ is used.

      $var =~ /foo/;

!~ determines to which variable the regex is applied,
   and negates the result of the match; it returns
   false if the match succeeds, and true if it fails.

     $var !~ /foo/;

m/pattern/igmsoxc searches a string for a pattern match,
   applying the given options.

      i  case-Insensitive
      g  Global - all occurrences
      m  Multiline mode - ^ and $ match internal lines
      s  match as a Single line - . matches \n
      o  compile pattern Once
      x  eXtended legibility - free whitespace and comments
      c  don't reset pos on failed matches when using /g

   If 'pattern' is an empty string, the last I<successfully> matched
   regex is used. Delimiters other than '/' may be used for both this
   operator and the following ones.

qr/pattern/imsox lets you store a regex in a variable,
   or pass one around. Modifiers as for m// and are stored
   within the regex.
```

```
  s/pattern/replacement/igmsoxe substitutes matches of
     'pattern' with 'replacement'. Modifiers as for m//
     with one addition:

        e  Evaluate replacement as an expression

     'e' may be specified multiple times. 'replacement' is interpreted
     as a double quoted string unless a single-quote (') is the delimiter.

  ?pattern? is like m/pattern/ but matches only once. No alternate
      delimiters can be used. Must be reset with L<reset|perlfunc/reset>.
```

41.1.2 SYNTAX

```
   \       Escapes the character immediately following it
   .       Matches any single character except a newline (unless /s is used)
   ^       Matches at the beginning of the string (or line, if /m is used)
   $       Matches at the end of the string (or line, if /m is used)
   *       Matches the preceding element 0 or more times
   +       Matches the preceding element 1 or more times
   ?       Matches the preceding element 0 or 1 times
   {...}   Specifies a range of occurrences for the element preceding it
   [...]   Matches any one of the characters contained within the brackets
   (...)   Groups subexpressions for capturing to $1, $2...
   (?:...) Groups subexpressions without capturing (cluster)
   |       Matches either the subexpression preceding or following it
   \1, \2 ...  The text from the Nth group
```

41.1.3 ESCAPE SEQUENCES

These work as in normal strings.

```
   \a       Alarm (beep)
   \e       Escape
   \f       Formfeed
   \n       Newline
   \r       Carriage return
   \t       Tab
   \038     Any octal ASCII value
   \x7f     Any hexadecimal ASCII value
   \x{263a} A wide hexadecimal value
   \cx      Control-x
   \N{name} A named character

   \l  Lowercase next character
   \u  Titlecase next character
   \L  Lowercase until \E
   \U  Uppercase until \E
   \Q  Disable pattern metacharacters until \E
   \E  End case modification
```

For Titlecase, see Titlecase.

This one works differently from normal strings:

```
   \b  An assertion, not backspace, except in a character class
```

41.1.4 CHARACTER CLASSES

```
[amy]    Match 'a', 'm' or 'y'
[f-j]    Dash specifies "range"
[f-j-]   Dash escaped or at start or end means 'dash'
[^f-j]   Caret indicates "match any character _except_ these"
```

The following sequences work within or without a character class. The first six are locale aware, all are Unicode aware. The default character class equivalent are given. See *perllocale* and *perlunicode* for details.

```
\d      A digit                     [0-9]
\D      A nondigit                  [^0-9]
\w      A word character            [a-zA-Z0-9_]
\W      A non-word character        [^a-zA-Z0-9_]
\s      A whitespace character      [ \t\n\r\f]
\S      A non-whitespace character  [^ \t\n\r\f]

\C      Match a byte (with Unicode, '.' matches a character)
\pP     Match P-named (Unicode) property
\p{...} Match Unicode property with long name
\PP     Match non-P
\P{...} Match lack of Unicode property with long name
\X      Match extended unicode sequence
```

POSIX character classes and their Unicode and Perl equivalents:

```
alnum   IsAlnum              Alphanumeric
alpha   IsAlpha              Alphabetic
ascii   IsASCII              Any ASCII char
blank   IsSpace  [ \t]       Horizontal whitespace (GNU extension)
cntrl   IsCntrl              Control characters
digit   IsDigit  \d          Digits
graph   IsGraph              Alphanumeric and punctuation
lower   IsLower              Lowercase chars (locale and Unicode aware)
print   IsPrint              Alphanumeric, punct, and space
punct   IsPunct              Punctuation
space   IsSpace  [\s\ck]     Whitespace
        IsSpacePerl   \s     Perl's whitespace definition
upper   IsUpper              Uppercase chars (locale and Unicode aware)
word    IsWord   \w          Alphanumeric plus _ (Perl extension)
xdigit  IsXDigit [0-9A-Fa-f] Hexadecimal digit
```

Within a character class:

```
 POSIX       traditional   Unicode
 [:digit:]       \d        \p{IsDigit}
 [:^digit:]      \D        \P{IsDigit}
```

41.1.5 ANCHORS

All are zero-width assertions.

```
^  Match string start (or line, if /m is used)
$  Match string end (or line, if /m is used) or before newline
\b Match word boundary (between \w and \W)
\B Match except at word boundary (between \w and \w or \W and \W)
\A Match string start (regardless of /m)
\Z Match string end (before optional newline)
\z Match absolute string end
\G Match where previous m//g left off
```

41.1.6 QUANTIFIERS

Quantifiers are greedy by default – match the **longest** leftmost.

```
   Maximal Minimal Allowed range
   ------- ------- -------------
   {n,m}   {n,m}?  Must occur at least n times but no more than m times
   {n,}    {n,}?   Must occur at least n times
   {n}     {n}?    Must occur exactly n times
   *       *?      0 or more times (same as {0,})
   +       +?      1 or more times (same as {1,})
   ?       ??      0 or 1 time (same as {0,1})
```

There is no quantifier {,n} – that gets understood as a literal string.

41.1.7 EXTENDED CONSTRUCTS

```
   (?#text)          A comment
   (?imxs-imsx:...)  Enable/disable option (as per m// modifiers)
   (?=...)           Zero-width positive lookahead assertion
   (?!...)           Zero-width negative lookahead assertion
   (?<=...)          Zero-width positive lookbehind assertion
   (?<!...)          Zero-width negative lookbehind assertion
   (?>...)           Grab what we can, prohibit backtracking
   (?{ code })       Embedded code, return value becomes $^R
   (??{ code })      Dynamic regex, return value used as regex
   (?(cond)yes|no)   cond being integer corresponding to capturing parens
   (?(cond)yes)         or a lookaround/eval zero-width assertion
```

41.1.8 VARIABLES

```
   $_    Default variable for operators to use
   $*    Enable multiline matching (deprecated; not in 5.9.0 or later)

   $&    Entire matched string
   $`    Everything prior to matched string
   $'    Everything after to matched string
```

The use of those last three will slow down **all** regex use within your program. Consult *perlvar* for `@LAST_MATCH_START` to see equivalent expressions that won't cause slow down. See also *Devel::SawAmpersand*.

```
   $1, $2 ...  hold the Xth captured expr
   $+    Last parenthesized pattern match
   $^N   Holds the most recently closed capture
   $^R   Holds the result of the last (?{...}) expr
   @-    Offsets of starts of groups. $-[0] holds start of whole match
   @+    Offsets of ends of groups. $+[0] holds end of whole match
```

Captured groups are numbered according to their *opening* paren.

41.1.9 FUNCTIONS

```
lc          Lowercase a string
lcfirst     Lowercase first char of a string
uc          Uppercase a string
ucfirst     Titlecase first char of a string

pos         Return or set current match position
quotemeta   Quote metacharacters
reset       Reset ?pattern? status
study       Analyze string for optimizing matching

split       Use regex to split a string into parts
```

The first four of these are like the escape sequences `\L`, `\l`, `\U`, and `\u`. For Titlecase, see Titlecase.

41.1.10 TERMINOLOGY

Titlecase

Unicode concept which most often is equal to uppercase, but for certain characters like the German "sharp s" there is a difference.

Chapter 42

perlref

Perl references and nested data structures

42.1 NOTE

This is complete documentation about all aspects of references. For a shorter, tutorial introduction to just the essential features, see *perlreftut*.

42.2 DESCRIPTION

Before release 5 of Perl it was difficult to represent complex data structures, because all references had to be symbolic–and even then it was difficult to refer to a variable instead of a symbol table entry. Perl now not only makes it easier to use symbolic references to variables, but also lets you have "hard" references to any piece of data or code. Any scalar may hold a hard reference. Because arrays and hashes contain scalars, you can now easily build arrays of arrays, arrays of hashes, hashes of arrays, arrays of hashes of functions, and so on.

Hard references are smart–they keep track of reference counts for you, automatically freeing the thing referred to when its reference count goes to zero. (Reference counts for values in self-referential or cyclic data structures may not go to zero without a little help; see Two-Phased Garbage Collection in *perlobj* for a detailed explanation.) If that thing happens to be an object, the object is destructed. See *perlobj* for more about objects. (In a sense, everything in Perl is an object, but we usually reserve the word for references to objects that have been officially "blessed" into a class package.)

Symbolic references are names of variables or other objects, just as a symbolic link in a Unix filesystem contains merely the name of a file. The `*glob` notation is something of a symbolic reference. (Symbolic references are sometimes called "soft references", but please don't call them that; references are confusing enough without useless synonyms.)

In contrast, hard references are more like hard links in a Unix file system: They are used to access an underlying object without concern for what its (other) name is. When the word "reference" is used without an adjective, as in the following paragraph, it is usually talking about a hard reference.

References are easy to use in Perl. There is just one overriding principle: Perl does no implicit referencing or dereferencing. When a scalar is holding a reference, it always behaves as a simple scalar. It doesn't magically start being an array or hash or subroutine; you have to tell it explicitly to do so, by dereferencing it.

42.2.1 Making References

References can be created in several ways.

1. By using the backslash operator on a variable, subroutine, or value. (This works much like the & (address-of) operator in C.) This typically creates *another* reference to a variable, because there's already a reference to the variable in the symbol table. But the symbol table reference might go away, and you'll still have the reference that the backslash returned. Here are some examples:

```
$scalarref = \$foo;
$arrayref  = \@ARGV;
$hashref   = \%ENV;
$coderef   = \&handler;
$globref   = \*foo;
```

It isn't possible to create a true reference to an IO handle (filehandle or dirhandle) using the backslash operator. The most you can get is a reference to a typeglob, which is actually a complete symbol table entry. But see the explanation of the `*foo{THING}` syntax below. However, you can still use type globs and globrefs as though they were IO handles.

2. A reference to an anonymous array can be created using square brackets:

```
$arrayref = [1, 2, ['a', 'b', 'c']];
```

Here we've created a reference to an anonymous array of three elements whose final element is itself a reference to another anonymous array of three elements. (The multidimensional syntax described later can be used to access this. For example, after the above, `$arrayref->[2][1]` would have the value "b".)

Taking a reference to an enumerated list is not the same as using square brackets–instead it's the same as creating a list of references!

```
@list = (\$a, \@b, \%c);
@list = \($a, @b, %c);      # same thing!
```

As a special case, `\(@foo)` returns a list of references to the contents of `@foo`, not a reference to `@foo` itself. Likewise for `%foo`, except that the key references are to copies (since the keys are just strings rather than full-fledged scalars).

3. A reference to an anonymous hash can be created using curly brackets:

```
$hashref = {
    'Adam'  => 'Eve',
    'Clyde' => 'Bonnie',
};
```

Anonymous hash and array composers like these can be intermixed freely to produce as complicated a structure as you want. The multidimensional syntax described below works for these too. The values above are literals, but variables and expressions would work just as well, because assignment operators in Perl (even within local() or my()) are executable statements, not compile-time declarations.

Because curly brackets (braces) are used for several other things including BLOCKs, you may occasionally have to disambiguate braces at the beginning of a statement by putting a + or a `return` in front so that Perl realizes the opening brace isn't starting a BLOCK. The economy and mnemonic value of using curlies is deemed worth this occasional extra hassle.

For example, if you wanted a function to make a new hash and return a reference to it, you have these options:

```
sub hashem {        { @_ } }   # silently wrong
sub hashem {       +{ @_ } }   # ok
sub hashem { return { @_ } }   # ok
```

On the other hand, if you want the other meaning, you can do this:

```
sub showem {        { @_ } }   # ambiguous (currently ok, but may change)
sub showem {       {; @_ } }   # ok
sub showem { { return @_ } }   # ok
```

The leading `+{` and `{;` always serve to disambiguate the expression to mean either the HASH reference, or the BLOCK.

4. A reference to an anonymous subroutine can be created by using `sub` without a subname:

   ```
   $coderef = sub { print "Boink!\n" };
   ```

   Note the semicolon. Except for the code inside not being immediately executed, a `sub {}` is not so much a declaration as it is an operator, like `do{}` or `eval{}`. (However, no matter how many times you execute that particular line (unless you're in an `eval("...")`), $coderef will still have a reference to the *same* anonymous subroutine.)

   Anonymous subroutines act as closures with respect to my() variables, that is, variables lexically visible within the current scope. Closure is a notion out of the Lisp world that says if you define an anonymous function in a particular lexical context, it pretends to run in that context even when it's called outside the context.

   In human terms, it's a funny way of passing arguments to a subroutine when you define it as well as when you call it. It's useful for setting up little bits of code to run later, such as callbacks. You can even do object-oriented stuff with it, though Perl already provides a different mechanism to do that–see *perlobj*.

   You might also think of closure as a way to write a subroutine template without using eval(). Here's a small example of how closures work:

   ```
   sub newprint {
       my $x = shift;
       return sub { my $y = shift; print "$x, $y!\n"; };
   }
   $h = newprint("Howdy");
   $g = newprint("Greetings");

   # Time passes...

   &$h("world");
   &$g("earthlings");
   ```

   This prints

   ```
   Howdy, world!
   Greetings, earthlings!
   ```

   Note particularly that $x continues to refer to the value passed into newprint() *despite* "my $x" having gone out of scope by the time the anonymous subroutine runs. That's what a closure is all about.

   This applies only to lexical variables, by the way. Dynamic variables continue to work as they have always worked. Closure is not something that most Perl programmers need trouble themselves about to begin with.

5. References are often returned by special subroutines called constructors. Perl objects are just references to a special type of object that happens to know which package it's associated with. Constructors are just special subroutines that know how to create that association. They do so by starting with an ordinary reference, and it remains an ordinary reference even while it's also being an object. Constructors are often named new() and called indirectly:

   ```
   $objref = new Doggie (Tail => 'short', Ears => 'long');
   ```

   But don't have to be:

   ```
   $objref   = Doggie->new(Tail => 'short', Ears => 'long');
   ```

```
use Term::Cap;
$terminal = Term::Cap->Tgetent( { OSPEED => 9600 });

use Tk;
$main    = MainWindow->new();
$menubar = $main->Frame(-relief              => "raised",
                        -borderwidth         => 2)
```

6. References of the appropriate type can spring into existence if you dereference them in a context that assumes they exist. Because we haven't talked about dereferencing yet, we can't show you any examples yet.

7. A reference can be created by using a special syntax, lovingly known as the *foo{THING} syntax. *foo{THING} returns a reference to the THING slot in *foo (which is the symbol table entry which holds everything known as foo).

   ```
   $scalarref = *foo{SCALAR};
   $arrayref  = *ARGV{ARRAY};
   $hashref   = *ENV{HASH};
   $coderef   = *handler{CODE};
   $ioref     = *STDIN{IO};
   $globref   = *foo{GLOB};
   ```

   All of these are self-explanatory except for `*foo{IO}`. It returns the IO handle, used for file handles (open in *perlfunc*), sockets (socket in *perlfunc* and socketpair in *perlfunc*), and directory handles (opendir in *perlfunc*). For compatibility with previous versions of Perl, `*foo{FILEHANDLE}` is a synonym for `*foo{IO}`, though it is deprecated as of 5.8.0. If deprecation warnings are in effect, it will warn of its use.

   `*foo{THING}` returns undef if that particular THING hasn't been used yet, except in the case of scalars. `*foo{SCALAR}` returns a reference to an anonymous scalar if $foo hasn't been used yet. This might change in a future release.

   `*foo{IO}` is an alternative to the `*HANDLE` mechanism given in Typeglobs and Filehandles in *perldata* for passing filehandles into or out of subroutines, or storing into larger data structures. Its disadvantage is that it won't create a new filehandle for you. Its advantage is that you have less risk of clobbering more than you want to with a typeglob assignment. (It still conflates file and directory handles, though.) However, if you assign the incoming value to a scalar instead of a typeglob as we do in the examples below, there's no risk of that happening.

   ```
   splutter(*STDOUT);          # pass the whole glob
   splutter(*STDOUT{IO});      # pass both file and dir handles

   sub splutter {
       my $fh = shift;
       print $fh "her um well a hmmm\n";
   }

   $rec = get_rec(*STDIN);     # pass the whole glob
   $rec = get_rec(*STDIN{IO}); # pass both file and dir handles

   sub get_rec {
       my $fh = shift;
       return scalar <$fh>;
   }
   ```

42.2.2 Using References

That's it for creating references. By now you're probably dying to know how to use references to get back to your long-lost data. There are several basic methods.

1. Anywhere you'd put an identifier (or chain of identifiers) as part of a variable or subroutine name, you can replace the identifier with a simple scalar variable containing a reference of the correct type:

   ```
   $bar = $$scalarref;
   push(@$arrayref, $filename);
   $$arrayref[0] = "January";
   $$hashref{"KEY"} = "VALUE";
   &$coderef(1,2,3);
   print $globref "output\n";
   ```

   It's important to understand that we are specifically *not* dereferencing `$arrayref[0]` or `$hashref{"KEY"}` there. The dereference of the scalar variable happens *before* it does any key lookups. Anything more complicated than a simple scalar variable must use methods 2 or 3 below. However, a "simple scalar" includes an identifier that itself uses method 1 recursively. Therefore, the following prints "howdy".

   ```
   $refrefref = \\\"howdy";
   print $$$$refrefref;
   ```

2. Anywhere you'd put an identifier (or chain of identifiers) as part of a variable or subroutine name, you can replace the identifier with a BLOCK returning a reference of the correct type. In other words, the previous examples could be written like this:

   ```
   $bar = ${$scalarref};
   push(@{$arrayref}, $filename);
   ${$arrayref}[0] = "January";
   ${$hashref}{"KEY"} = "VALUE";
   &{$coderef}(1,2,3);
   $globref->print("output\n");  # iff IO::Handle is loaded
   ```

   Admittedly, it's a little silly to use the curlies in this case, but the BLOCK can contain any arbitrary expression, in particular, subscripted expressions:

   ```
   &{ $dispatch{$index} }(1,2,3);      # call correct routine
   ```

   Because of being able to omit the curlies for the simple case of `$$x`, people often make the mistake of viewing the dereferencing symbols as proper operators, and wonder about their precedence. If they were, though, you could use parentheses instead of braces. That's not the case. Consider the difference below; case 0 is a short-hand version of case 1, *not* case 2:

   ```
   $$hashref{"KEY"}   = "VALUE";       # CASE 0
   ${$hashref}{"KEY"} = "VALUE";       # CASE 1
   ${$hashref{"KEY"}} = "VALUE";       # CASE 2
   ${$hashref->{"KEY"}} = "VALUE";     # CASE 3
   ```

   Case 2 is also deceptive in that you're accessing a variable called %hashref, not dereferencing through $hashref to the hash it's presumably referencing. That would be case 3.

3. Subroutine calls and lookups of individual array elements arise often enough that it gets cumbersome to use method 2. As a form of syntactic sugar, the examples for method 2 may be written:

```
    $arrayref->[0] = "January";   # Array element
    $hashref->{"KEY"} = "VALUE";  # Hash element
    $coderef->(1,2,3);            # Subroutine call
```

The left side of the arrow can be any expression returning a reference, including a previous dereference. Note that `$array[$x]` is *not* the same thing as `$array->[$x]` here:

```
    $array[$x]->{"foo"}->[0] = "January";
```

This is one of the cases we mentioned earlier in which references could spring into existence when in an lvalue context. Before this statement, `$array[$x]` may have been undefined. If so, it's automatically defined with a hash reference so that we can look up `{"foo"}` in it. Likewise `$array[$x]->{"foo"}` will automatically get defined with an array reference so that we can look up `[0]` in it. This process is called *autovivification*.

One more thing here. The arrow is optional *between* brackets subscripts, so you can shrink the above down to

```
    $array[$x]{"foo"}[0] = "January";
```

Which, in the degenerate case of using only ordinary arrays, gives you multidimensional arrays just like C's:

```
    $score[$x][$y][$z] += 42;
```

Well, okay, not entirely like C's arrays, actually. C doesn't know how to grow its arrays on demand. Perl does.

4. If a reference happens to be a reference to an object, then there are probably methods to access the things referred to, and you should probably stick to those methods unless you're in the class package that defines the object's methods. In other words, be nice, and don't violate the object's encapsulation without a very good reason. Perl does not enforce encapsulation. We are not totalitarians here. We do expect some basic civility though.

Using a string or number as a reference produces a symbolic reference, as explained above. Using a reference as a number produces an integer representing its storage location in memory. The only useful thing to be done with this is to compare two references numerically to see whether they refer to the same location.

```
if ($ref1 == $ref2) {  # cheap numeric compare of references
    print "refs 1 and 2 refer to the same thing\n";
}
```

Using a reference as a string produces both its referent's type, including any package blessing as described in *perlobj*, as well as the numeric address expressed in hex. The ref() operator returns just the type of thing the reference is pointing to, without the address. See ref in *perlfunc* for details and examples of its use.

The bless() operator may be used to associate the object a reference points to with a package functioning as an object class. See *perlobj*.

A typeglob may be dereferenced the same way a reference can, because the dereference syntax always indicates the type of reference desired. So `${*foo}` and `${\$foo}` both indicate the same scalar variable.

Here's a trick for interpolating a subroutine call into a string:

```
print "My sub returned @{[mysub(1,2,3)]} that time.\n";
```

The way it works is that when the `@{...}` is seen in the double-quoted string, it's evaluated as a block. The block creates a reference to an anonymous array containing the results of the call to `mysub(1,2,3)`. So the whole block returns a reference to an array, which is then dereferenced by `@{...}` and stuck into the double-quoted string. This chicanery is also useful for arbitrary expressions:

```
print "That yields @{[$n + 5]} widgets\n";
```

42.2.3 Symbolic references

We said that references spring into existence as necessary if they are undefined, but we didn't say what happens if a value used as a reference is already defined, but *isn't* a hard reference. If you use it as a reference, it'll be treated as a symbolic reference. That is, the value of the scalar is taken to be the *name* of a variable, rather than a direct link to a (possibly) anonymous value.

People frequently expect it to work like this. So it does.

```
    $name = "foo";
    $$name = 1;                 # Sets $foo
    ${$name} = 2;               # Sets $foo
    ${$name x 2} = 3;           # Sets $foofoo
    $name->[0] = 4;             # Sets $foo[0]
    @$name = ();                # Clears @foo
    &$name();                   # Calls &foo() (as in Perl 4)
    $pack = "THAT";
    ${"${pack}::$name"} = 5;    # Sets $THAT::foo without eval
```

This is powerful, and slightly dangerous, in that it's possible to intend (with the utmost sincerity) to use a hard reference, and accidentally use a symbolic reference instead. To protect against that, you can say

```
    use strict 'refs';
```

and then only hard references will be allowed for the rest of the enclosing block. An inner block may countermand that with

```
    no strict 'refs';
```

Only package variables (globals, even if localized) are visible to symbolic references. Lexical variables (declared with my()) aren't in a symbol table, and thus are invisible to this mechanism. For example:

```
    local $value = 10;
    $ref = "value";
    {
        my $value = 20;
        print $$ref;
    }
```

This will still print 10, not 20. Remember that local() affects package variables, which are all "global" to the package.

42.2.4 Not-so-symbolic references

A new feature contributing to readability in perl version 5.001 is that the brackets around a symbolic reference behave more like quotes, just as they always have within a string. That is,

```
    $push = "pop on ";
    print "${push}over";
```

has always meant to print "pop on over", even though push is a reserved word. This has been generalized to work the same outside of quotes, so that

```
    print ${push} . "over";
```

and even

```
    print ${ push } . "over";
```

will have the same effect. (This would have been a syntax error in Perl 5.000, though Perl 4 allowed it in the spaceless form.) This construct is *not* considered to be a symbolic reference when you're using strict refs:

```
    use strict 'refs';
    ${ bareword };      # Okay, means $bareword.
    ${ "bareword" };    # Error, symbolic reference.
```

Similarly, because of all the subscripting that is done using single words, we've applied the same rule to any bareword that is used for subscripting a hash. So now, instead of writing

```
    $array{ "aaa" }{ "bbb" }{ "ccc" }
```

you can write just

```
    $array{ aaa }{ bbb }{ ccc }
```

and not worry about whether the subscripts are reserved words. In the rare event that you do wish to do something like

```
    $array{ shift }
```

you can force interpretation as a reserved word by adding anything that makes it more than a bareword:

```
    $array{ shift() }
    $array{ +shift }
    $array{ shift @_ }
```

The `use warnings` pragma or the **-w** switch will warn you if it interprets a reserved word as a string. But it will no longer warn you about using lowercase words, because the string is effectively quoted.

42.2.5 Pseudo-hashes: Using an array as a hash

WARNING: This section describes an experimental feature. Details may change without notice in future versions.

NOTE: The current user-visible implementation of pseudo-hashes (the weird use of the first array element) is deprecated starting from Perl 5.8.0 and will be removed in Perl 5.10.0, and the feature will be implemented differently. Not only is the current interface rather ugly, but the current implementation slows down normal array and hash use quite noticeably. The 'fields' pragma interface will remain available.

Beginning with release 5.005 of Perl, you may use an array reference in some contexts that would normally require a hash reference. This allows you to access array elements using symbolic names, as if they were fields in a structure.

For this to work, the array must contain extra information. The first element of the array has to be a hash reference that maps field names to array indices. Here is an example:

```
    $struct = [{foo => 1, bar => 2}, "FOO", "BAR"];

    $struct->{foo};  # same as $struct->[1], i.e. "FOO"
    $struct->{bar};  # same as $struct->[2], i.e. "BAR"

    keys %$struct;   # will return ("foo", "bar") in some order
    values %$struct; # will return ("FOO", "BAR") in same some order

    while (my($k,$v) = each %$struct) {
       print "$k => $v\n";
    }
```

Perl will raise an exception if you try to access nonexistent fields. To avoid inconsistencies, always use the fields::phash() function provided by the `fields` pragma.

```
    use fields;
    $pseudohash = fields::phash(foo => "FOO", bar => "BAR");
```

For better performance, Perl can also do the translation from field names to array indices at compile time for typed object references. See *fields*.

There are two ways to check for the existence of a key in a pseudo-hash. The first is to use exists(). This checks to see if the given field has ever been set. It acts this way to match the behavior of a regular hash. For instance:

```
    use fields;
    $phash = fields::phash([qw(foo bar pants)], ['FOO']);
    $phash->{pants} = undef;

    print exists $phash->{foo};    # true, 'foo' was set in the declaration
    print exists $phash->{bar};    # false, 'bar' has not been used.
    print exists $phash->{pants};  # true, your 'pants' have been touched
```

The second is to use exists() on the hash reference sitting in the first array element. This checks to see if the given key is a valid field in the pseudo-hash.

```
    print exists $phash->[0]{bar};      # true, 'bar' is a valid field
    print exists $phash->[0]{shoes};# false, 'shoes' can't be used
```

delete() on a pseudo-hash element only deletes the value corresponding to the key, not the key itself. To delete the key, you'll have to explicitly delete it from the first hash element.

```
    print delete $phash->{foo};     # prints $phash->[1], "FOO"
    print exists $phash->{foo};     # false
    print exists $phash->[0]{foo};  # true, key still exists
    print delete $phash->[0]{foo};  # now key is gone
    print $phash->{foo};            # runtime exception
```

42.2.6 Function Templates

As explained above, a closure is an anonymous function with access to the lexical variables visible when that function was compiled. It retains access to those variables even though it doesn't get run until later, such as in a signal handler or a Tk callback.

Using a closure as a function template allows us to generate many functions that act similarly. Suppose you wanted functions named after the colors that generated HTML font changes for the various colors:

```
    print "Be ", red("careful"), "with that ", green("light");
```

The red() and green() functions would be similar. To create these, we'll assign a closure to a typeglob of the name of the function we're trying to build.

```
    @colors = qw(red blue green yellow orange purple violet);
    for my $name (@colors) {
        no strict 'refs';       # allow symbol table manipulation
        *$name = *{uc $name} = sub { "<FONT COLOR='$name'>@_</FONT>" };
    }
```

Now all those different functions appear to exist independently. You can call red(), RED(), blue(), BLUE(), green(), etc. This technique saves on both compile time and memory use, and is less error-prone as well, since syntax checks happen at compile time. It's critical that any variables in the anonymous subroutine be lexicals in order to create a proper closure. That's the reasons for the `my` on the loop iteration variable.

This is one of the only places where giving a prototype to a closure makes much sense. If you wanted to impose scalar context on the arguments of these functions (probably not a wise idea for this particular example), you could have written it this way instead:

```
*$name = sub ($) { "<FONT COLOR='$name'>$_[0]</FONT>" };
```

However, since prototype checking happens at compile time, the assignment above happens too late to be of much use. You could address this by putting the whole loop of assignments within a BEGIN block, forcing it to occur during compilation.

Access to lexicals that change over type–like those in the `for` loop above–only works with closures, not general subroutines. In the general case, then, named subroutines do not nest properly, although anonymous ones do. If you are accustomed to using nested subroutines in other programming languages with their own private variables, you'll have to work at it a bit in Perl. The intuitive coding of this type of thing incurs mysterious warnings about "will not stay shared". For example, this won't work:

```
sub outer {
    my $x = $_[0] + 35;
    sub inner { return $x * 19 }   # WRONG
    return $x + inner();
}
```

A work-around is the following:

```
sub outer {
    my $x = $_[0] + 35;
    local *inner = sub { return $x * 19 };
    return $x + inner();
}
```

Now inner() can only be called from within outer(), because of the temporary assignments of the closure (anonymous subroutine). But when it does, it has normal access to the lexical variable $x from the scope of outer().

This has the interesting effect of creating a function local to another function, something not normally supported in Perl.

42.3 WARNING

You may not (usefully) use a reference as the key to a hash. It will be converted into a string:

```
$x{ \$a } = $a;
```

If you try to dereference the key, it won't do a hard dereference, and you won't accomplish what you're attempting. You might want to do something more like

```
$r = \@a;
$x{ $r } = $r;
```

And then at least you can use the values(), which will be real refs, instead of the keys(), which won't.

The standard Tie::RefHash module provides a convenient workaround to this.

42.4 SEE ALSO

Besides the obvious documents, source code can be instructive. Some pathological examples of the use of references can be found in the *t/op/ref.t* regression test in the Perl source directory.

See also *perldsc* and *perllol* for how to use references to create complex data structures, and *perltoot*, *perlobj*, and *perlbot* for how to use them to create objects.

Chapter 43

perlform

Perl formats

43.1 DESCRIPTION

Perl has a mechanism to help you generate simple reports and charts. To facilitate this, Perl helps you code up your output page close to how it will look when it's printed. It can keep track of things like how many lines are on a page, what page you're on, when to print page headers, etc. Keywords are borrowed from FORTRAN: format() to declare and write() to execute; see their entries in *perlfunc*. Fortunately, the layout is much more legible, more like BASIC's PRINT USING statement. Think of it as a poor man's nroff(1).

Formats, like packages and subroutines, are declared rather than executed, so they may occur at any point in your program. (Usually it's best to keep them all together though.) They have their own namespace apart from all the other "types" in Perl. This means that if you have a function named "Foo", it is not the same thing as having a format named "Foo". However, the default name for the format associated with a given filehandle is the same as the name of the filehandle. Thus, the default format for STDOUT is named "STDOUT", and the default format for filehandle TEMP is named "TEMP". They just look the same. They aren't.

Output record formats are declared as follows:

```
    format NAME =
    FORMLIST
    .
```

If the name is omitted, format "STDOUT" is defined. A single "." in column 1 is used to terminate a format. FORMLIST consists of a sequence of lines, each of which may be one of three types:

1. A comment, indicated by putting a '#' in the first column.
2. A "picture" line giving the format for one output line.
3. An argument line supplying values to plug into the previous picture line.

Picture lines contain output field definitions, intermingled with literal text. These lines do not undergo any kind of variable interpolation. Field definitions are made up from a set of characters, for starting and extending a field to its desired width. This is the complete set of characters for field definitions:

```
   @    start of regular field
   ^    start of special field
   <    pad character for left adjustification
   |    pad character for centering
   >    pad character for right adjustificat
   #    pad character for a right justified numeric field
   0    instead of first #: pad number with leading zeroes
   .    decimal point within a numeric field
   ...  terminate a text field, show "..." as truncation evidence
   @*   variable width field for a multi-line value
   ^*   variable width field for next line of a multi-line value
   ~    suppress line with all fields empty
   ~~   repeat line until all fields are exhausted
```

Each field in a picture line starts with either "@" (at) or "^" (caret), indicating what we'll call, respectively, a "regular" or "special" field. The choice of pad characters determines whether a field is textual or numeric. The tilde operators are not part of a field. Let's look at the various possibilities in detail.

43.1.1 Text Fields

The length of the field is supplied by padding out the field with multiple "<", ">", or "|" characters to specify a non-numeric field with, respectively, left justification, right justification, or centering. For a regular field, the value (up to the first newline) is taken and printed according to the selected justification, truncating excess characters. If you terminate a text field with "...", three dots will be shown if the value is truncated. A special text field may be used to do rudimentary multi-line text block filling; see Using Fill Mode for details.

```
   Example:
      format STDOUT =
      @<<<<<<   @||||||   @>>>>>>
      "left",   "middle", "right"
      .
   Output:
      left      middle    right
```

43.1.2 Numeric Fields

Using "#" as a padding character specifies a numeric field, with right justification. An optional "." defines the position of the decimal point. With a "0" (zero) instead of the first "#", the formatted number will be padded with leading zeroes if necessary. A special numeric field is blanked out if the value is undefined. If the resulting value would exceed the width specified the field is filled with "#" as overflow evidence.

```
   Example:
      format STDOUT =
      @###   @.###   @##.###  @###   @###   ^####
       42,   3.1415,  undef,    0, 10000,   undef
      .
   Output:
        42   3.142     0.000     0   ####
```

43.1.3 The Field @* for Variable Width Multi-Line Text

The field "@*" can be used for printing multi-line, nontruncated values; it should (but need not) appear by itself on a line. A final line feed is chomped off, but all other characters are emitted verbatim.

43.1.4 The Field ^* for Variable Width One-line-at-a-time Text

Like "@*", this is a variable width field. The value supplied must be a scalar variable. Perl puts the first line (up to the first "\n") of the text into the field, and then chops off the front of the string so that the next time the variable is referenced, more of the text can be printed. The variable will *not* be restored.

```
Example:
   $text = "line 1\nline 2\nline 3";
   format STDOUT =
   Text: ^*
         $text
   ~~    ^*
         $text
   .
Output:
   Text: line 1
         line 2
         line 3
```

43.1.5 Specifying Values

The values are specified on the following format line in the same order as the picture fields. The expressions providing the values must be separated by commas. They are all evaluated in a list context before the line is processed, so a single list expression could produce multiple list elements. The expressions may be spread out to more than one line if enclosed in braces. If so, the opening brace must be the first token on the first line. If an expression evaluates to a number with a decimal part, and if the corresponding picture specifies that the decimal part should appear in the output (that is, any picture except multiple "#" characters **without** an embedded "."), the character used for the decimal point is **always** determined by the current LC_NUMERIC locale. This means that, if, for example, the run-time environment happens to specify a German locale, "," will be used instead of the default ".". See *perllocale* and §43.3 for more information.

43.1.6 Using Fill Mode

On text fields the caret enables a kind of fill mode. Instead of an arbitrary expression, the value supplied must be a scalar variable that contains a text string. Perl puts the next portion of the text into the field, and then chops off the front of the string so that the next time the variable is referenced, more of the text can be printed. (Yes, this means that the variable itself is altered during execution of the write() call, and is not restored.) The next portion of text is determined by a crude line breaking algorithm. You may use the carriage return character (`\r`) to force a line break. You can change which characters are legal to break on by changing the variable `$:` (that's $FORMAT_LINE_BREAK_CHARACTERS if you're using the English module) to a list of the desired characters.

Normally you would use a sequence of fields in a vertical stack associated with the same scalar variable to print out a block of text. You might wish to end the final field with the text "...", which will appear in the output if the text was too long to appear in its entirety.

43.1.7 Suppressing Lines Where All Fields Are Void

Using caret fields can produce lines where all fields are blank. You can suppress such lines by putting a "˜" (tilde) character anywhere in the line. The tilde will be translated to a space upon output.

43.1.8 Repeating Format Lines

If you put two contiguous tilde characters "˜˜" anywhere into a line, the line will be repeated until all the fields on the line are exhausted, i.e. undefined. For special (caret) text fields this will occur sooner or later, but if you use a text field of the at variety, the expression you supply had better not give the same value every time forever! (`shift(@f)` is a simple example that would work.) Don't use a regular (at) numeric field in such lines, because it will never go blank.

43.1.9 Top of Form Processing

Top-of-form processing is by default handled by a format with the same name as the current filehandle with "_TOP" concatenated to it. It's triggered at the top of each page. See write in *perlfunc*.

Examples:

```
# a report on the /etc/passwd file
format STDOUT_TOP =
                        Passwd File
Name                Login    Office   Uid   Gid Home
------------------------------------------------------------------
.
format STDOUT =
@<<<<<<<<<<<<<<<<<< @||||||| @<<<<<<@>>>> @>>>> @<<<<<<<<<<<<<<<<<
$name,              $login,  $office,$uid,$gid, $home
.

# a report from a bug report form
format STDOUT_TOP =
                        Bug Reports
@<<<<<<<<<<<<<<<<<<<<<<<     @|||         @>>>>>>>>>>>>>>>>>>>>>>>
$system,                      $%,         $date
------------------------------------------------------------------
.
format STDOUT =
Subject: @<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<
         $subject
Index: @<<<<<<<<<<<<<<<<<<<<<<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
       $index,                       $description
Priority: @<<<<<<<<<< Date: @<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
          $priority,        $date,   $description
From: @<<<<<<<<<<<<<<<<<<<<<<<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
      $from,                         $description
Assigned to: @<<<<<<<<<<<<<<<<<<<<<< ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
             $programmer,            $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                     $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                     $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                     $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<
                                     $description
~                                    ^<<<<<<<<<<<<<<<<<<<<<<<<...
                                     $description
.
```

It is possible to intermix print()s with write()s on the same output channel, but you'll have to handle `$-` (`$FORMAT_LINES_LEFT`) yourself.

43.1.10 Format Variables

The current format name is stored in the variable `$˜` (`$FORMAT_NAME`), and the current top of form format name is in `$ˆ` (`$FORMAT_TOP_NAME`). The current output page number is stored in `$%` (`$FORMAT_PAGE_NUMBER`), and the number of lines on the page is in `$=` (`$FORMAT_LINES_PER_PAGE`). Whether to autoflush output on this handle is stored in `$|` (`$OUTPUT_AUTOFLUSH`). The string output before each top of page (except the first) is stored in `$ˆL` (`$FORMAT_FORMFEED`). These variables are set on a per-filehandle basis, so you'll need to select() into a different one to affect them:

```
    select((select(OUTF),
            $~ = "My_Other_Format",
            $^ = "My_Top_Format"
           )[0]);
```

Pretty ugly, eh? It's a common idiom though, so don't be too surprised when you see it. You can at least use a temporary variable to hold the previous filehandle: (this is a much better approach in general, because not only does legibility improve, you now have intermediary stage in the expression to single-step the debugger through):

```
    $ofh = select(OUTF);
    $~ = "My_Other_Format";
    $^ = "My_Top_Format";
    select($ofh);
```

If you use the English module, you can even read the variable names:

```
    use English '-no_match_vars';
    $ofh = select(OUTF);
    $FORMAT_NAME     = "My_Other_Format";
    $FORMAT_TOP_NAME = "My_Top_Format";
    select($ofh);
```

But you still have those funny select()s. So just use the FileHandle module. Now, you can access these special variables using lowercase method names instead:

```
    use FileHandle;
    format_name     OUTF "My_Other_Format";
    format_top_name OUTF "My_Top_Format";
```

Much better!

43.2 NOTES

Because the values line may contain arbitrary expressions (for at fields, not caret fields), you can farm out more sophisticated processing to other functions, like sprintf() or one of your own. For example:

```
    format Ident =
        @<<<<<<<<<<<<<<<
        &commify($n)
    .
```

To get a real at or caret into the field, do this:

```
    format Ident =
    I have an @ here.
            "@"
    .
```

To center a whole line of text, do something like this:

```
    format Ident =
    @|||||||||||||||||||||||||||||||||||||||||||||||
            "Some text line"
    .
```

There is no builtin way to say "float this to the right hand side of the page, however wide it is." You have to specify where it goes. The truly desperate can generate their own format on the fly, based on the current number of columns, and then eval() it:

```
    $format  = "format STDOUT = \n"
             . '^' . '<' x $cols . "\n"
             . '$entry' . "\n"
             . "\t^" . "<" x ($cols-8) . "~~\n"
             . '$entry' . "\n"
             . ".\n";
    print $format if $Debugging;
    eval $format;
    die $@ if $@;
```

Which would generate a format looking something like this:

```
 format STDOUT =
 ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<
 $entry
         ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<~~
 $entry
 .
```

Here's a little program that's somewhat like fmt(1):

```
 format =
 ^<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<<< ~~
 $_

 .

 $/ = '';
 while (<>) {
     s/\s*\n\s*/ /g;
     write;
 }
```

43.2.1 Footers

While $FORMAT_TOP_NAME contains the name of the current header format, there is no corresponding mechanism to automatically do the same thing for a footer. Not knowing how big a format is going to be until you evaluate it is one of the major problems. It's on the TODO list.

Here's one strategy: If you have a fixed-size footer, you can get footers by checking $FORMAT_LINES_LEFT before each write() and print the footer yourself if necessary.

Here's another strategy: Open a pipe to yourself, using `open(MYSELF, "|-")` (see open() in *perlfunc*) and always write() to MYSELF instead of STDOUT. Have your child process massage its STDIN to rearrange headers and footers however you like. Not very convenient, but doable.

43.2.2 Accessing Formatting Internals

For low-level access to the formatting mechanism. you may use formline() and access `$^A` (the $ACCUMULATOR variable) directly.

For example:

```
    $str = formline <<'END', 1,2,3;
    @<<<  @|||  @>>>
    END
    print "Wow, I just stored ‘$^A’ in the accumulator!\n";
```

Or to make an swrite() subroutine, which is to write() what sprintf() is to printf(), do this:

```
    use Carp;
    sub swrite {
        croak "usage: swrite PICTURE ARGS" unless @_;
        my $format = shift;
        $^A = "";
        formline($format,@_);
        return $^A;
    }

    $string = swrite(<<’END’, 1, 2, 3);
 Check me out
 @<<<  @|||  @>>>
 END
    print $string;
```

43.3 WARNINGS

The lone dot that ends a format can also prematurely end a mail message passing through a misconfigured Internet mailer (and based on experience, such misconfiguration is the rule, not the exception). So when sending format code through mail, you should indent it so that the format-ending dot is not on the left margin; this will prevent SMTP cutoff.

Lexical variables (declared with "my") are not visible within a format unless the format is declared within the scope of the lexical variable. (They weren’t visible at all before version 5.001.)

Formats are the only part of Perl that unconditionally use information from a program’s locale; if a program’s environment specifies an LC_NUMERIC locale, it is always used to specify the decimal point character in formatted output. Perl ignores all other aspects of locale handling unless the `use locale` pragma is in effect. Formatted output cannot be controlled by `use locale` because the pragma is tied to the block structure of the program, and, for historical reasons, formats exist outside that block structure. See *perllocale* for further discussion of locale handling.

Within strings that are to be displayed in a fixed length text field, each control character is substituted by a space. (But remember the special meaning of `\r` when using fill mode.) This is done to avoid misalignment when control characters "disappear" on some output media.

Chapter 44

perlobj

Perl objects

44.1 DESCRIPTION

First you need to understand what references are in Perl. See *perlref* for that. Second, if you still find the following reference work too complicated, a tutorial on object-oriented programming in Perl can be found in *perltoot* and *perltooc*.

If you're still with us, then here are three very simple definitions that you should find reassuring.

1. An object is simply a reference that happens to know which class it belongs to.
2. A class is simply a package that happens to provide methods to deal with object references.
3. A method is simply a subroutine that expects an object reference (or a package name, for class methods) as the first argument.

We'll cover these points now in more depth.

44.1.1 An Object is Simply a Reference

Unlike say C++, Perl doesn't provide any special syntax for constructors. A constructor is merely a subroutine that returns a reference to something "blessed" into a class, generally the class that the subroutine is defined in. Here is a typical constructor:

```
    package Critter;
    sub new { bless {} }
```

That word `new` isn't special. You could have written a construct this way, too:

```
    package Critter;
    sub spawn { bless {} }
```

This might even be preferable, because the C++ programmers won't be tricked into thinking that `new` works in Perl as it does in C++. It doesn't. We recommend that you name your constructors whatever makes sense in the context of the problem you're solving. For example, constructors in the Tk extension to Perl are named after the widgets they create.

One thing that's different about Perl constructors compared with those in C++ is that in Perl, they have to allocate their own memory. (The other things is that they don't automatically call overridden base-class constructors.) The `{}` allocates an anonymous hash containing no key/value pairs, and returns it The bless() takes that reference and tells the object it references that it's now a Critter, and returns the reference. This is for convenience, because the referenced object itself knows that it has been blessed, and the reference to it could have been returned directly, like this:

```
    sub new {
        my $self = {};
        bless $self;
        return $self;
    }
```

You often see such a thing in more complicated constructors that wish to call methods in the class as part of the construction:

```
    sub new {
        my $self = {};
        bless $self;
        $self->initialize();
        return $self;
    }
```

If you care about inheritance (and you should; see Modules: Creation, Use, and Abuse in *perlmodlib*), then you want to use the two-arg form of bless so that your constructors may be inherited:

```
    sub new {
        my $class = shift;
        my $self = {};
        bless $self, $class;
        $self->initialize();
        return $self;
    }
```

Or if you expect people to call not just `CLASS->new()` but also `$obj->new()`, then use something like the following. (Note that using this to call new() on an instance does not automatically perform any copying. If you want a shallow or deep copy of an object, you'll have to specifically allow for that.) The initialize() method used will be of whatever $class we blessed the object into:

```
    sub new {
        my $this = shift;
        my $class = ref($this) || $this;
        my $self = {};
        bless $self, $class;
        $self->initialize();
        return $self;
    }
```

Within the class package, the methods will typically deal with the reference as an ordinary reference. Outside the class package, the reference is generally treated as an opaque value that may be accessed only through the class's methods.

Although a constructor can in theory re-bless a referenced object currently belonging to another class, this is almost certainly going to get you into trouble. The new class is responsible for all cleanup later. The previous blessing is forgotten, as an object may belong to only one class at a time. (Although of course it's free to inherit methods from many classes.) If you find yourself having to do this, the parent class is probably misbehaving, though.

A clarification: Perl objects are blessed. References are not. Objects know which package they belong to. References do not. The bless() function uses the reference to find the object. Consider the following example:

```
    $a = {};
    $b = $a;
    bless $a, BLAH;
    print "\$b is a ", ref($b), "\n";
```

This reports $b as being a BLAH, so obviously bless() operated on the object and not on the reference.

44.1.2 A Class is Simply a Package

Unlike say C++, Perl doesn't provide any special syntax for class definitions. You use a package as a class by putting method definitions into the class.

There is a special array within each package called @ISA, which says where else to look for a method if you can't find it in the current package. This is how Perl implements inheritance. Each element of the @ISA array is just the name of another package that happens to be a class package. The classes are searched (depth first) for missing methods in the order that they occur in @ISA. The classes accessible through @ISA are known as base classes of the current class.

All classes implicitly inherit from class `UNIVERSAL` as their last base class. Several commonly used methods are automatically supplied in the UNIVERSAL class; see §44.1.6 for more details.

If a missing method is found in a base class, it is cached in the current class for efficiency. Changing @ISA or defining new subroutines invalidates the cache and causes Perl to do the lookup again.

If neither the current class, its named base classes, nor the UNIVERSAL class contains the requested method, these three places are searched all over again, this time looking for a method named AUTOLOAD(). If an AUTOLOAD is found, this method is called on behalf of the missing method, setting the package global $AUTOLOAD to be the fully qualified name of the method that was intended to be called.

If none of that works, Perl finally gives up and complains.

If you want to stop the AUTOLOAD inheritance say simply

```
        sub AUTOLOAD;
```

and the call will die using the name of the sub being called.

Perl classes do method inheritance only. Data inheritance is left up to the class itself. By and large, this is not a problem in Perl, because most classes model the attributes of their object using an anonymous hash, which serves as its own little namespace to be carved up by the various classes that might want to do something with the object. The only problem with this is that you can't sure that you aren't using a piece of the hash that isn't already used. A reasonable workaround is to prepend your fieldname in the hash with the package name.

```
    sub bump {
        my $self = shift;
        $self->{ __PACKAGE__ . ".count"}++;
    }
```

44.1.3 A Method is Simply a Subroutine

Unlike say C++, Perl doesn't provide any special syntax for method definition. (It does provide a little syntax for method invocation though. More on that later.) A method expects its first argument to be the object (reference) or package (string) it is being invoked on. There are two ways of calling methods, which we'll call class methods and instance methods.

A class method expects a class name as the first argument. It provides functionality for the class as a whole, not for any individual object belonging to the class. Constructors are often class methods, but see *perltoot* and *perltooc* for alternatives. Many class methods simply ignore their first argument, because they already know what package they're in and don't care what package they were invoked via. (These aren't necessarily the same, because class methods follow the inheritance tree just like ordinary instance methods.) Another typical use for class methods is to look up an object by name:

```
    sub find {
        my ($class, $name) = @_;
        $objtable{$name};
    }
```

An instance method expects an object reference as its first argument. Typically it shifts the first argument into a "self" or "this" variable, and then uses that as an ordinary reference.

```
    sub display {
        my $self = shift;
        my @keys = @_ ? @_ : sort keys %$self;
        foreach $key (@keys) {
            print "\t$key => $self->{$key}\n";
        }
    }
```

44.1.4 Method Invocation

For various historical and other reasons, Perl offers two equivalent ways to write a method call. The simpler and more common way is to use the arrow notation:

```
    my $fred = Critter->find("Fred");
    $fred->display("Height", "Weight");
```

You should already be familiar with the use of the `->` operator with references. In fact, since `$fred` above is a reference to an object, you could think of the method call as just another form of dereferencing.
Whatever is on the left side of the arrow, whether a reference or a class name, is passed to the method subroutine as its first argument. So the above code is mostly equivalent to:

```
    my $fred = Critter::find("Critter", "Fred");
    Critter::display($fred, "Height", "Weight");
```

How does Perl know which package the subroutine is in? By looking at the left side of the arrow, which must be either a package name or a reference to an object, i.e. something that has been blessed to a package. Either way, that's the package where Perl starts looking. If that package has no subroutine with that name, Perl starts looking for it in any base classes of that package, and so on.
If you need to, you *can* force Perl to start looking in some other package:

```
    my $barney = MyCritter->Critter::find("Barney");
    $barney->Critter::display("Height", "Weight");
```

Here `MyCritter` is presumably a subclass of `Critter` that defines its own versions of find() and display(). We haven't specified what those methods do, but that doesn't matter above since we've forced Perl to start looking for the subroutines in `Critter`.
As a special case of the above, you may use the `SUPER` pseudo-class to tell Perl to start looking for the method in the packages named in the current class's `@ISA` list.

```
    package MyCritter;
    use base 'Critter';    # sets @MyCritter::ISA = ('Critter');

    sub display {
        my ($self, @args) = @_;
        $self->SUPER::display("Name", @args);
    }
```

It is important to note that `SUPER` refers to the superclass(es) of the *current package* and not to the superclass(es) of the object. Also, the `SUPER` pseudo-class can only currently be used as a modifier to a method name, but not in any of the other ways that class names are normally used, eg:

```
    something->SUPER::method(...);      # OK
    SUPER::method(...);                 # WRONG
    SUPER->method(...);                 # WRONG
```

Instead of a class name or an object reference, you can also use any expression that returns either of those on the left side of the arrow. So the following statement is valid:

```
    Critter->find("Fred")->display("Height", "Weight");
```

and so is the following:

```
    my $fred = (reverse "rettirC")->find(reverse "derF");
```

44.1.5 Indirect Object Syntax

The other way to invoke a method is by using the so-called "indirect object" notation. This syntax was available in Perl 4 long before objects were introduced, and is still used with filehandles like this:

```
print STDERR "help!!!\n";
```

The same syntax can be used to call either object or class methods.

```
my $fred = find Critter "Fred";
display $fred "Height", "Weight";
```

Notice that there is no comma between the object or class name and the parameters. This is how Perl can tell you want an indirect method call instead of an ordinary subroutine call.

But what if there are no arguments? In that case, Perl must guess what you want. Even worse, it must make that guess *at compile time*. Usually Perl gets it right, but when it doesn't you get a function call compiled as a method, or vice versa. This can introduce subtle bugs that are hard to detect.

For example, a call to a method `new` in indirect notation – as C++ programmers are wont to make – can be miscompiled into a subroutine call if there's already a `new` function in scope. You'd end up calling the current package's `new` as a subroutine, rather than the desired class's method. The compiler tries to cheat by remembering bareword `require`s, but the grief when it messes up just isn't worth the years of debugging it will take you to track down such subtle bugs.

There is another problem with this syntax: the indirect object is limited to a name, a scalar variable, or a block, because it would have to do too much lookahead otherwise, just like any other postfix dereference in the language. (These are the same quirky rules as are used for the filehandle slot in functions like `print` and `printf`.) This can lead to horribly confusing precedence problems, as in these next two lines:

```
move $obj->{FIELD};                 # probably wrong!
move $ary[$i];                      # probably wrong!
```

Those actually parse as the very surprising:

```
$obj->move->{FIELD};                # Well, lookee here
$ary->move([$i]);                   # Didn't expect this one, eh?
```

Rather than what you might have expected:

```
$obj->{FIELD}->move();              # You should be so lucky.
$ary[$i]->move;                     # Yeah, sure.
```

To get the correct behavior with indirect object syntax, you would have to use a block around the indirect object:

```
move {$obj->{FIELD}};
move {$ary[$i]};
```

Even then, you still have the same potential problem if there happens to be a function named `move` in the current package. **The `->` notation suffers from neither of these disturbing ambiguities, so we recommend you use it exclusively.** However, you may still end up having to read code using the indirect object notation, so it's important to be familiar with it.

44.1.6 Default UNIVERSAL methods

The `UNIVERSAL` package automatically contains the following methods that are inherited by all other classes:

isa(CLASS)

`isa` returns *true* if its object is blessed into a subclass of `CLASS`

You can also call `UNIVERSAL::isa` as a subroutine with two arguments. The first does not need to be an object or even a reference. This allows you to check what a reference points to, or whether something is a reference of a given type. Example

```
if(UNIVERSAL::isa($ref, 'ARRAY')) {
    #...
}
```

To determine if a reference is a blessed object, you can write

```
print "It's an object\n" if UNIVERSAL::isa($val, 'UNIVERSAL');
```

can(METHOD)

`can` checks to see if its object has a method called `METHOD`, if it does then a reference to the sub is returned, if it does not then *undef* is returned.

`UNIVERSAL::can` can also be called as a subroutine with two arguments. It'll always return *undef* if its first argument isn't an object or a class name. So here's another way to check if a reference is a blessed object

```
print "It's still an object\n" if UNIVERSAL::can($val, 'can');
```

You can also use the `blessed` function of Scalar::Util:

```
use Scalar::Util 'blessed';

my $blessing = blessed $suspected_object;
```

`blessed` returns the name of the package the argument has been blessed into, or `undef`.

VERSION([NEED)]

`VERSION` returns the version number of the class (package). If the NEED argument is given then it will check that the current version (as defined by the $VERSION variable in the given package) not less than NEED; it will die if this is not the case. This method is normally called as a class method. This method is called automatically by the `VERSION` form of `use`.

```
use A 1.2 qw(some imported subs);
# implies:
A->VERSION(1.2);
```

NOTE: `can` directly uses Perl's internal code for method lookup, and `isa` uses a very similar method and cache-ing strategy. This may cause strange effects if the Perl code dynamically changes @ISA in any package.

You may add other methods to the UNIVERSAL class via Perl or XS code. You do not need to `use UNIVERSAL` to make these methods available to your program (and you should not do so).

44.1.7 Destructors

When the last reference to an object goes away, the object is automatically destroyed. (This may even be after you exit, if you've stored references in global variables.) If you want to capture control just before the object is freed, you may define a DESTROY method in your class. It will automatically be called at the appropriate moment, and you can do any extra cleanup you need to do. Perl passes a reference to the object under destruction as the first (and only) argument. Beware that the reference is a read-only value, and cannot be modified by manipulating `$_[0]` within the destructor. The object itself (i.e. the thingy the reference points to, namely `${$_[0]}`, `@{$_[0]}`, `%{$_[0]}` etc.) is not similarly constrained.

If you arrange to re-bless the reference before the destructor returns, perl will again call the DESTROY method for the re-blessed object after the current one returns. This can be used for clean delegation of object destruction, or for ensuring that destructors in the base classes of your choosing get called. Explicitly calling DESTROY is also possible, but is usually never needed.

Do not confuse the previous discussion with how objects *CONTAINED* in the current one are destroyed. Such objects will be freed and destroyed automatically when the current object is freed, provided no other references to them exist elsewhere.

44.1.8 Summary

That's about all there is to it. Now you need just to go off and buy a book about object-oriented design methodology, and bang your forehead with it for the next six months or so.

44.1.9 Two-Phased Garbage Collection

For most purposes, Perl uses a fast and simple, reference-based garbage collection system. That means there's an extra dereference going on at some level, so if you haven't built your Perl executable using your C compiler's `-O` flag, performance will suffer. If you *have* built Perl with `cc -O`, then this probably won't matter.

A more serious concern is that unreachable memory with a non-zero reference count will not normally get freed. Therefore, this is a bad idea:

```
    {
        my $a;
        $a = \$a;
    }
```

Even thought $a *should* go away, it can't. When building recursive data structures, you'll have to break the self-reference yourself explicitly if you don't care to leak. For example, here's a self-referential node such as one might use in a sophisticated tree structure:

```
    sub new_node {
        my $class = shift;
        my $node  = {};
        $node->{LEFT} = $node->{RIGHT} = $node;
        $node->{DATA} = [ @_ ];
        return bless $node => $class;
    }
```

If you create nodes like that, they (currently) won't go away unless you break their self reference yourself. (In other words, this is not to be construed as a feature, and you shouldn't depend on it.)

Almost.

When an interpreter thread finally shuts down (usually when your program exits), then a rather costly but complete mark-and-sweep style of garbage collection is performed, and everything allocated by that thread gets destroyed. This is essential to support Perl as an embedded or a multithreadable language. For example, this program demonstrates Perl's two-phased garbage collection:

```
#!/usr/bin/perl
package Subtle;

sub new {
    my $test;
    $test = \$test;
    warn "CREATING " . \$test;
    return bless \$test;
}

sub DESTROY {
    my $self = shift;
    warn "DESTROYING $self";
}

package main;

warn "starting program";
{
    my $a = Subtle->new;
    my $b = Subtle->new;
    $$a = 0;  # break selfref
    warn "leaving block";
}

warn "just exited block";
warn "time to die...";
exit;
```

When run as */foo/test*, the following output is produced:

```
starting program at /foo/test line 18.
CREATING SCALAR(0x8e5b8) at /foo/test line 7.
CREATING SCALAR(0x8e57c) at /foo/test line 7.
leaving block at /foo/test line 23.
DESTROYING Subtle=SCALAR(0x8e5b8) at /foo/test line 13.
just exited block at /foo/test line 26.
time to die... at /foo/test line 27.
DESTROYING Subtle=SCALAR(0x8e57c) during global destruction.
```

Notice that "global destruction" bit there? That's the thread garbage collector reaching the unreachable.

Objects are always destructed, even when regular refs aren't. Objects are destructed in a separate pass before ordinary refs just to prevent object destructors from using refs that have been themselves destructed. Plain refs are only garbage-collected if the destruct level is greater than 0. You can test the higher levels of global destruction by setting the PERL_DESTRUCT_LEVEL environment variable, presuming `-DDEBUGGING` was enabled during perl build time. See PERL_DESTRUCT_LEVEL in *perlhack* for more information.

A more complete garbage collection strategy will be implemented at a future date.

In the meantime, the best solution is to create a non-recursive container class that holds a pointer to the self-referential data structure. Define a DESTROY method for the containing object's class that manually breaks the circularities in the self-referential structure.

44.2 SEE ALSO

A kinder, gentler tutorial on object-oriented programming in Perl can be found in *perltoot*, *perlboot* and *perltooc*. You should also check out *perlbot* for other object tricks, traps, and tips, as well as *perlmodlib* for some style guides on constructing both modules and classes.

Chapter 45

perltie

How to hide an object class in a simple variable

45.1 SYNOPSIS

```
 tie VARIABLE, CLASSNAME, LIST

 $object = tied VARIABLE

 untie VARIABLE
```

45.2 DESCRIPTION

Prior to release 5.0 of Perl, a programmer could use dbmopen() to connect an on-disk database in the standard Unix dbm(3x) format magically to a %HASH in their program. However, their Perl was either built with one particular dbm library or another, but not both, and you couldn't extend this mechanism to other packages or types of variables.

Now you can.

The tie() function binds a variable to a class (package) that will provide the implementation for access methods for that variable. Once this magic has been performed, accessing a tied variable automatically triggers method calls in the proper class. The complexity of the class is hidden behind magic methods calls. The method names are in ALL CAPS, which is a convention that Perl uses to indicate that they're called implicitly rather than explicitly–just like the BEGIN() and END() functions.

In the tie() call, `VARIABLE` is the name of the variable to be enchanted. `CLASSNAME` is the name of a class implementing objects of the correct type. Any additional arguments in the `LIST` are passed to the appropriate constructor method for that class–meaning TIESCALAR(), TIEARRAY(), TIEHASH(), or TIEHANDLE(). (Typically these are arguments such as might be passed to the dbminit() function of C.) The object returned by the "new" method is also returned by the tie() function, which would be useful if you wanted to access other methods in `CLASSNAME`. (You don't actually have to return a reference to a right "type" (e.g., HASH or `CLASSNAME`) so long as it's a properly blessed object.) You can also retrieve a reference to the underlying object using the tied() function.

Unlike dbmopen(), the tie() function will not `use` or `require` a module for you–you need to do that explicitly yourself.

45.2.1 Tying Scalars

A class implementing a tied scalar should define the following methods: TIESCALAR, FETCH, STORE, and possibly UNTIE and/or DESTROY.

Let's look at each in turn, using as an example a tie class for scalars that allows the user to do something like:

```
    tie $his_speed, 'Nice', getppid();
    tie $my_speed,  'Nice', $$;
```

And now whenever either of those variables is accessed, its current system priority is retrieved and returned. If those variables are set, then the process's priority is changed!

We'll use Jarkko Hietaniemi <*jhi@iki.fi*>'s BSD::Resource class (not included) to access the PRIO_PROCESS, PRIO_MIN, and PRIO_MAX constants from your system, as well as the getpriority() and setpriority() system calls. Here's the preamble of the class.

```
    package Nice;
    use Carp;
    use BSD::Resource;
    use strict;
    $Nice::DEBUG = 0 unless defined $Nice::DEBUG;
```

TIESCALAR classname, LIST

This is the constructor for the class. That means it is expected to return a blessed reference to a new scalar (probably anonymous) that it's creating. For example:

```
    sub TIESCALAR {
        my $class = shift;
        my $pid = shift || $$; # 0 means me

        if ($pid !~ /^\d+$/) {
            carp "Nice::Tie::Scalar got non-numeric pid $pid" if $^W;
            return undef;
        }

        unless (kill 0, $pid) { # EPERM or ERSCH, no doubt
            carp "Nice::Tie::Scalar got bad pid $pid: $!" if $^W;
            return undef;
        }

        return bless \$pid, $class;
    }
```

This tie class has chosen to return an error rather than raising an exception if its constructor should fail. While this is how dbmopen() works, other classes may well not wish to be so forgiving. It checks the global variable `$^W` to see whether to emit a bit of noise anyway.

FETCH this

This method will be triggered every time the tied variable is accessed (read). It takes no arguments beyond its self reference, which is the object representing the scalar we're dealing with. Because in this case we're using just a SCALAR ref for the tied scalar object, a simple $$self allows the method to get at the real value stored there. In our example below, that real value is the process ID to which we've tied our variable.

```
    sub FETCH {
        my $self = shift;
        confess "wrong type" unless ref $self;
        croak "usage error" if @_;
        my $nicety;
        local($!) = 0;
        $nicety = getpriority(PRIO_PROCESS, $$self);
        if ($!) { croak "getpriority failed: $!" }
        return $nicety;
    }
```

This time we've decided to blow up (raise an exception) if the renice fails–there's no place for us to return an error otherwise, and it's probably the right thing to do.

STORE this, value

This method will be triggered every time the tied variable is set (assigned). Beyond its self reference, it also expects one (and only one) argument–the new value the user is trying to assign. Don't worry about returning a value from STORE – the semantic of assignment returning the assigned value is implemented with FETCH.

```
sub STORE {
    my $self = shift;
    confess "wrong type" unless ref $self;
    my $new_nicety = shift;
    croak "usage error" if @_;

    if ($new_nicety < PRIO_MIN) {
        carp sprintf
          "WARNING: priority %d less than minimum system priority %d",
              $new_nicety, PRIO_MIN if $^W;
        $new_nicety = PRIO_MIN;
    }

    if ($new_nicety > PRIO_MAX) {
        carp sprintf
          "WARNING: priority %d greater than maximum system priority %d",
              $new_nicety, PRIO_MAX if $^W;
        $new_nicety = PRIO_MAX;
    }

    unless (defined setpriority(PRIO_PROCESS, $$self, $new_nicety)) {
        confess "setpriority failed: $!";
    }
}
```

UNTIE this

This method will be triggered when the `untie` occurs. This can be useful if the class needs to know when no further calls will be made. (Except DESTROY of course.) See The `untie` Gotcha below for more details.

DESTROY this

This method will be triggered when the tied variable needs to be destructed. As with other object classes, such a method is seldom necessary, because Perl deallocates its moribund object's memory for you automatically–this isn't C++, you know. We'll use a DESTROY method here for debugging purposes only.

```
sub DESTROY {
    my $self = shift;
    confess "wrong type" unless ref $self;
    carp "[ Nice::DESTROY pid $$self ]" if $Nice::DEBUG;
}
```

That's about all there is to it. Actually, it's more than all there is to it, because we've done a few nice things here for the sake of completeness, robustness, and general aesthetics. Simpler TIESCALAR classes are certainly possible.

45.2.2 Tying Arrays

A class implementing a tied ordinary array should define the following methods: TIEARRAY, FETCH, STORE, FETCHSIZE, STORESIZE and perhaps UNTIE and/or DESTROY.

FETCHSIZE and STORESIZE are used to provide `$#array` and equivalent `scalar(@array)` access.

The methods POP, PUSH, SHIFT, UNSHIFT, SPLICE, DELETE, and EXISTS are required if the perl operator with the corresponding (but lowercase) name is to operate on the tied array. The **Tie::Array** class can be used as a base class to implement the first five of these in terms of the basic methods above. The default implementations of DELETE and EXISTS in **Tie::Array** simply `croak`.

In addition EXTEND will be called when perl would have pre-extended allocation in a real array.

For this discussion, we'll implement an array whose elements are a fixed size at creation. If you try to create an element larger than the fixed size, you'll take an exception. For example:

```
use FixedElem_Array;
tie @array, 'FixedElem_Array', 3;
$array[0] = 'cat';  # ok.
$array[1] = 'dogs'; # exception, length('dogs') > 3.
```

The preamble code for the class is as follows:

```
package FixedElem_Array;
use Carp;
use strict;
```

TIEARRAY classname, LIST

This is the constructor for the class. That means it is expected to return a blessed reference through which the new array (probably an anonymous ARRAY ref) will be accessed.

In our example, just to show you that you don't *really* have to return an ARRAY reference, we'll choose a HASH reference to represent our object. A HASH works out well as a generic record type: the `{ELEMSIZE}` field will store the maximum element size allowed, and the `{ARRAY}` field will hold the true ARRAY ref. If someone outside the class tries to dereference the object returned (doubtless thinking it an ARRAY ref), they'll blow up. This just goes to show you that you should respect an object's privacy.

```
sub TIEARRAY {
  my $class    = shift;
  my $elemsize = shift;
  if ( @_ || $elemsize =~ /\D/ ) {
    croak "usage: tie ARRAY, '" . __PACKAGE__ . "', elem_size";
  }
  return bless {
    ELEMSIZE => $elemsize,
    ARRAY    => [],
  }, $class;
}
```

FETCH this, index

This method will be triggered every time an individual element the tied array is accessed (read). It takes one argument beyond its self reference: the index whose value we're trying to fetch.

```
sub FETCH {
  my $self  = shift;
  my $index = shift;
  return $self->{ARRAY}->[$index];
}
```

If a negative array index is used to read from an array, the index will be translated to a positive one internally by calling FETCHSIZE before being passed to FETCH. You may disable this feature by assigning a true value to the variable `$NEGATIVE_INDICES` in the tied array class.

As you may have noticed, the name of the FETCH method (et al.) is the same for all accesses, even though the constructors differ in names (TIESCALAR vs TIEARRAY). While in theory you could have the same class servicing several tied types, in practice this becomes cumbersome, and it's easiest to keep them at simply one tie type per class.

STORE this, index, value

This method will be triggered every time an element in the tied array is set (written). It takes two arguments beyond its self reference: the index at which we're trying to store something and the value we're trying to put there.

In our example, `undef` is really `$self->{ELEMSIZE}` number of spaces so we have a little more work to do here:

```
sub STORE {
  my $self = shift;
  my( $index, $value ) = @_;
  if ( length $value > $self->{ELEMSIZE} ) {
    croak "length of $value is greater than $self->{ELEMSIZE}";
  }
  # fill in the blanks
  $self->EXTEND( $index ) if $index > $self->FETCHSIZE();
  # right justify to keep element size for smaller elements
  $self->{ARRAY}->[$index] = sprintf "%$self->{ELEMSIZE}s", $value;
}
```

Negative indexes are treated the same as with FETCH.

FETCHSIZE this

Returns the total number of items in the tied array associated with object *this*. (Equivalent to `scalar(@array)`). For example:

```
sub FETCHSIZE {
  my $self = shift;
  return scalar @{$self->{ARRAY}};
}
```

STORESIZE this, count

Sets the total number of items in the tied array associated with object *this* to be *count*. If this makes the array larger then class's mapping of `undef` should be returned for new positions. If the array becomes smaller then entries beyond count should be deleted.

In our example, 'undef' is really an element containing `$self->{ELEMSIZE}` number of spaces. Observe:

```
sub STORESIZE {
  my $self  = shift;
  my $count = shift;
  if ( $count > $self->FETCHSIZE() ) {
    foreach ( $count - $self->FETCHSIZE() .. $count ) {
      $self->STORE( $_, '' );
    }
  } elsif ( $count < $self->FETCHSIZE() ) {
    foreach ( 0 .. $self->FETCHSIZE() - $count - 2 ) {
      $self->POP();
    }
  }
}
```

EXTEND this, count

Informative call that array is likely to grow to have *count* entries. Can be used to optimize allocation. This method need do nothing.

In our example, we want to make sure there are no blank (`undef`) entries, so `EXTEND` will make use of `STORESIZE` to fill elements as needed:

```
sub EXTEND {
  my $self  = shift;
  my $count = shift;
  $self->STORESIZE( $count );
}
```

EXISTS this, key

Verify that the element at index *key* exists in the tied array *this*.

In our example, we will determine that if an element consists of `$self->{ELEMSIZE}` spaces only, it does not exist:

```
sub EXISTS {
  my $self  = shift;
  my $index = shift;
  return 0 if ! defined $self->{ARRAY}->[$index] ||
              $self->{ARRAY}->[$index] eq ' ' x $self->{ELEMSIZE};
  return 1;
}
```

DELETE this, key

Delete the element at index *key* from the tied array *this*.

In our example, a deleted item is `$self->{ELEMSIZE}` spaces:

```
sub DELETE {
  my $self  = shift;
  my $index = shift;
  return $self->STORE( $index, '' );
}
```

CLEAR this

Clear (remove, delete, ...) all values from the tied array associated with object *this*. For example:

```
sub CLEAR {
  my $self = shift;
  return $self->{ARRAY} = [];
}
```

PUSH this, LIST

Append elements of *LIST* to the array. For example:

```
sub PUSH {
  my $self = shift;
  my @list = @_;
  my $last = $self->FETCHSIZE();
  $self->STORE( $last + $_, $list[$_] ) foreach 0 .. $#list;
  return $self->FETCHSIZE();
}
```

POP this

Remove last element of the array and return it. For example:

```
sub POP {
  my $self = shift;
  return pop @{$self->{ARRAY}};
}
```

SHIFT this

Remove the first element of the array (shifting other elements down) and return it. For example:

```
sub SHIFT {
  my $self = shift;
  return shift @{$self->{ARRAY}};
}
```

UNSHIFT this, LIST

Insert LIST elements at the beginning of the array, moving existing elements up to make room. For example:

```
sub UNSHIFT {
  my $self = shift;
  my @list = @_;
  my $size = scalar( @list );
  # make room for our list
  @{$self->{ARRAY}}[ $size .. $#{$self->{ARRAY}} + $size ]
   = @{$self->{ARRAY}};
  $self->STORE( $_, $list[$_] ) foreach 0 .. $#list;
}
```

SPLICE this, offset, length, LIST

Perform the equivalent of `splice` on the array.

offset is optional and defaults to zero, negative values count back from the end of the array.

length is optional and defaults to rest of the array.

LIST may be empty.

Returns a list of the original *length* elements at *offset*.

In our example, we'll use a little shortcut if there is a *LIST*:

```
sub SPLICE {
  my $self   = shift;
  my $offset = shift || 0;
  my $length = shift || $self->FETCHSIZE() - $offset;
  my @list   = ();
  if ( @_ ) {
    tie @list, __PACKAGE__, $self->{ELEMSIZE};
    @list   = @_;
  }
  return splice @{$self->{ARRAY}}, $offset, $length, @list;
}
```

UNTIE this

Will be called when `untie` happens. (See The `untie` Gotcha below.)

DESTROY this

This method will be triggered when the tied variable needs to be destructed. As with the scalar tie class, this is almost never needed in a language that does its own garbage collection, so this time we'll just leave it out.

45.2.3 Tying Hashes

Hashes were the first Perl data type to be tied (see dbmopen()). A class implementing a tied hash should define the following methods: TIEHASH is the constructor. FETCH and STORE access the key and value pairs. EXISTS reports whether a key is present in the hash, and DELETE deletes one. CLEAR empties the hash by deleting all the key and value pairs. FIRSTKEY and NEXTKEY implement the keys() and each() functions to iterate over all the keys. SCALAR is triggered when the tied hash is evaluated in scalar context. UNTIE is called when `untie` happens, and DESTROY is called when the tied variable is garbage collected.

If this seems like a lot, then feel free to inherit from merely the standard Tie::StdHash module for most of your methods, redefining only the interesting ones. See *Tie::Hash* for details.

Remember that Perl distinguishes between a key not existing in the hash, and the key existing in the hash but having a corresponding value of `undef`. The two possibilities can be tested with the `exists()` and `defined()` functions.

Here's an example of a somewhat interesting tied hash class: it gives you a hash representing a particular user's dot files. You index into the hash with the name of the file (minus the dot) and you get back that dot file's contents. For example:

```
    use DotFiles;
    tie %dot, 'DotFiles';
    if ( $dot{profile} =~ /MANPATH/ ||
         $dot{login}   =~ /MANPATH/ ||
         $dot{cshrc}   =~ /MANPATH/    )
    {
        print "you seem to set your MANPATH\n";
    }
```

Or here's another sample of using our tied class:

```
    tie %him, 'DotFiles', 'daemon';
    foreach $f ( keys %him ) {
        printf "daemon dot file %s is size %d\n",
            $f, length $him{$f};
    }
```

In our tied hash DotFiles example, we use a regular hash for the object containing several important fields, of which only the `{LIST}` field will be what the user thinks of as the real hash.

USER
: whose dot files this object represents

HOME
: where those dot files live

CLOBBER
: whether we should try to change or remove those dot files

LIST
: the hash of dot file names and content mappings

Here's the start of *Dotfiles.pm*:

```
    package DotFiles;
    use Carp;
    sub whowasi { (caller(1))[3] . '()' }
    my $DEBUG = 0;
    sub debug { $DEBUG = @_ ? shift : 1 }
```

For our example, we want to be able to emit debugging info to help in tracing during development. We keep also one convenience function around internally to help print out warnings; whowasi() returns the function name that calls it.

Here are the methods for the DotFiles tied hash.

TIEHASH classname, LIST

This is the constructor for the class. That means it is expected to return a blessed reference through which the new object (probably but not necessarily an anonymous hash) will be accessed.

Here's the constructor:

```
sub TIEHASH {
    my $self = shift;
    my $user = shift || $>;
    my $dotdir = shift || '';
    croak "usage: @{[&whowasi]} [USER [DOTDIR]]" if @_;
    $user = getpwuid($user) if $user =~ /^\d+$/;
    my $dir = (getpwnam($user))[7]
            || croak "@{[&whowasi]}: no user $user";
    $dir .= "/$dotdir" if $dotdir;

    my $node = {
        USER    => $user,
        HOME    => $dir,
        LIST    => {},
        CLOBBER => 0,
    };

    opendir(DIR, $dir)
            || croak "@{[&whowasi]}: can't opendir $dir: $!";
    foreach $dot ( grep /^\./ && -f "$dir/$_", readdir(DIR)) {
        $dot =~ s/^\.//;
        $node->{LIST}{$dot} = undef;
    }
    closedir DIR;
    return bless $node, $self;
}
```

It's probably worth mentioning that if you're going to filetest the return values out of a readdir, you'd better prepend the directory in question. Otherwise, because we didn't chdir() there, it would have been testing the wrong file.

FETCH this, key

This method will be triggered every time an element in the tied hash is accessed (read). It takes one argument beyond its self reference: the key whose value we're trying to fetch.

Here's the fetch for our DotFiles example.

```
sub FETCH {
    carp &whowasi if $DEBUG;
    my $self = shift;
    my $dot = shift;
    my $dir = $self->{HOME};
    my $file = "$dir/.$dot";

    unless (exists $self->{LIST}->{$dot} || -f $file) {
        carp "@{[&whowasi]}: no $dot file" if $DEBUG;
        return undef;
    }
```

```
        if (defined $self->{LIST}->{$dot}) {
            return $self->{LIST}->{$dot};
        } else {
            return $self->{LIST}->{$dot} = ‘cat $dir/.$dot‘;
        }
    }
```

It was easy to write by having it call the Unix cat(1) command, but it would probably be more portable to open the file manually (and somewhat more efficient). Of course, because dot files are a Unixy concept, we’re not that concerned.

STORE this, key, value

This method will be triggered every time an element in the tied hash is set (written). It takes two arguments beyond its self reference: the index at which we’re trying to store something, and the value we’re trying to put there.

Here in our DotFiles example, we’ll be careful not to let them try to overwrite the file unless they’ve called the clobber() method on the original object reference returned by tie().

```
    sub STORE {
        carp &whowasi if $DEBUG;
        my $self = shift;
        my $dot = shift;
        my $value = shift;
        my $file = $self->{HOME} . "/.$dot";
        my $user = $self->{USER};

        croak "@{[&whowasi]}: $file not clobberable"
            unless $self->{CLOBBER};

        open(F, "> $file") || croak "can’t open $file: $!";
        print F $value;
        close(F);
    }
```

If they wanted to clobber something, they might say:

```
    $ob = tie %daemon_dots, ’daemon’;
    $ob->clobber(1);
    $daemon_dots{signature} = "A true daemon\n";
```

Another way to lay hands on a reference to the underlying object is to use the tied() function, so they might alternately have set clobber using:

```
    tie %daemon_dots, ’daemon’;
    tied(%daemon_dots)->clobber(1);
```

The clobber method is simply:

```
    sub clobber {
        my $self = shift;
        $self->{CLOBBER} = @_ ? shift : 1;
    }
```

DELETE this, key

This method is triggered when we remove an element from the hash, typically by using the delete() function. Again, we’ll be careful to check whether they really want to clobber files.

```
    sub DELETE   {
        carp &whowasi if $DEBUG;

        my $self = shift;
        my $dot = shift;
        my $file = $self->{HOME} . "/.$dot";
        croak "@{[&whowasi]}: won't remove file $file"
            unless $self->{CLOBBER};
        delete $self->{LIST}->{$dot};
        my $success = unlink($file);
        carp "@{[&whowasi]}: can't unlink $file: $!" unless $success;
        $success;
    }
```

The value returned by DELETE becomes the return value of the call to delete(). If you want to emulate the normal behavior of delete(), you should return whatever FETCH would have returned for this key. In this example, we have chosen instead to return a value which tells the caller whether the file was successfully deleted.

CLEAR this

This method is triggered when the whole hash is to be cleared, usually by assigning the empty list to it.

In our example, that would remove all the user's dot files! It's such a dangerous thing that they'll have to set CLOBBER to something higher than 1 to make it happen.

```
    sub CLEAR    {
        carp &whowasi if $DEBUG;
        my $self = shift;
        croak "@{[&whowasi]}: won't remove all dot files for $self->{USER}"
            unless $self->{CLOBBER} > 1;
        my $dot;
        foreach $dot ( keys %{$self->{LIST}}) {
            $self->DELETE($dot);
        }
    }
```

EXISTS this, key

This method is triggered when the user uses the exists() function on a particular hash. In our example, we'll look at the `{LIST}` hash element for this:

```
    sub EXISTS   {
        carp &whowasi if $DEBUG;
        my $self = shift;
        my $dot = shift;
        return exists $self->{LIST}->{$dot};
    }
```

FIRSTKEY this

This method will be triggered when the user is going to iterate through the hash, such as via a keys() or each() call.

```
    sub FIRSTKEY {
        carp &whowasi if $DEBUG;
        my $self = shift;
        my $a = keys %{$self->{LIST}};          # reset each() iterator
        each %{$self->{LIST}}
    }
```

NEXTKEY this, lastkey

This method gets triggered during a keys() or each() iteration. It has a second argument which is the last key that had been accessed. This is useful if you're carrying about ordering or calling the iterator from more than one sequence, or not really storing things in a hash anywhere.

For our example, we're using a real hash so we'll do just the simple thing, but we'll have to go through the LIST field indirectly.

```
sub NEXTKEY  {
    carp &whowasi if $DEBUG;
    my $self = shift;
    return each %{ $self->{LIST} }
}
```

SCALAR this

This is called when the hash is evaluated in scalar context. In order to mimic the behaviour of untied hashes, this method should return a false value when the tied hash is considered empty. If this method does not exist, perl will make some educated guesses and return true when the hash is inside an iteration. If this isn't the case, FIRSTKEY is called, and the result will be a false value if FIRSTKEY returns the empty list, true otherwise.

However, you should **not** blindly rely on perl always doing the right thing. Particularly, perl will mistakenly return true when you clear the hash by repeatedly calling DELETE until it is empty. You are therefore advised to supply your own SCALAR method when you want to be absolutely sure that your hash behaves nicely in scalar context.

In our example we can just call `scalar` on the underlying hash referenced by `$self->{LIST}`:

```
sub SCALAR {
    carp &whowasi if $DEBUG;
    my $self = shift;
    return scalar %{ $self->{LIST} }
}
```

UNTIE this

This is called when `untie` occurs. See The `untie` Gotcha below.

DESTROY this

This method is triggered when a tied hash is about to go out of scope. You don't really need it unless you're trying to add debugging or have auxiliary state to clean up. Here's a very simple function:

```
sub DESTROY  {
    carp &whowasi if $DEBUG;
}
```

Note that functions such as keys() and values() may return huge lists when used on large objects, like DBM files. You may prefer to use the each() function to iterate over such. Example:

```
# print out history file offsets
use NDBM_File;
tie(%HIST, 'NDBM_File', '/usr/lib/news/history', 1, 0);
while (($key,$val) = each %HIST) {
    print $key, ' = ', unpack('L',$val), "\n";
}
untie(%HIST);
```

45.2.4 Tying FileHandles

This is partially implemented now.

A class implementing a tied filehandle should define the following methods: TIEHANDLE, at least one of PRINT, PRINTF, WRITE, READLINE, GETC, READ, and possibly CLOSE, UNTIE and DESTROY. The class can also provide: BINMODE, OPEN, EOF, FILENO, SEEK, TELL - if the corresponding perl operators are used on the handle.

When STDERR is tied, its PRINT method will be called to issue warnings and error messages. This feature is temporarily disabled during the call, which means you can use `warn()` inside PRINT without starting a recursive loop. And just like `__WARN__` and `__DIE__` handlers, STDERR's PRINT method may be called to report parser errors, so the caveats mentioned under %SIG in *perlvar* apply.

All of this is especially useful when perl is embedded in some other program, where output to STDOUT and STDERR may have to be redirected in some special way. See nvi and the Apache module for examples.

In our example we're going to create a shouting handle.

```
    package Shout;
```

TIEHANDLE classname, LIST

This is the constructor for the class. That means it is expected to return a blessed reference of some sort. The reference can be used to hold some internal information.

```
    sub TIEHANDLE { print "<shout>\n"; my $i; bless \$i, shift }
```

WRITE this, LIST

This method will be called when the handle is written to via the `syswrite` function.

```
    sub WRITE {
        $r = shift;
        my($buf,$len,$offset) = @_;
        print "WRITE called, \$buf=$buf, \$len=$len, \$offset=$offset";
    }
```

PRINT this, LIST

This method will be triggered every time the tied handle is printed to with the `print()` function. Beyond its self reference it also expects the list that was passed to the print function.

```
    sub PRINT { $r = shift; $$r++; print join($,,map(uc($_),@_)),$\ }
```

PRINTF this, LIST

This method will be triggered every time the tied handle is printed to with the `printf()` function. Beyond its self reference it also expects the format and list that was passed to the printf function.

```
    sub PRINTF {
        shift;
        my $fmt = shift;
        print sprintf($fmt, @_);
    }
```

READ this, LIST

This method will be called when the handle is read from via the `read` or `sysread` functions.

```
        sub READ {
            my $self = shift;
            my $bufref = \$_[0];
            my(undef,$len,$offset) = @_;
            print "READ called, \$buf=$bufref, \$len=$len, \$offset=$offset";
            # add to $$bufref, set $len to number of characters read
            $len;
        }
```

READLINE this

This method will be called when the handle is read from via <HANDLE>. The method should return undef when there is no more data.

```
        sub READLINE { $r = shift; "READLINE called $$r times\n"; }
```

GETC this

This method will be called when the `getc` function is called.

```
        sub GETC { print "Don't GETC, Get Perl"; return "a"; }
```

CLOSE this

This method will be called when the handle is closed via the `close` function.

```
        sub CLOSE { print "CLOSE called.\n" }
```

UNTIE this

As with the other types of ties, this method will be called when `untie` happens. It may be appropriate to "auto CLOSE" when this occurs. See The `untie` Gotcha below.

DESTROY this

As with the other types of ties, this method will be called when the tied handle is about to be destroyed. This is useful for debugging and possibly cleaning up.

```
        sub DESTROY { print "</shout>\n" }
```

Here's how to use our little example:

```
    tie(*FOO,'Shout');
    print FOO "hello\n";
    $a = 4; $b = 6;
    print FOO $a, " plus ", $b, " equals ", $a + $b, "\n";
    print <FOO>;
```

45.2.5 UNTIE this

You can define for all tie types an UNTIE method that will be called at untie(). See The `untie` Gotcha below.

45.2.6 The `untie` Gotcha

If you intend making use of the object returned from either tie() or tied(), and if the tie's target class defines a destructor, there is a subtle gotcha you *must* guard against.

As setup, consider this (admittedly rather contrived) example of a tie; all it does is use a file to keep a log of the values assigned to a scalar.

```
    package Remember;

    use strict;
    use warnings;
    use IO::File;

    sub TIESCALAR {
        my $class = shift;
        my $filename = shift;
        my $handle = new IO::File "> $filename"
                         or die "Cannot open $filename: $!\n";

        print $handle "The Start\n";
        bless {FH => $handle, Value => 0}, $class;
    }

    sub FETCH {
        my $self = shift;
        return $self->{Value};
    }

    sub STORE {
        my $self = shift;
        my $value = shift;
        my $handle = $self->{FH};
        print $handle "$value\n";
        $self->{Value} = $value;
    }

    sub DESTROY {
        my $self = shift;
        my $handle = $self->{FH};
        print $handle "The End\n";
        close $handle;
    }

    1;
```

Here is an example that makes use of this tie:

```
    use strict;
    use Remember;

    my $fred;
    tie $fred, 'Remember', 'myfile.txt';
    $fred = 1;
    $fred = 4;
    $fred = 5;
    untie $fred;
    system "cat myfile.txt";
```

This is the output when it is executed:

```
The Start
1
4
5
The End
```

So far so good. Those of you who have been paying attention will have spotted that the tied object hasn't been used so far. So lets add an extra method to the Remember class to allow comments to be included in the file – say, something like this:

```
sub comment {
    my $self = shift;
    my $text = shift;
    my $handle = $self->{FH};
    print $handle $text, "\n";
}
```

And here is the previous example modified to use the `comment` method (which requires the tied object):

```
use strict;
use Remember;

my ($fred, $x);
$x = tie $fred, 'Remember', 'myfile.txt';
$fred = 1;
$fred = 4;
comment $x "changing...";
$fred = 5;
untie $fred;
system "cat myfile.txt";
```

When this code is executed there is no output. Here's why:

When a variable is tied, it is associated with the object which is the return value of the TIESCALAR, TIEARRAY, or TIEHASH function. This object normally has only one reference, namely, the implicit reference from the tied variable. When untie() is called, that reference is destroyed. Then, as in the first example above, the object's destructor (DESTROY) is called, which is normal for objects that have no more valid references; and thus the file is closed.

In the second example, however, we have stored another reference to the tied object in $x. That means that when untie() gets called there will still be a valid reference to the object in existence, so the destructor is not called at that time, and thus the file is not closed. The reason there is no output is because the file buffers have not been flushed to disk.

Now that you know what the problem is, what can you do to avoid it? Prior to the introduction of the optional UNTIE method the only way was the good old `-w` flag. Which will spot any instances where you call untie() and there are still valid references to the tied object. If the second script above this near the top `use warnings 'untie'` or was run with the `-w` flag, Perl prints this warning message:

```
untie attempted while 1 inner references still exist
```

To get the script to work properly and silence the warning make sure there are no valid references to the tied object *before* untie() is called:

```
undef $x;
untie $fred;
```

Now that UNTIE exists the class designer can decide which parts of the class functionality are really associated with `untie` and which with the object being destroyed. What makes sense for a given class depends on whether the inner references are being kept so that non-tie-related methods can be called on the object. But in most cases it probably makes sense to move the functionality that would have been in DESTROY to the UNTIE method.

If the UNTIE method exists then the warning above does not occur. Instead the UNTIE method is passed the count of "extra" references and can issue its own warning if appropriate. e.g. to replicate the no UNTIE case this method can be used:

```
    sub UNTIE
    {
     my ($obj,$count) = @_;
     carp "untie attempted while $count inner references still exist" if $count;
    }
```

45.3 SEE ALSO

See DB_File or *Config* for some interesting tie() implementations. A good starting point for many tie() implementations is with one of the modules *Tie::Scalar*, *Tie::Array*, *Tie::Hash*, or *Tie::Handle*.

45.4 BUGS

The bucket usage information provided by `scalar(%hash)` is not available. What this means is that using %tied_hash in boolean context doesn't work right (currently this always tests false, regardless of whether the hash is empty or hash elements).

Localizing tied arrays or hashes does not work. After exiting the scope the arrays or the hashes are not restored.

Counting the number of entries in a hash via `scalar(keys(%hash))` or `scalar(values(%hash))` is inefficient since it needs to iterate through all the entries with FIRSTKEY/NEXTKEY.

Tied hash/array slices cause multiple FETCH/STORE pairs, there are no tie methods for slice operations.

You cannot easily tie a multilevel data structure (such as a hash of hashes) to a dbm file. The first problem is that all but GDBM and Berkeley DB have size limitations, but beyond that, you also have problems with how references are to be represented on disk. One experimental module that does attempt to address this need partially is the MLDBM module. Check your nearest CPAN site as described in *perlmodlib* for source code to MLDBM.

Tied filehandles are still incomplete. sysopen(), truncate(), flock(), fcntl(), stat() and -X can't currently be trapped.

perldbmfilter

Perl DBM Filters

46.1 SYNOPSIS

```
    $db = tie %hash, 'DBM', ...

    $old_filter = $db->filter_store_key  ( sub { ... } ) ;
    $old_filter = $db->filter_store_value( sub { ... } ) ;
    $old_filter = $db->filter_fetch_key  ( sub { ... } ) ;
    $old_filter = $db->filter_fetch_value( sub { ... } ) ;
```

46.2 DESCRIPTION

The four `filter_*` methods shown above are available in all the DBM modules that ship with Perl, namely DB_File, GDBM_File, NDBM_File, ODBM_File and SDBM_File.

Each of the methods work identically, and are used to install (or uninstall) a single DBM Filter. The only difference between them is the place that the filter is installed.

To summarise:

filter_store_key

If a filter has been installed with this method, it will be invoked every time you write a key to a DBM database.

filter_store_value

If a filter has been installed with this method, it will be invoked every time you write a value to a DBM database.

filter_fetch_key

If a filter has been installed with this method, it will be invoked every time you read a key from a DBM database.

filter_fetch_value

If a filter has been installed with this method, it will be invoked every time you read a value from a DBM database.

You can use any combination of the methods from none to all four.

All filter methods return the existing filter, if present, or `undef` in not.

To delete a filter pass `undef` to it.

46.2.1 The Filter

When each filter is called by Perl, a local copy of `$_` will contain the key or value to be filtered. Filtering is achieved by modifying the contents of `$_`. The return code from the filter is ignored.

46.2.2 An Example – the NULL termination problem.

DBM Filters are useful for a class of problems where you *always* want to make the same transformation to all keys, all values or both.

For example, consider the following scenario. You have a DBM database that you need to share with a third-party C application. The C application assumes that *all* keys and values are NULL terminated. Unfortunately when Perl writes to DBM databases it doesn't use NULL termination, so your Perl application will have to manage NULL termination itself. When you write to the database you will have to use something like this:

```
    $hash{"$key\0"} = "$value\0" ;
```

Similarly the NULL needs to be taken into account when you are considering the length of existing keys/values.

It would be much better if you could ignore the NULL terminations issue in the main application code and have a mechanism that automatically added the terminating NULL to all keys and values whenever you write to the database and have them removed when you read from the database. As I'm sure you have already guessed, this is a problem that DBM Filters can fix very easily.

```
    use strict ;
    use warnings ;
    use SDBM_File ;
    use Fcntl ;

    my %hash ;
    my $filename = "filt" ;
    unlink $filename ;

    my $db = tie(%hash, 'SDBM_File', $filename, O_RDWR|O_CREAT, 0640)
      or die "Cannot open $filename: $!\n" ;

    # Install DBM Filters
    $db->filter_fetch_key  ( sub { s/\0$//    } ) ;
    $db->filter_store_key  ( sub { $_ .= "\0" } ) ;
    $db->filter_fetch_value(
        sub { no warnings 'uninitialized' ;s/\0$// } ) ;
    $db->filter_store_value( sub { $_ .= "\0" } ) ;

    $hash{"abc"} = "def" ;
    my $a = $hash{"ABC"} ;
    # ...
    undef $db ;
    untie %hash ;
```

The code above uses SDBM_File, but it will work with any of the DBM modules.

Hopefully the contents of each of the filters should be self-explanatory. Both "fetch" filters remove the terminating NULL, and both "store" filters add a terminating NULL.

46.2.3 Another Example – Key is a C int.

Here is another real-life example. By default, whenever Perl writes to a DBM database it always writes the key and value as strings. So when you use this:

```
    $hash{12345} = "something" ;
```

the key 12345 will get stored in the DBM database as the 5 byte string "12345". If you actually want the key to be stored in the DBM database as a C int, you will have to use `pack` when writing, and `unpack` when reading.

Here is a DBM Filter that does it:

```
    use strict ;
    use warnings ;
    use DB_File ;
    my %hash ;
    my $filename = "filt" ;
    unlink $filename ;

    my $db = tie %hash, 'DB_File', $filename, O_CREAT|O_RDWR, 0666, $DB_HASH
      or die "Cannot open $filename: $!\n" ;

    $db->filter_fetch_key  ( sub { $_ = unpack("i", $_) } ) ;
    $db->filter_store_key  ( sub { $_ = pack ("i", $_) } ) ;
    $hash{123} = "def" ;
    # ...
    undef $db ;
    untie %hash ;
```

The code above uses DB_File, but again it will work with any of the DBM modules.

This time only two filters have been used – we only need to manipulate the contents of the key, so it wasn't necessary to install any value filters.

Chapter 47

perlipc

Perl interprocess communication (signals, fifos, pipes, safe subprocesses, sockets, and semaphores)

47.1 DESCRIPTION

The basic IPC facilities of Perl are built out of the good old Unix signals, named pipes, pipe opens, the Berkeley socket routines, and SysV IPC calls. Each is used in slightly different situations.

47.2 Signals

Perl uses a simple signal handling model: the %SIG hash contains names or references of user-installed signal handlers. These handlers will be called with an argument which is the name of the signal that triggered it. A signal may be generated intentionally from a particular keyboard sequence like control-C or control-Z, sent to you from another process, or triggered automatically by the kernel when special events transpire, like a child process exiting, your process running out of stack space, or hitting file size limit.

For example, to trap an interrupt signal, set up a handler like this:

```
sub catch_zap {
    my $signame = shift;
    $shucks++;
    die "Somebody sent me a SIG$signame";
}
$SIG{INT} = 'catch_zap';  # could fail in modules
$SIG{INT} = \&catch_zap;  # best strategy
```

Prior to Perl 5.7.3 it was necessary to do as little as you possibly could in your handler; notice how all we do is set a global variable and then raise an exception. That's because on most systems, libraries are not re-entrant; particularly, memory allocation and I/O routines are not. That meant that doing nearly *anything* in your handler could in theory trigger a memory fault and subsequent core dump - see Deferred Signals (Safe Signals) below.

The names of the signals are the ones listed out by `kill -l` on your system, or you can retrieve them from the Config module. Set up an @signame list indexed by number to get the name and a %signo table indexed by name to get the number:

```
use Config;
defined $Config{sig_name} || die "No sigs?";
foreach $name (split(' ', $Config{sig_name})) {
    $signo{$name} = $i;
    $signame[$i] = $name;
    $i++;
}
```

So to check whether signal 17 and SIGALRM were the same, do just this:

```
    print "signal #17 = $signame[17]\n";
    if ($signo{ALRM}) {
        print "SIGALRM is $signo{ALRM}\n";
    }
```

You may also choose to assign the strings `'IGNORE'` or `'DEFAULT'` as the handler, in which case Perl will try to discard the signal or do the default thing.

On most Unix platforms, the `CHLD` (sometimes also known as `CLD`) signal has special behavior with respect to a value of `'IGNORE'`. Setting `$SIG{CHLD}` to `'IGNORE'` on such a platform has the effect of not creating zombie processes when the parent process fails to `wait()` on its child processes (i.e. child processes are automatically reaped). Calling `wait()` with `$SIG{CHLD}` set to `'IGNORE'` usually returns `-1` on such platforms.

Some signals can be neither trapped nor ignored, such as the KILL and STOP (but not the TSTP) signals. One strategy for temporarily ignoring signals is to use a local() statement, which will be automatically restored once your block is exited. (Remember that local() values are "inherited" by functions called from within that block.)

```
    sub precious {
        local $SIG{INT} = 'IGNORE';
        &more_functions;
    }
    sub more_functions {
        # interrupts still ignored, for now...
    }
```

Sending a signal to a negative process ID means that you send the signal to the entire Unix process-group. This code sends a hang-up signal to all processes in the current process group (and sets $SIG{HUP} to IGNORE so it doesn't kill itself):

```
    {
        local $SIG{HUP} = 'IGNORE';
        kill HUP => -$$;
        # snazzy writing of: kill('HUP', -$$)
    }
```

Another interesting signal to send is signal number zero. This doesn't actually affect a child process, but instead checks whether it's alive or has changed its UID.

```
    unless (kill 0 => $kid_pid) {
        warn "something wicked happened to $kid_pid";
    }
```

When directed at a process whose UID is not identical to that of the sending process, signal number zero may fail because you lack permission to send the signal, even though the process is alive. You may be able to determine the cause of failure using `%!`.

```
    unless (kill 0 => $pid or $!{EPERM}) {
        warn "$pid looks dead";
    }
```

You might also want to employ anonymous functions for simple signal handlers:

```
    $SIG{INT} = sub { die "\nOutta here!\n" };
```

But that will be problematic for the more complicated handlers that need to reinstall themselves. Because Perl's signal mechanism is currently based on the signal(3) function from the C library, you may sometimes be so misfortunate as to run on systems where that function is "broken", that is, it behaves in the old unreliable SysV way rather than the newer, more reasonable BSD and POSIX fashion. So you'll see defensive people writing signal handlers like this:

```
sub REAPER {
    $waitedpid = wait;
    # loathe sysV: it makes us not only reinstate
    # the handler, but place it after the wait
    $SIG{CHLD} = \&REAPER;
}
$SIG{CHLD} = \&REAPER;
# now do something that forks...
```

or better still:

```
use POSIX ":sys_wait_h";
sub REAPER {
    my $child;
    # If a second child dies while in the signal handler caused by the
    # first death, we won't get another signal. So must loop here else
    # we will leave the unreaped child as a zombie. And the next time
    # two children die we get another zombie. And so on.
    while (($child = waitpid(-1,WNOHANG)) > 0) {
        $Kid_Status{$child} = $?;
    }
    $SIG{CHLD} = \&REAPER;  # still loathe sysV
}
$SIG{CHLD} = \&REAPER;
# do something that forks...
```

Signal handling is also used for timeouts in Unix, While safely protected within an `eval{}` block, you set a signal handler to trap alarm signals and then schedule to have one delivered to you in some number of seconds. Then try your blocking operation, clearing the alarm when it's done but not before you've exited your `eval{}` block. If it goes off, you'll use die() to jump out of the block, much as you might using longjmp() or throw() in other languages.

Here's an example:

```
eval {
    local $SIG{ALRM} = sub { die "alarm clock restart" };
    alarm 10;
    flock(FH, 2);   # blocking write lock
    alarm 0;
};
if ($@ and $@ !~ /alarm clock restart/) { die }
```

If the operation being timed out is system() or qx(), this technique is liable to generate zombies. If this matters to you, you'll need to do your own fork() and exec(), and kill the errant child process.

For more complex signal handling, you might see the standard POSIX module. Lamentably, this is almost entirely undocumented, but the *t/lib/posix.t* file from the Perl source distribution has some examples in it.

47.2.1 Handling the SIGHUP Signal in Daemons

A process that usually starts when the system boots and shuts down when the system is shut down is called a daemon (Disk And Execution MONitor). If a daemon process has a configuration file which is modified after the process has been started, there should be a way to tell that process to re-read its configuration file, without stopping the process.

Many daemons provide this mechanism using the `SIGHUP` signal handler. When you want to tell the daemon to re-read the file you simply send it the `SIGHUP` signal.

Not all platforms automatically reinstall their (native) signal handlers after a signal delivery. This means that the handler works only the first time the signal is sent. The solution to this problem is to use `POSIX` signal handlers if available, their behaviour is well-defined.

The following example implements a simple daemon, which restarts itself every time the `SIGHUP` signal is received. The actual code is located in the subroutine `code()`, which simply prints some debug info to show that it works and should be replaced with the real code.

```
#!/usr/bin/perl -w

use POSIX ();
use FindBin ();
use File::Basename ();
use File::Spec::Functions;

$|=1;

# make the daemon cross-platform, so exec always calls the script
# itself with the right path, no matter how the script was invoked.
my $script = File::Basename::basename($0);
my $SELF = catfile $FindBin::Bin, $script;

# POSIX unmasks the sigprocmask properly
my $sigset = POSIX::SigSet->new();
my $action = POSIX::SigAction->new('sigHUP_handler',
                                   $sigset,
                                   &POSIX::SA_NODEFER);
POSIX::sigaction(&POSIX::SIGHUP, $action);

sub sigHUP_handler {
    print "got SIGHUP\n";
    exec($SELF, @ARGV) or die "Couldn't restart: $!\n";
}

code();

sub code {
    print "PID: $$\n";
    print "ARGV: @ARGV\n";
    my $c = 0;
    while (++$c) {
        sleep 2;
        print "$c\n";
    }
}
__END__
```

47.3 A named pipe (often referred to as a FIFO) is an old Unix IPC mechanism for processes communicating on the same machine. It works just like a regular, connected anonymous pipes, except that the processes rendezvous using a filename and don't have to be related.

To create a named pipe, use the Unix command mknod(1) or on some systems, mkfifo(1). These may not be in your normal path.

```
    # system return val is backwards, so && not ||
    #
    $ENV{PATH} .= ":/etc:/usr/etc";
    if  (      system('mknod',  $path, 'p')
            && system('mkfifo', $path) )
    {
        die "mk{nod,fifo} $path failed";
    }
```

A fifo is convenient when you want to connect a process to an unrelated one. When you open a fifo, the program will block until there's something on the other end.

For example, let's say you'd like to have your *.signature* file be a named pipe that has a Perl program on the other end. Now every time any program (like a mailer, news reader, finger program, etc.) tries to read from that file, the reading program will block and your program will supply the new signature. We'll use the pipe-checking file test **-p** to find out whether anyone (or anything) has accidentally removed our fifo.

```
    chdir; # go home
    $FIFO = '.signature';
    $ENV{PATH} .= ":/etc:/usr/games";

    while (1) {
        unless (-p $FIFO) {
            unlink $FIFO;
            system('mknod', $FIFO, 'p')
                && die "can't mknod $FIFO: $!";
        }

        # next line blocks until there's a reader
        open (FIFO, "> $FIFO") || die "can't write $FIFO: $!";
        print FIFO "John Smith (smith\@host.org)\n", `fortune -s`;
        close FIFO;
        sleep 2;    # to avoid dup signals
    }
```

Deferred Signals (Safe Signals)

In Perls before Perl 5.7.3 by installing Perl code to deal with signals, you were exposing yourself to danger from two things. First, few system library functions are re-entrant. If the signal interrupts while Perl is executing one function (like malloc(3) or printf(3)), and your signal handler then calls the same function again, you could get unpredictable behavior–often, a core dump. Second, Perl isn't itself re-entrant at the lowest levels. If the signal interrupts Perl while Perl is changing its own internal data structures, similarly unpredictable behaviour may result.

There were two things you could do, knowing this: be paranoid or be pragmatic. The paranoid approach was to do as little as possible in your signal handler. Set an existing integer variable that already has a value, and return. This doesn't help you if you're in a slow system call, which will just restart. That means you have to `die` to longjump(3) out of the handler. Even this is a little cavalier for the true paranoiac, who avoids `die` in a handler because the system *is* out to get you. The pragmatic approach was to say "I know the risks, but prefer the convenience", and to do anything you wanted in your signal handler, and be prepared to clean up core dumps now and again.

In Perl 5.7.3 and later to avoid these problems signals are "deferred"– that is when the signal is delivered to the process by the system (to the C code that implements Perl) a flag is set, and the handler returns immediately. Then at strategic "safe" points in the Perl interpreter (e.g. when it is about to execute a new opcode) the flags are checked and the Perl level handler from %SIG is executed. The "deferred" scheme allows much more flexibility in the coding of signal handler as we know Perl interpreter is in a safe state, and that we are not in a system library function when the handler is called. However the implementation does differ from previous Perls in the following ways:

Long running opcodes

As Perl interpreter only looks at the signal flags when it about to execute a new opcode if a signal arrives during a long running opcode (e.g. a regular expression operation on a very large string) then signal will not be seen until operation completes.

Interrupting IO

When a signal is delivered (e.g. INT control-C) the operating system breaks into IO operations like `read` (used to implement Perls <> operator). On older Perls the handler was called immediately (and as `read` is not "unsafe" this worked well). With the "deferred" scheme the handler is not called immediately, and if Perl is using system's `stdio` library that library may re-start the `read` without returning to Perl and giving it a chance to call the %SIG handler. If this happens on your system the solution is to use `:perlio` layer to do IO - at least on those handles which you want to be able to break into with signals. (The `:perlio` layer checks the signal flags and calls %SIG handlers before resuming IO operation.)

Note that the default in Perl 5.7.3 and later is to automatically use the `:perlio` layer.

Note that some networking library functions like gethostbyname() are known to have their own implementations of timeouts which may conflict with your timeouts. If you are having problems with such functions, you can try using the POSIX sigaction() function, which bypasses the Perl safe signals (note that this means subjecting yourself to possible memory corruption, as described above). Instead of setting `$SIG{ALRM}` try something like the following:

```
use POSIX;
sigaction SIGALRM, new POSIX::SigAction sub { die "alarm\n" }
    or die "Error setting SIGALRM handler: $!\n";
```

Restartable system calls

On systems that supported it, older versions of Perl used the SA_RESTART flag when installing %SIG handlers. This meant that restartable system calls would continue rather than returning when a signal arrived. In order to deliver deferred signals promptly, Perl 5.7.3 and later do *not* use SA_RESTART. Consequently, restartable system calls can fail (with $! set to `EINTR`) in places where they previously would have succeeded.

Note that the default `:perlio` layer will retry `read`, `write` and `close` as described above and that interrupted `wait` and `waitpid` calls will always be retried.

Signals as "faults"

Certain signals e.g. SEGV, ILL, BUS are generated as a result of virtual memory or other "faults". These are normally fatal and there is little a Perl-level handler can do with them. (In particular the old signal scheme was particularly unsafe in such cases.) However if a %SIG handler is set the new scheme simply sets a flag and returns as described above. This may cause the operating system to try the offending machine instruction again and - as nothing has changed - it will generate the signal again. The result of this is a rather odd "loop". In future Perl's signal mechanism may be changed to avoid this - perhaps by simply disallowing %SIG handlers on signals of that type. Until then the work-round is not to set a %SIG handler on those signals. (Which signals they are is operating system dependant.)

Signals triggered by operating system state

On some operating systems certain signal handlers are supposed to "do something" before returning. One example can be CHLD or CLD which indicates a child process has completed. On some operating systems the signal handler is expected to `wait` for the completed child process. On such systems the deferred signal scheme will not work for those signals (it does not do the `wait`). Again the failure will look like a loop as the operating system will re-issue the signal as there are un-waited-for completed child processes.

If you want the old signal behaviour back regardless of possible memory corruption, set the environment variable `PERL_SIGNALS` to `"unsafe"` (a new feature since Perl 5.8.1).

47.3.1 Using open() for IPC

Perl's basic open() statement can also be used for unidirectional interprocess communication by either appending or prepending a pipe symbol to the second argument to open(). Here's how to start something up in a child process you intend to write to:

```
open(SPOOLER, "| cat -v | lpr -h 2>/dev/null")
                || die "can't fork: $!";
local $SIG{PIPE} = sub { die "spooler pipe broke" };
print SPOOLER "stuff\n";
close SPOOLER || die "bad spool: $! $?";
```

And here's how to start up a child process you intend to read from:

```
open(STATUS, "netstat -an 2>&1 |")
                || die "can't fork: $!";
while (<STATUS>) {
    next if /^(tcp|udp)/;
    print;
}
close STATUS || die "bad netstat: $! $?";
```

If one can be sure that a particular program is a Perl script that is expecting filenames in @ARGV, the clever programmer can write something like this:

```
% program f1 "cmd1|" - f2 "cmd2|" f3 < tmpfile
```

and irrespective of which shell it's called from, the Perl program will read from the file *f1*, the process *cmd1*, standard input (*tmpfile* in this case), the *f2* file, the *cmd2* command, and finally the *f3* file. Pretty nifty, eh?

You might notice that you could use backticks for much the same effect as opening a pipe for reading:

```
print grep { !/^(tcp|udp)/ } `netstat -an 2>&1`;
die "bad netstat" if $?;
```

While this is true on the surface, it's much more efficient to process the file one line or record at a time because then you don't have to read the whole thing into memory at once. It also gives you finer control of the whole process, letting you to kill off the child process early if you'd like.

Be careful to check both the open() and the close() return values. If you're *writing* to a pipe, you should also trap SIGPIPE. Otherwise, think of what happens when you start up a pipe to a command that doesn't exist: the open() will in all likelihood succeed (it only reflects the fork()'s success), but then your output will fail–spectacularly. Perl can't know whether the command worked because your command is actually running in a separate process whose exec() might have failed. Therefore, while readers of bogus commands return just a quick end of file, writers to bogus command will trigger a signal they'd better be prepared to handle. Consider:

```
open(FH, "|bogus")  or die "can't fork: $!";
print FH "bang\n"   or die "can't write: $!";
close FH            or die "can't close: $!";
```

That won't blow up until the close, and it will blow up with a SIGPIPE. To catch it, you could use this:

```
$SIG{PIPE} = 'IGNORE';
open(FH, "|bogus")  or die "can't fork: $!";
print FH "bang\n"   or die "can't write: $!";
close FH            or die "can't close: status=$?";
```

Filehandles

Both the main process and any child processes it forks share the same STDIN, STDOUT, and STDERR filehandles. If both processes try to access them at once, strange things can happen. You may also want to close or reopen the filehandles for the child. You can get around this by opening your pipe with open(), but on some systems this means that the child process cannot outlive the parent.

Background Processes

You can run a command in the background with:

```
    system("cmd &");
```

The command's STDOUT and STDERR (and possibly STDIN, depending on your shell) will be the same as the parent's. You won't need to catch SIGCHLD because of the double-fork taking place (see below for more details).

Complete Dissociation of Child from Parent

In some cases (starting server processes, for instance) you'll want to completely dissociate the child process from the parent. This is often called daemonization. A well behaved daemon will also chdir() to the root directory (so it doesn't prevent unmounting the filesystem containing the directory from which it was launched) and redirect its standard file descriptors from and to */dev/null* (so that random output doesn't wind up on the user's terminal).

```
    use POSIX 'setsid';

    sub daemonize {
        chdir '/'               or die "Can't chdir to /: $!";
        open STDIN, '/dev/null' or die "Can't read /dev/null: $!";
        open STDOUT, '>/dev/null'
                                or die "Can't write to /dev/null: $!";
        defined(my $pid = fork) or die "Can't fork: $!";
        exit if $pid;
        setsid                  or die "Can't start a new session: $!";
        open STDERR, '>&STDOUT' or die "Can't dup stdout: $!";
    }
```

The fork() has to come before the setsid() to ensure that you aren't a process group leader (the setsid() will fail if you are). If your system doesn't have the setsid() function, open */dev/tty* and use the `TIOCNOTTY` ioctl() on it instead. See *tty*(4) for details.

Non-Unix users should check their Your_OS::Process module for other solutions.

Safe Pipe Opens

Another interesting approach to IPC is making your single program go multiprocess and communicate between (or even amongst) yourselves. The open() function will accept a file argument of either `"-|"` or `"|-"` to do a very interesting thing: it forks a child connected to the filehandle you've opened. The child is running the same program as the parent. This is useful for safely opening a file when running under an assumed UID or GID, for example. If you open a pipe *to* minus, you can write to the filehandle you opened and your kid will find it in his STDIN. If you open a pipe *from* minus, you can read from the filehandle you opened whatever your kid writes to his STDOUT.

```
    use English '-no_match_vars';
    my $sleep_count = 0;
    do {
        $pid = open(KID_TO_WRITE, "|-");
        unless (defined $pid) {
            warn "cannot fork: $!";
            die "bailing out" if $sleep_count++ > 6;
            sleep 10;
        }
    } until defined $pid;

    if ($pid) {  # parent
        print KID_TO_WRITE @some_data;
        close(KID_TO_WRITE) || warn "kid exited $?";
    } else {     # child
        ($EUID, $EGID) = ($UID, $GID); # suid progs only
        open (FILE, "> /safe/file")
            || die "can't open /safe/file: $!";
        while (<STDIN>) {
            print FILE; # child's STDIN is parent's KID
        }
        exit;  # don't forget this
    }
```

Another common use for this construct is when you need to execute something without the shell's interference. With system(), it's straightforward, but you can't use a pipe open or backticks safely. That's because there's no way to stop the shell from getting its hands on your arguments. Instead, use lower-level control to call exec() directly.

Here's a safe backtick or pipe open for read:

```
    # add error processing as above
    $pid = open(KID_TO_READ, "-|");

    if ($pid) {   # parent
        while (<KID_TO_READ>) {
            # do something interesting
        }
        close(KID_TO_READ) || warn "kid exited $?";

    } else {      # child
        ($EUID, $EGID) = ($UID, $GID); # suid only
        exec($program, @options, @args)
            || die "can't exec program: $!";
        # NOTREACHED
    }
```

And here's a safe pipe open for writing:

```
    # add error processing as above
    $pid = open(KID_TO_WRITE, "|-");
    $SIG{PIPE} = sub { die "whoops, $program pipe broke" };

    if ($pid) {  # parent
        for (@data) {
            print KID_TO_WRITE;
        }
        close(KID_TO_WRITE) || warn "kid exited $?";
    } else {     # child
        ($EUID, $EGID) = ($UID, $GID);
        exec($program, @options, @args)
            || die "can't exec program: $!";
        # NOTREACHED
    }
```

Since Perl 5.8.0, you can also use the list form of `open` for pipes : the syntax

```
    open KID_PS, "-|", "ps", "aux" or die $!;
```

forks the ps(1) command (without spawning a shell, as there are more than three arguments to open()), and reads its standard output via the `KID_PS` filehandle. The corresponding syntax to read from command pipes (with `"|-"` in place of `"-|"`) is also implemented.

Note that these operations are full Unix forks, which means they may not be correctly implemented on alien systems. Additionally, these are not true multithreading. If you'd like to learn more about threading, see the *modules* file mentioned below in the SEE ALSO section.

Bidirectional Communication with Another Process

While this works reasonably well for unidirectional communication, what about bidirectional communication? The obvious thing you'd like to do doesn't actually work:

```
    open(PROG_FOR_READING_AND_WRITING, "| some program |")
```

and if you forget to use the `use warnings` pragma or the **-w** flag, then you'll miss out entirely on the diagnostic message:

```
    Can't do bidirectional pipe at -e line 1.
```

If you really want to, you can use the standard open2() library function to catch both ends. There's also an open3() for tridirectional I/O so you can also catch your child's STDERR, but doing so would then require an awkward select() loop and wouldn't allow you to use normal Perl input operations.

If you look at its source, you'll see that open2() uses low-level primitives like Unix pipe() and exec() calls to create all the connections. While it might have been slightly more efficient by using socketpair(), it would have then been even less portable than it already is. The open2() and open3() functions are unlikely to work anywhere except on a Unix system or some other one purporting to be POSIX compliant.

Here's an example of using open2():

```
    use FileHandle;
    use IPC::Open2;
    $pid = open2(*Reader, *Writer, "cat -u -n" );
    print Writer "stuff\n";
    $got = <Reader>;
```

The problem with this is that Unix buffering is really going to ruin your day. Even though your `Writer` filehandle is auto-flushed, and the process on the other end will get your data in a timely manner, you can't usually do anything to force it to give it back to you in a similarly quick fashion. In this case, we could, because we gave *cat* a **-u** flag to make it unbuffered. But very few Unix commands are designed to operate over pipes, so this seldom works unless you yourself wrote the program on the other end of the double-ended pipe.

A solution to this is the nonstandard *Comm.pl* library. It uses pseudo-ttys to make your program behave more reasonably:

```
require 'Comm.pl';
$ph = open_proc('cat -n');
for (1..10) {
    print $ph "a line\n";
    print "got back ", scalar <$ph>;
}
```

This way you don't have to have control over the source code of the program you're using. The *Comm* library also has expect() and interact() functions. Find the library (and we hope its successor *IPC::Chat*) at your nearest CPAN archive as detailed in the SEE ALSO section below.

The newer Expect.pm module from CPAN also addresses this kind of thing. This module requires two other modules from CPAN: IO::Pty and IO::Stty. It sets up a pseudo-terminal to interact with programs that insist on using talking to the terminal device driver. If your system is amongst those supported, this may be your best bet.

Bidirectional Communication with Yourself

If you want, you may make low-level pipe() and fork() to stitch this together by hand. This example only talks to itself, but you could reopen the appropriate handles to STDIN and STDOUT and call other processes.

```
#!/usr/bin/perl -w
# pipe1 - bidirectional communication using two pipe pairs
#         designed for the socketpair-challenged
use IO::Handle;     # thousands of lines just for autoflush :-(
pipe(PARENT_RDR, CHILD_WTR);               # XXX: failure?
pipe(CHILD_RDR,  PARENT_WTR);              # XXX: failure?
CHILD_WTR->autoflush(1);
PARENT_WTR->autoflush(1);

if ($pid = fork) {
    close PARENT_RDR; close PARENT_WTR;
    print CHILD_WTR "Parent Pid $$ is sending this\n";
    chomp($line = <CHILD_RDR>);
    print "Parent Pid $$ just read this: `$line'\n";
    close CHILD_RDR; close CHILD_WTR;
    waitpid($pid,0);
} else {
    die "cannot fork: $!" unless defined $pid;
    close CHILD_RDR; close CHILD_WTR;
    chomp($line = <PARENT_RDR>);
    print "Child Pid $$ just read this: `$line'\n";
    print PARENT_WTR "Child Pid $$ is sending this\n";
    close PARENT_RDR; close PARENT_WTR;
    exit;
}
```

But you don't actually have to make two pipe calls. If you have the socketpair() system call, it will do this all for you.

```
#!/usr/bin/perl -w
# pipe2 - bidirectional communication using socketpair
#   "the best ones always go both ways"

use Socket;
use IO::Handle;     # thousands of lines just for autoflush :-(
# We say AF_UNIX because although *_LOCAL is the
# POSIX 1003.1g form of the constant, many machines
# still don't have it.
socketpair(CHILD, PARENT, AF_UNIX, SOCK_STREAM, PF_UNSPEC)
                            or  die "socketpair: $!";
```

```
    CHILD->autoflush(1);
    PARENT->autoflush(1);

    if ($pid = fork) {
        close PARENT;
        print CHILD "Parent Pid $$ is sending this\n";
        chomp($line = <CHILD>);
        print "Parent Pid $$ just read this: ‘$line’\n";
        close CHILD;
        waitpid($pid,0);
    } else {
        die "cannot fork: $!" unless defined $pid;
        close CHILD;
        chomp($line = <PARENT>);
        print "Child Pid $$ just read this: ‘$line’\n";
        print PARENT "Child Pid $$ is sending this\n";
        close PARENT;
        exit;
    }
```

47.3.2 Sockets: Client/Server Communication

While not limited to Unix-derived operating systems (e.g., WinSock on PCs provides socket support, as do some VMS libraries), you may not have sockets on your system, in which case this section probably isn't going to do you much good. With sockets, you can do both virtual circuits (i.e., TCP streams) and datagrams (i.e., UDP packets). You may be able to do even more depending on your system.

The Perl function calls for dealing with sockets have the same names as the corresponding system calls in C, but their arguments tend to differ for two reasons: first, Perl filehandles work differently than C file descriptors. Second, Perl already knows the length of its strings, so you don't need to pass that information.

One of the major problems with old socket code in Perl was that it used hard-coded values for some of the constants, which severely hurt portability. If you ever see code that does anything like explicitly setting `$AF_INET = 2`, you know you're in for big trouble: An immeasurably superior approach is to use the `Socket` module, which more reliably grants access to various constants and functions you'll need.

If you're not writing a server/client for an existing protocol like NNTP or SMTP, you should give some thought to how your server will know when the client has finished talking, and vice-versa. Most protocols are based on one-line messages and responses (so one party knows the other has finished when a "\n" is received) or multi-line messages and responses that end with a period on an empty line ("\n.\n" terminates a message/response).

Internet Line Terminators

The Internet line terminator is "\015\012". Under ASCII variants of Unix, that could usually be written as "\r\n", but under other systems, "\r\n" might at times be "\015\015\012", "\012\012\015", or something completely different. The standards specify writing "\015\012" to be conformant (be strict in what you provide), but they also recommend accepting a lone "\012" on input (but be lenient in what you require). We haven't always been very good about that in the code in this manpage, but unless you're on a Mac, you'll probably be ok.

Internet TCP Clients and Servers

Use Internet-domain sockets when you want to do client-server communication that might extend to machines outside of your own system.

Here's a sample TCP client using Internet-domain sockets:

```
#!/usr/bin/perl -w
use strict;
use Socket;
my ($remote,$port, $iaddr, $paddr, $proto, $line);

$remote  = shift || 'localhost';
$port    = shift || 2345;  # random port
if ($port =~ /\D/) { $port = getservbyname($port, 'tcp') }
die "No port" unless $port;
$iaddr   = inet_aton($remote)               || die "no host: $remote";
$paddr   = sockaddr_in($port, $iaddr);

$proto   = getprotobyname('tcp');
socket(SOCK, PF_INET, SOCK_STREAM, $proto)  || die "socket: $!";
connect(SOCK, $paddr)    || die "connect: $!";
while (defined($line = <SOCK>)) {
    print $line;
}

close (SOCK)            || die "close: $!";
exit;
```

And here's a corresponding server to go along with it. We'll leave the address as INADDR_ANY so that the kernel can choose the appropriate interface on multihomed hosts. If you want sit on a particular interface (like the external side of a gateway or firewall machine), you should fill this in with your real address instead.

```
#!/usr/bin/perl -Tw
use strict;
BEGIN { $ENV{PATH} = '/usr/ucb:/bin' }
use Socket;
use Carp;
my $EOL = "\015\012";

sub logmsg { print "$0 $$: @_ at ", scalar localtime, "\n" }

my $port = shift || 2345;
my $proto = getprotobyname('tcp');

($port) = $port =~ /^(\d+)$/                        or die "invalid port";

socket(Server, PF_INET, SOCK_STREAM, $proto)        || die "socket: $!";
setsockopt(Server, SOL_SOCKET, SO_REUSEADDR,
                                    pack("l", 1))   || die "setsockopt: $!";
bind(Server, sockaddr_in($port, INADDR_ANY))        || die "bind: $!";
listen(Server,SOMAXCONN)                            || die "listen: $!";

logmsg "server started on port $port";

my $paddr;

$SIG{CHLD} = \&REAPER;

for ( ; $paddr = accept(Client,Server); close Client) {
    my($port,$iaddr) = sockaddr_in($paddr);
    my $name = gethostbyaddr($iaddr,AF_INET);
```

```
        logmsg "connection from $name [",
                inet_ntoa($iaddr), "]
                at port $port";

        print Client "Hello there, $name, it's now ",
                        scalar localtime, $EOL;
    }
```

And here's a multithreaded version. It's multithreaded in that like most typical servers, it spawns (forks) a slave server to handle the client request so that the master server can quickly go back to service a new client.

```
    #!/usr/bin/perl -Tw
    use strict;
    BEGIN { $ENV{PATH} = '/usr/ucb:/bin' }
    use Socket;
    use Carp;
    my $EOL = "\015\012";

    sub spawn;  # forward declaration
    sub logmsg { print "$0 $$: @_ at ", scalar localtime, "\n" }

    my $port = shift || 2345;
    my $proto = getprotobyname('tcp');

    ($port) = $port =~ /^(\d+)$/                        or die "invalid port";

    socket(Server, PF_INET, SOCK_STREAM, $proto)        || die "socket: $!";
    setsockopt(Server, SOL_SOCKET, SO_REUSEADDR,
                                    pack("l", 1))   || die "setsockopt: $!";
    bind(Server, sockaddr_in($port, INADDR_ANY))        || die "bind: $!";
    listen(Server,SOMAXCONN)                            || die "listen: $!";

    logmsg "server started on port $port";

    my $waitedpid = 0;
    my $paddr;

    use POSIX ":sys_wait_h";
    sub REAPER {
        my $child;
        while (($waitedpid = waitpid(-1,WNOHANG)) > 0) {
            logmsg "reaped $waitedpid" . ($? ? " with exit $?" : '');
        }
        $SIG{CHLD} = \&REAPER;  # loathe sysV
    }

    $SIG{CHLD} = \&REAPER;

    for ( $waitedpid = 0;
          ($paddr = accept(Client,Server)) || $waitedpid;
          $waitedpid = 0, close Client)
    {
        next if $waitedpid and not $paddr;
        my($port,$iaddr) = sockaddr_in($paddr);
        my $name = gethostbyaddr($iaddr,AF_INET);
        logmsg "connection from $name [",
                inet_ntoa($iaddr), "]
                at port $port";

        spawn sub {
            $|=1;
            print "Hello there, $name, it's now ", scalar localtime, $EOL;
            exec '/usr/games/fortune'           # XXX: `wrong' line terminators
                or confess "can't exec fortune: $!";
        };

    }

    sub spawn {
        my $coderef = shift;

        unless (@_ == 0 && $coderef && ref($coderef) eq 'CODE') {
            confess "usage: spawn CODEREF";
        }

        my $pid;
        if (!defined($pid = fork)) {
            logmsg "cannot fork: $!";
            return;
        } elsif ($pid) {
            logmsg "begat $pid";
            return; # I'm the parent
        }
        # else I'm the child -- go spawn

        open(STDIN,  "<&Client")   || die "can't dup client to stdin";
        open(STDOUT, ">&Client")   || die "can't dup client to stdout";
        ## open(STDERR, ">&STDOUT") || die "can't dup stdout to stderr";
        exit &$coderef();
    }
```

This server takes the trouble to clone off a child version via fork() for each incoming request. That way it can handle many requests at once, which you might not always want. Even if you don't fork(), the listen() will allow that many pending connections. Forking servers have to be particularly careful about cleaning up their dead children (called "zombies" in Unix parlance), because otherwise you'll quickly fill up your process table.

We suggest that you use the **-T** flag to use taint checking (see *perlsec*) even if we aren't running setuid or setgid. This is always a good idea for servers and other programs run on behalf of someone else (like CGI scripts), because it lessens the chances that people from the outside will be able to compromise your system.

Let's look at another TCP client. This one connects to the TCP "time" service on a number of different machines and shows how far their clocks differ from the system on which it's being run:

```
    #!/usr/bin/perl  -w
    use strict;
    use Socket;

    my $SECS_of_70_YEARS = 2208988800;
    sub ctime { scalar localtime(shift) }
    my $iaddr = gethostbyname('localhost');
    my $proto = getprotobyname('tcp');
    my $port = getservbyname('time', 'tcp');
    my $paddr = sockaddr_in(0, $iaddr);
    my($host);

    $| = 1;
    printf "%-24s %8s %s\n",  "localhost", 0, ctime(time());

    foreach $host (@ARGV) {
        printf "%-24s ", $host;
        my $hisiaddr = inet_aton($host)     || die "unknown host";
        my $hispaddr = sockaddr_in($port, $hisiaddr);
        socket(SOCKET, PF_INET, SOCK_STREAM, $proto)   || die "socket: $!";
        connect(SOCKET, $hispaddr)          || die "bind: $!";
        my $rtime = '    ';
        read(SOCKET, $rtime, 4);
        close(SOCKET);
        my $histime = unpack("N", $rtime) - $SECS_of_70_YEARS ;
        printf "%8d %s\n", $histime - time, ctime($histime);
    }
```

Unix-Domain TCP Clients and Servers

That's fine for Internet-domain clients and servers, but what about local communications? While you can use the same setup, sometimes you don't want to. Unix-domain sockets are local to the current host, and are often used internally to implement pipes. Unlike Internet domain sockets, Unix domain sockets can show up in the file system with an ls(1) listing.

```
    % ls -l /dev/log
    srw-rw-rw-  1 root            0 Oct 31 07:23 /dev/log
```

You can test for these with Perl's **-S** file test:

```
    unless ( -S '/dev/log' ) {
        die "something's wicked with the log system";
    }
```

Here's a sample Unix-domain client:

```
    #!/usr/bin/perl -w
    use Socket;
    use strict;
    my ($rendezvous, $line);

    $rendezvous = shift || 'catsock';
    socket(SOCK, PF_UNIX, SOCK_STREAM, 0)       || die "socket: $!";
    connect(SOCK, sockaddr_un($rendezvous))     || die "connect: $!";
    while (defined($line = <SOCK>)) {
        print $line;
    }
    exit;
```

And here's a corresponding server. You don't have to worry about silly network terminators here because Unix domain sockets are guaranteed to be on the localhost, and thus everything works right.

```
#!/usr/bin/perl -Tw
use strict;
use Socket;
use Carp;

BEGIN { $ENV{PATH} = '/usr/ucb:/bin' }
sub spawn;  # forward declaration
sub logmsg { print "$0 $$: @_ at ", scalar localtime, "\n" }

my $NAME = 'catsock';
my $uaddr = sockaddr_un($NAME);
my $proto = getprotobyname('tcp');

socket(Server,PF_UNIX,SOCK_STREAM,0)        || die "socket: $!";
unlink($NAME);
bind  (Server, $uaddr)                      || die "bind: $!";
listen(Server,SOMAXCONN)                    || die "listen: $!";

logmsg "server started on $NAME";

my $waitedpid;

use POSIX ":sys_wait_h";
sub REAPER {
    my $child;
    while (($waitedpid = waitpid(-1,WNOHANG)) > 0) {
        logmsg "reaped $waitedpid" . ($? ? " with exit $?" : '');
    }
    $SIG{CHLD} = \&REAPER;  # loathe sysV
}

$SIG{CHLD} = \&REAPER;

for ( $waitedpid = 0;
      accept(Client,Server) || $waitedpid;
      $waitedpid = 0, close Client)
{
    next if $waitedpid;
    logmsg "connection on $NAME";
    spawn sub {
        print "Hello there, it's now ", scalar localtime, "\n";
        exec '/usr/games/fortune' or die "can't exec fortune: $!";
    };
}

sub spawn {
    my $coderef = shift;

    unless (@_ == 0 && $coderef && ref($coderef) eq 'CODE') {
        confess "usage: spawn CODEREF";
    }
```

```
        my $pid;
        if (!defined($pid = fork)) {
            logmsg "cannot fork: $!";
            return;
        } elsif ($pid) {
            logmsg "begat $pid";
            return; # I'm the parent
        }
        # else I'm the child -- go spawn

        open(STDIN,  "<&Client")   || die "can't dup client to stdin";
        open(STDOUT, ">&Client")   || die "can't dup client to stdout";
        ## open(STDERR, ">&STDOUT") || die "can't dup stdout to stderr";
        exit &$coderef();
    }
```

As you see, it's remarkably similar to the Internet domain TCP server, so much so, in fact, that we've omitted several duplicate functions–spawn(), logmsg(), ctime(), and REAPER()–which are exactly the same as in the other server.

So why would you ever want to use a Unix domain socket instead of a simpler named pipe? Because a named pipe doesn't give you sessions. You can't tell one process's data from another's. With socket programming, you get a separate session for each client: that's why accept() takes two arguments.

For example, let's say that you have a long running database server daemon that you want folks from the World Wide Web to be able to access, but only if they go through a CGI interface. You'd have a small, simple CGI program that does whatever checks and logging you feel like, and then acts as a Unix-domain client and connects to your private server.

47.3.3 TCP Clients with IO::Socket

For those preferring a higher-level interface to socket programming, the IO::Socket module provides an object-oriented approach. IO::Socket is included as part of the standard Perl distribution as of the 5.004 release. If you're running an earlier version of Perl, just fetch IO::Socket from CPAN, where you'll also find modules providing easy interfaces to the following systems: DNS, FTP, Ident (RFC 931), NIS and NISPlus, NNTP, Ping, POP3, SMTP, SNMP, SSLeay, Telnet, and Time–just to name a few.

A Simple Client

Here's a client that creates a TCP connection to the "daytime" service at port 13 of the host name "localhost" and prints out everything that the server there cares to provide.

```
    #!/usr/bin/perl -w
    use IO::Socket;
    $remote = IO::Socket::INET->new(
                        Proto    => "tcp",
                        PeerAddr => "localhost",
                        PeerPort => "daytime(13)",
                    )
                  or die "cannot connect to daytime port at localhost";
    while ( <$remote> ) { print }
```

When you run this program, you should get something back that looks like this:

```
    Wed May 14 08:40:46 MDT 1997
```

Here are what those parameters to the `new` constructor mean:

`Proto`

This is which protocol to use. In this case, the socket handle returned will be connected to a TCP socket, because we want a stream-oriented connection, that is, one that acts pretty much like a plain old file. Not all sockets are this of this type. For example, the UDP protocol can be used to make a datagram socket, used for message-passing.

`PeerAddr`

This is the name or Internet address of the remote host the server is running on. We could have specified a longer name like `"www.perl.com"`, or an address like `"204.148.40.9"`. For demonstration purposes, we've used the special hostname `"localhost"`, which should always mean the current machine you're running on. The corresponding Internet address for localhost is `"127.1"`, if you'd rather use that.

`PeerPort`

This is the service name or port number we'd like to connect to. We could have gotten away with using just `"daytime"` on systems with a well-configured system services file,[FOOTNOTE: The system services file is in */etc/services* under Unix] but just in case, we've specified the port number (13) in parentheses. Using just the number would also have worked, but constant numbers make careful programmers nervous.

Notice how the return value from the `new` constructor is used as a filehandle in the `while` loop? That's what's called an indirect filehandle, a scalar variable containing a filehandle. You can use it the same way you would a normal filehandle. For example, you can read one line from it this way:

```
    $line = <$handle>;
```

all remaining lines from is this way:

```
    @lines = <$handle>;
```

and send a line of data to it this way:

```
    print $handle "some data\n";
```

A Webget Client

Here's a simple client that takes a remote host to fetch a document from, and then a list of documents to get from that host. This is a more interesting client than the previous one because it first sends something to the server before fetching the server's response.

```
    #!/usr/bin/perl -w
    use IO::Socket;
    unless (@ARGV > 1) { die "usage: $0 host document ..." }
    $host = shift(@ARGV);
    $EOL = "\015\012";
    $BLANK = $EOL x 2;
    foreach $document ( @ARGV ) {
        $remote = IO::Socket::INET->new( Proto     => "tcp",
                                         PeerAddr  => $host,
                                         PeerPort  => "http(80)",
                                       );
        unless ($remote) { die "cannot connect to http daemon on $host" }
        $remote->autoflush(1);
        print $remote "GET $document HTTP/1.0" . $BLANK;
        while ( <$remote> ) { print }
        close $remote;
    }
```

The web server handing the "http" service, which is assumed to be at its standard port, number 80. If the web server you're trying to connect to is at a different port (like 1080 or 8080), you should specify as the named-parameter pair, `PeerPort => 8080`. The `autoflush` method is used on the socket because otherwise the system would buffer up the output we sent it. (If you're on a Mac, you'll also need to change every `"\n"` in your code that sends data over the network to be a `"\015\012"` instead.)

Connecting to the server is only the first part of the process: once you have the connection, you have to use the server's language. Each server on the network has its own little command language that it expects as input. The string that we send to the server starting with "GET" is in HTTP syntax. In this case, we simply request each specified document. Yes, we really are making a new connection for each document, even though it's the same host. That's the way you always used to have to speak HTTP. Recent versions of web browsers may request that the remote server leave the connection open a little while, but the server doesn't have to honor such a request.

Here's an example of running that program, which we'll call *webget*:

```
% webget www.perl.com /guanaco.html
HTTP/1.1 404 File Not Found
Date: Thu, 08 May 1997 18:02:32 GMT
Server: Apache/1.2b6
Connection: close
Content-type: text/html

<HEAD><TITLE>404 File Not Found</TITLE></HEAD>
<BODY><H1>File Not Found</H1>
The requested URL /guanaco.html was not found on this server.<P>
</BODY>
```

Ok, so that's not very interesting, because it didn't find that particular document. But a long response wouldn't have fit on this page.

For a more fully-featured version of this program, you should look to the *lwp-request* program included with the LWP modules from CPAN.

Interactive Client with IO::Socket

Well, that's all fine if you want to send one command and get one answer, but what about setting up something fully interactive, somewhat like the way *telnet* works? That way you can type a line, get the answer, type a line, get the answer, etc.

This client is more complicated than the two we've done so far, but if you're on a system that supports the powerful `fork` call, the solution isn't that rough. Once you've made the connection to whatever service you'd like to chat with, call `fork` to clone your process. Each of these two identical process has a very simple job to do: the parent copies everything from the socket to standard output, while the child simultaneously copies everything from standard input to the socket. To accomplish the same thing using just one process would be *much* harder, because it's easier to code two processes to do one thing than it is to code one process to do two things. (This keep-it-simple principle a cornerstones of the Unix philosophy, and good software engineering as well, which is probably why it's spread to other systems.)

Here's the code:

```
#!/usr/bin/perl -w
use strict;
use IO::Socket;
my ($host, $port, $kidpid, $handle, $line);

unless (@ARGV == 2) { die "usage: $0 host port" }
($host, $port) = @ARGV;
```

```
    # create a tcp connection to the specified host and port
    $handle = IO::Socket::INET->new(Proto     => "tcp",
                                    PeerAddr  => $host,
                                    PeerPort  => $port)
           or die "can't connect to port $port on $host: $!";

    $handle->autoflush(1);              # so output gets there right away
    print STDERR "[Connected to $host:$port]\n";

    # split the program into two processes, identical twins
    die "can't fork: $!" unless defined($kidpid = fork());

    # the if{} block runs only in the parent process
    if ($kidpid) {
        # copy the socket to standard output
        while (defined ($line = <$handle>)) {
            print STDOUT $line;
        }
        kill("TERM", $kidpid);                  # send SIGTERM to child
    }
    # the else{} block runs only in the child process
    else {
        # copy standard input to the socket
        while (defined ($line = <STDIN>)) {
            print $handle $line;
        }
    }
```

The `kill` function in the parent's `if` block is there to send a signal to our child process (current running in the `else` block) as soon as the remote server has closed its end of the connection.

If the remote server sends data a byte at time, and you need that data immediately without waiting for a newline (which might not happen), you may wish to replace the `while` loop in the parent with the following:

```
    my $byte;
    while (sysread($handle, $byte, 1) == 1) {
        print STDOUT $byte;
    }
```

Making a system call for each byte you want to read is not very efficient (to put it mildly) but is the simplest to explain and works reasonably well.

47.3.4 TCP Servers with IO::Socket

As always, setting up a server is little bit more involved than running a client. The model is that the server creates a special kind of socket that does nothing but listen on a particular port for incoming connections. It does this by calling the `IO::Socket::INET->new()` method with slightly different arguments than the client did.

Proto

This is which protocol to use. Like our clients, we'll still specify `"tcp"` here.

LocalPort

We specify a local port in the `LocalPort` argument, which we didn't do for the client. This is service name or port number for which you want to be the server. (Under Unix, ports under 1024 are restricted to the superuser.) In our sample, we'll use port 9000, but you can use any port that's not currently in use on your system. If you try to use one already in used, you'll get an "Address already in use" message. Under Unix, the `netstat -a` command will show which services current have servers.

Listen

The `Listen` parameter is set to the maximum number of pending connections we can accept until we turn away incoming clients. Think of it as a call-waiting queue for your telephone. The low-level Socket module has a special symbol for the system maximum, which is SOMAXCONN.

Reuse

The `Reuse` parameter is needed so that we restart our server manually without waiting a few minutes to allow system buffers to clear out.

Once the generic server socket has been created using the parameters listed above, the server then waits for a new client to connect to it. The server blocks in the `accept` method, which eventually accepts a bidirectional connection from the remote client. (Make sure to autoflush this handle to circumvent buffering.)

To add to user-friendliness, our server prompts the user for commands. Most servers don't do this. Because of the prompt without a newline, you'll have to use the `sysread` variant of the interactive client above.

This server accepts one of five different commands, sending output back to the client. Note that unlike most network servers, this one only handles one incoming client at a time. Multithreaded servers are covered in Chapter 6 of the Camel.

Here's the code. We'll

```
#!/usr/bin/perl -w
use IO::Socket;
use Net::hostent;              # for OO version of gethostbyaddr

$PORT = 9000;                  # pick something not in use

$server = IO::Socket::INET->new( Proto     => 'tcp',
                                 LocalPort => $PORT,
                                 Listen    => SOMAXCONN,
                                 Reuse     => 1);

die "can't setup server" unless $server;
print "[Server $0 accepting clients]\n";

while ($client = $server->accept()) {
  $client->autoflush(1);
  print $client "Welcome to $0; type help for command list.\n";
  $hostinfo = gethostbyaddr($client->peeraddr);
  printf "[Connect from %s]\n", $hostinfo ? $hostinfo->name : $client->peerhost;
  print $client "Command? ";
  while ( <$client>) {
    next unless /\S/;       # blank line
    if    (/quit|exit/i)    { last;                                   }
    elsif (/date|time/i)    { printf $client "%s\n", scalar localtime;  }
    elsif (/who/i )         { print  $client `who 2>&1`;              }
    elsif (/cookie/i )      { print  $client `/usr/games/fortune 2>&1`; }
    elsif (/motd/i )        { print  $client `cat /etc/motd 2>&1`;      }
    else {
      print $client "Commands: quit date who cookie motd\n";
    }
  } continue {
     print $client "Command? ";
  }
  close $client;
}
```

47.3.5 UDP: Message Passing

Another kind of client-server setup is one that uses not connections, but messages. UDP communications involve much lower overhead but also provide less reliability, as there are no promises that messages will arrive at all, let alone in order and unmangled. Still, UDP offers some advantages over TCP, including being able to "broadcast" or "multicast" to a whole bunch of destination hosts at once (usually on your local subnet). If you find yourself overly concerned about reliability and start building checks into your message system, then you probably should use just TCP to start with.

Note that UDP datagrams are *not* a bytestream and should not be treated as such. This makes using I/O mechanisms with internal buffering like stdio (i.e. print() and friends) especially cumbersome. Use syswrite(), or better send(), like in the example below.

Here's a UDP program similar to the sample Internet TCP client given earlier. However, instead of checking one host at a time, the UDP version will check many of them asynchronously by simulating a multicast and then using select() to do a timed-out wait for I/O. To do something similar with TCP, you'd have to use a different socket handle for each host.

```
#!/usr/bin/perl -w
use strict;
use Socket;
use Sys::Hostname;

my ( $count, $hisiaddr, $hispaddr, $histime,
     $host, $iaddr, $paddr, $port, $proto,
     $rin, $rout, $rtime, $SECS_of_70_YEARS);

$SECS_of_70_YEARS      = 2208988800;

$iaddr = gethostbyname(hostname());
$proto = getprotobyname('udp');
$port = getservbyname('time', 'udp');
$paddr = sockaddr_in(0, $iaddr); # 0 means let kernel pick

socket(SOCKET, PF_INET, SOCK_DGRAM, $proto)   || die "socket: $!";
bind(SOCKET, $paddr)                          || die "bind: $!";

$| = 1;
printf "%-12s %8s %s\n",  "localhost", 0, scalar localtime time;
$count = 0;
for $host (@ARGV) {
    $count++;
    $hisiaddr = inet_aton($host)    || die "unknown host";
    $hispaddr = sockaddr_in($port, $hisiaddr);
    defined(send(SOCKET, 0, 0, $hispaddr))    || die "send $host: $!";
}

$rin = '';
vec($rin, fileno(SOCKET), 1) = 1;

# timeout after 10.0 seconds
while ($count && select($rout = $rin, undef, undef, 10.0)) {
    $rtime = '';
    ($hispaddr = recv(SOCKET, $rtime, 4, 0))        || die "recv: $!";
    ($port, $hisiaddr) = sockaddr_in($hispaddr);
    $host = gethostbyaddr($hisiaddr, AF_INET);
    $histime = unpack("N", $rtime) - $SECS_of_70_YEARS ;
    printf "%-12s ", $host;
    printf "%8d %s\n", $histime - time, scalar localtime($histime);
    $count--;
}
```

Note that this example does not include any retries and may consequently fail to contact a reachable host. The most prominent reason for this is congestion of the queues on the sending host if the number of list of hosts to contact is sufficiently large.

47.3.6 SysV IPC

While System V IPC isn't so widely used as sockets, it still has some interesting uses. You can't, however, effectively use SysV IPC or Berkeley mmap() to have shared memory so as to share a variable amongst several processes. That's because Perl would reallocate your string when you weren't wanting it to.

Here's a small example showing shared memory usage.

```
use IPC::SysV qw(IPC_PRIVATE IPC_RMID S_IRWXU);

$size = 2000;
$id = shmget(IPC_PRIVATE, $size, S_IRWXU) || die "$!";
print "shm key $id\n";

$message = "Message #1";
shmwrite($id, $message, 0, 60) || die "$!";
print "wrote: '$message'\n";
shmread($id, $buff, 0, 60) || die "$!";
print "read : '$buff'\n";

# the buffer of shmread is zero-character end-padded.
substr($buff, index($buff, "\0")) = '';
print "un" unless $buff eq $message;
print "swell\n";

print "deleting shm $id\n";
shmctl($id, IPC_RMID, 0) || die "$!";
```

Here's an example of a semaphore:

```
use IPC::SysV qw(IPC_CREAT);

$IPC_KEY = 1234;
$id = semget($IPC_KEY, 10, 0666 | IPC_CREAT ) || die "$!";
print "shm key $id\n";
```

Put this code in a separate file to be run in more than one process. Call the file *take*:

```
# create a semaphore

$IPC_KEY = 1234;
$id = semget($IPC_KEY,  0 , 0 );
die if !defined($id);

$semnum = 0;
$semflag = 0;

# 'take' semaphore
# wait for semaphore to be zero
$semop = 0;
$opstring1 = pack("s!s!s!", $semnum, $semop, $semflag);

# Increment the semaphore count
$semop = 1;
$opstring2 = pack("s!s!s!", $semnum, $semop,  $semflag);
$opstring = $opstring1 . $opstring2;
```

```
    semop($id,$opstring) || die "$!";
```

Put this code in a separate file to be run in more than one process. Call this file *give*:

```
    # 'give' the semaphore
    # run this in the original process and you will see
    # that the second process continues

    $IPC_KEY = 1234;
    $id = semget($IPC_KEY, 0, 0);
    die if !defined($id);

    $semnum = 0;
    $semflag = 0;

    # Decrement the semaphore count
    $semop = -1;
    $opstring = pack("s!s!s!", $semnum, $semop, $semflag);

    semop($id,$opstring) || die "$!";
```

The SysV IPC code above was written long ago, and it's definitely clunky looking. For a more modern look, see the IPC::SysV module which is included with Perl starting from Perl 5.005.

A small example demonstrating SysV message queues:

```
    use IPC::SysV qw(IPC_PRIVATE IPC_RMID IPC_CREAT S_IRWXU);

    my $id = msgget(IPC_PRIVATE, IPC_CREAT | S_IRWXU);

    my $sent = "message";
    my $type_sent = 1234;
    my $rcvd;
    my $type_rcvd;

    if (defined $id) {
        if (msgsnd($id, pack("l! a*", $type_sent, $sent), 0)) {
            if (msgrcv($id, $rcvd, 60, 0, 0)) {
                ($type_rcvd, $rcvd) = unpack("l! a*", $rcvd);
                if ($rcvd eq $sent) {
                    print "okay\n";
                } else {
                    print "not okay\n";
                }
            } else {
                die "# msgrcv failed\n";
            }
        } else {
            die "# msgsnd failed\n";
        }
        msgctl($id, IPC_RMID, 0) || die "# msgctl failed: $!\n";
    } else {
        die "# msgget failed\n";
    }
```

47.3.7 NOTES

Most of these routines quietly but politely return `undef` when they fail instead of causing your program to die right then and there due to an uncaught exception. (Actually, some of the new *Socket* conversion functions croak() on bad arguments.) It is therefore essential to check return values from these functions. Always begin your socket programs this way for optimal success, and don't forget to add **-T** taint checking flag to the #! line for servers:

```
#!/usr/bin/perl -Tw
use strict;
use sigtrap;
use Socket;
```

47.3.8 BUGS

All these routines create system-specific portability problems. As noted elsewhere, Perl is at the mercy of your C libraries for much of its system behaviour. It's probably safest to assume broken SysV semantics for signals and to stick with simple TCP and UDP socket operations; e.g., don't try to pass open file descriptors over a local UDP datagram socket if you want your code to stand a chance of being portable.

47.3.9 AUTHOR

Tom Christiansen, with occasional vestiges of Larry Wall's original version and suggestions from the Perl Porters.

47.3.10 SEE ALSO

There's a lot more to networking than this, but this should get you started.

For intrepid programmers, the indispensable textbook is *Unix Network Programming, 2nd Edition, Volume 1* by W. Richard Stevens (published by Prentice-Hall). Note that most books on networking address the subject from the perspective of a C programmer; translation to Perl is left as an exercise for the reader.

The IO::Socket(3) manpage describes the object library, and the Socket(3) manpage describes the low-level interface to sockets. Besides the obvious functions in *perlfunc*, you should also check out the *modules* file at your nearest CPAN site. (See *perlmodlib* or best yet, the *Perl FAQ* for a description of what CPAN is and where to get it.)

Section 5 of the *modules* file is devoted to "Networking, Device Control (modems), and Interprocess Communication", and contains numerous unbundled modules numerous networking modules, Chat and Expect operations, CGI programming, DCE, FTP, IPC, NNTP, Proxy, Ptty, RPC, SNMP, SMTP, Telnet, Threads, and ToolTalk–just to name a few.

Chapter 48

perlfork

Perl's fork() emulation

48.1 SYNOPSIS

```
    NOTE:  As of the 5.8.0 release, fork() emulation has considerably
    matured.  However, there are still a few known bugs and differences
    from real fork() that might affect you.  See the "BUGS" and
    "CAVEATS AND LIMITATIONS" sections below.
```

Perl provides a fork() keyword that corresponds to the Unix system call of the same name. On most Unix-like platforms where the fork() system call is available, Perl's fork() simply calls it.

On some platforms such as Windows where the fork() system call is not available, Perl can be built to emulate fork() at the interpreter level. While the emulation is designed to be as compatible as possible with the real fork() at the level of the Perl program, there are certain important differences that stem from the fact that all the pseudo child "processes" created this way live in the same real process as far as the operating system is concerned.

This document provides a general overview of the capabilities and limitations of the fork() emulation. Note that the issues discussed here are not applicable to platforms where a real fork() is available and Perl has been configured to use it.

48.2 DESCRIPTION

The fork() emulation is implemented at the level of the Perl interpreter. What this means in general is that running fork() will actually clone the running interpreter and all its state, and run the cloned interpreter in a separate thread, beginning execution in the new thread just after the point where the fork() was called in the parent. We will refer to the thread that implements this child "process" as the pseudo-process.

To the Perl program that called fork(), all this is designed to be transparent. The parent returns from the fork() with a pseudo-process ID that can be subsequently used in any process manipulation functions; the child returns from the fork() with a value of `0` to signify that it is the child pseudo-process.

48.2.1 Behavior of other Perl features in forked pseudo-processes

Most Perl features behave in a natural way within pseudo-processes.

$ $ or $ PROCESS_ID

This special variable is correctly set to the pseudo-process ID. It can be used to identify pseudo-processes within a particular session. Note that this value is subject to recycling if any pseudo-processes are launched after others have been wait()-ed on.

%ENV

Each pseudo-process maintains its own virtual environment. Modifications to %ENV affect the virtual environment, and are only visible within that pseudo-process, and in any processes (or pseudo-processes) launched from it.

chdir() and all other builtins that accept filenames

Each pseudo-process maintains its own virtual idea of the current directory. Modifications to the current directory using chdir() are only visible within that pseudo-process, and in any processes (or pseudo-processes) launched from it. All file and directory accesses from the pseudo-process will correctly map the virtual working directory to the real working directory appropriately.

wait() and waitpid()

wait() and waitpid() can be passed a pseudo-process ID returned by fork(). These calls will properly wait for the termination of the pseudo-process and return its status.

kill()

kill() can be used to terminate a pseudo-process by passing it the ID returned by fork(). This should not be used except under dire circumstances, because the operating system may not guarantee integrity of the process resources when a running thread is terminated. Note that using kill() on a pseudo-process() may typically cause memory leaks, because the thread that implements the pseudo-process does not get a chance to clean up its resources.

exec()

Calling exec() within a pseudo-process actually spawns the requested executable in a separate process and waits for it to complete before exiting with the same exit status as that process. This means that the process ID reported within the running executable will be different from what the earlier Perl fork() might have returned. Similarly, any process manipulation functions applied to the ID returned by fork() will affect the waiting pseudo-process that called exec(), not the real process it is waiting for after the exec().

exit()

exit() always exits just the executing pseudo-process, after automatically wait()-ing for any outstanding child pseudo-processes. Note that this means that the process as a whole will not exit unless all running pseudo-processes have exited.

Open handles to files, directories and network sockets

All open handles are dup()-ed in pseudo-processes, so that closing any handles in one process does not affect the others. See below for some limitations.

48.2.2 Resource limits

In the eyes of the operating system, pseudo-processes created via the fork() emulation are simply threads in the same process. This means that any process-level limits imposed by the operating system apply to all pseudo-processes taken together. This includes any limits imposed by the operating system on the number of open file, directory and socket handles, limits on disk space usage, limits on memory size, limits on CPU utilization etc.

48.2.3 Killing the parent process

If the parent process is killed (either using Perl's kill() builtin, or using some external means) all the pseudo-processes are killed as well, and the whole process exits.

48.2.4 Lifetime of the parent process and pseudo-processes

During the normal course of events, the parent process and every pseudo-process started by it will wait for their respective pseudo-children to complete before they exit. This means that the parent and every pseudo-child created by it that is also a pseudo-parent will only exit after their pseudo-children have exited.

A way to mark a pseudo-processes as running detached from their parent (so that the parent would not have to wait() for them if it doesn't want to) will be provided in future.

48.2.5 CAVEATS AND LIMITATIONS

BEGIN blocks

The fork() emulation will not work entirely correctly when called from within a BEGIN block. The forked copy will run the contents of the BEGIN block, but will not continue parsing the source stream after the BEGIN block. For example, consider the following code:

```
    BEGIN {
        fork and exit;          # fork child and exit the parent
        print "inner\n";
    }
    print "outer\n";
```

This will print:

```
    inner
```

rather than the expected:

```
    inner
    outer
```

This limitation arises from fundamental technical difficulties in cloning and restarting the stacks used by the Perl parser in the middle of a parse.

Open filehandles

Any filehandles open at the time of the fork() will be dup()-ed. Thus, the files can be closed independently in the parent and child, but beware that the dup()-ed handles will still share the same seek pointer. Changing the seek position in the parent will change it in the child and vice-versa. One can avoid this by opening files that need distinct seek pointers separately in the child.

Forking pipe open() not yet implemented

The `open(FOO, "|-")` and `open(BAR, "-|")` constructs are not yet implemented. This limitation can be easily worked around in new code by creating a pipe explicitly. The following example shows how to write to a forked child:

```
    # simulate open(FOO, "|-")
    sub pipe_to_fork ($) {
        my $parent = shift;
        pipe my $child, $parent or die;
        my $pid = fork();
        die "fork() failed: $!" unless defined $pid;
        if ($pid) {
            close $child;
        }
        else {
            close $parent;
            open(STDIN, "<&=" . fileno($child)) or die;
        }
        $pid;
    }

    if (pipe_to_fork('FOO')) {
        # parent
        print FOO "pipe_to_fork\n";
        close FOO;
    }
    else {
        # child
        while (<STDIN>) { print; }
        exit(0);
    }
```

And this one reads from the child:

```
    # simulate open(FOO, "-|")
    sub pipe_from_fork ($) {
        my $parent = shift;
        pipe $parent, my $child or die;
        my $pid = fork();
        die "fork() failed: $!" unless defined $pid;
        if ($pid) {
            close $child;
        }
        else {
            close $parent;
            open(STDOUT, ">&=" . fileno($child)) or die;
        }
        $pid;
    }

    if (pipe_from_fork('BAR')) {
        # parent
        while (<BAR>) { print; }
        close BAR;
    }
    else {
        # child
        print "pipe_from_fork\n";
        exit(0);
    }
```

Forking pipe open() constructs will be supported in future.

Global state maintained by XSUBs

External subroutines (XSUBs) that maintain their own global state may not work correctly. Such XSUBs will either need to maintain locks to protect simultaneous access to global data from different pseudo-processes, or maintain all their state on the Perl symbol table, which is copied naturally when fork() is called. A callback mechanism that provides extensions an opportunity to clone their state will be provided in the near future.

Interpreter embedded in larger application

The fork() emulation may not behave as expected when it is executed in an application which embeds a Perl interpreter and calls Perl APIs that can evaluate bits of Perl code. This stems from the fact that the emulation only has knowledge about the Perl interpreter's own data structures and knows nothing about the containing application's state. For example, any state carried on the application's own call stack is out of reach.

Thread-safety of extensions

Since the fork() emulation runs code in multiple threads, extensions calling into non-thread-safe libraries may not work reliably when calling fork(). As Perl's threading support gradually becomes more widely adopted even on platforms with a native fork(), such extensions are expected to be fixed for thread-safety.

48.3 BUGS

- Having pseudo-process IDs be negative integers breaks down for the integer `-1` because the wait() and waitpid() functions treat this number as being special. The tacit assumption in the current implementation is that the system never allocates a thread ID of `1` for user threads. A better representation for pseudo-process IDs will be implemented in future.
- In certain cases, the OS-level handles created by the pipe(), socket(), and accept() operators are apparently not duplicated accurately in pseudo-processes. This only happens in some situations, but where it does happen, it may result in deadlocks between the read and write ends of pipe handles, or inability to send or receive data across socket handles.
- This document may be incomplete in some respects.

48.4 AUTHOR

Support for concurrent interpreters and the fork() emulation was implemented by ActiveState, with funding from Microsoft Corporation.

perlnumber

Semantics of numbers and numeric operations in Perl

49.1 SYNOPSIS

```
    $n = 1234;              # decimal integer
    $n = 0b1110011;         # binary integer
    $n = 01234;             # octal integer
    $n = 0x1234;            # hexadecimal integer
    $n = 12.34e-56;         # exponential notation
    $n = "-12.34e56";       # number specified as a string
    $n = "1234";            # number specified as a string
```

49.2 DESCRIPTION

This document describes how Perl internally handles numeric values.

Perl's operator overloading facility is completely ignored here. Operator overloading allows user-defined behaviors for numbers, such as operations over arbitrarily large integers, floating points numbers with arbitrary precision, operations over "exotic" numbers such as modular arithmetic or p-adic arithmetic, and so on. See *overload* for details.

49.3 Storing numbers

Perl can internally represent numbers in 3 different ways: as native integers, as native floating point numbers, and as decimal strings. Decimal strings may have an exponential notation part, as in `"12.34e-56"`. *Native* here means "a format supported by the C compiler which was used to build perl".

The term "native" does not mean quite as much when we talk about native integers, as it does when native floating point numbers are involved. The only implication of the term "native" on integers is that the limits for the maximal and the minimal supported true integral quantities are close to powers of 2. However, "native" floats have a most fundamental restriction: they may represent only those numbers which have a relatively "short" representation when converted to a binary fraction. For example, 0.9 cannot be represented by a native float, since the binary fraction for 0.9 is infinite:

```
  binary0.1110011001100...
```

with the sequence `1100` repeating again and again. In addition to this limitation, the exponent of the binary number is also restricted when it is represented as a floating point number. On typical hardware, floating point values can store numbers with up to 53 binary digits, and with binary exponents between -1024 and 1024. In decimal representation this is close to 16 decimal digits and decimal exponents in the range of -304..304. The upshot of all this is that Perl cannot store a number like 12345678901234567 as a floating point number on such architectures without loss of information.

Similarly, decimal strings can represent only those numbers which have a finite decimal expansion. Being strings, and thus of arbitrary length, there is no practical limit for the exponent or number of decimal digits for these numbers. (But realize that what we are discussing the rules for just the *storage* of these numbers. The fact that you can store such "large" numbers does not mean that the *operations* over these numbers will use all of the significant digits. See §49.4 for details.)

In fact numbers stored in the native integer format may be stored either in the signed native form, or in the unsigned native form. Thus the limits for Perl numbers stored as native integers would typically be -2**31..2**32-1, with appropriate modifications in the case of 64-bit integers. Again, this does not mean that Perl can do operations only over integers in this range: it is possible to store many more integers in floating point format.

Summing up, Perl numeric values can store only those numbers which have a finite decimal expansion or a "short" binary expansion.

49.4 Numeric operators and numeric conversions

As mentioned earlier, Perl can store a number in any one of three formats, but most operators typically understand only one of those formats. When a numeric value is passed as an argument to such an operator, it will be converted to the format understood by the operator.

Six such conversions are possible:

```
native integer        --> native floating point       (*)
native integer        --> decimal string
native floating_point --> native integer              (*)
native floating_point --> decimal string              (*)
decimal string        --> native integer
decimal string        --> native floating point       (*)
```

These conversions are governed by the following general rules:

- If the source number can be represented in the target form, that representation is used.
- If the source number is outside of the limits representable in the target form, a representation of the closest limit is used. (*Loss of information*)
- If the source number is between two numbers representable in the target form, a representation of one of these numbers is used. (*Loss of information*)
- In `native floating point -> native integer` conversions the magnitude of the result is less than or equal to the magnitude of the source. (*"Rounding to zero".*)
- If the `decimal string -> native integer` conversion cannot be done without loss of information, the result is compatible with the conversion sequence `decimal_string -> native_floating_point -> native_integer`. In particular, rounding is strongly biased to 0, though a number like `"0.99999999999999999999"` has a chance of being rounded to 1.

RESTRICTION: The conversions marked with `(*)` above involve steps performed by the C compiler. In particular, bugs/features of the compiler used may lead to breakage of some of the above rules.

49.5 Flavors of Perl numeric operations

Perl operations which take a numeric argument treat that argument in one of four different ways: they may force it to one of the integer/floating/ string formats, or they may behave differently depending on the format of the operand. Forcing a numeric value to a particular format does not change the number stored in the value.

All the operators which need an argument in the integer format treat the argument as in modular arithmetic, e.g., `mod 2**32` on a 32-bit architecture. `sprintf "%u", -1` therefore provides the same result as `sprintf "%u", ~0`.

Arithmetic operators

The binary operators `+ - * / %` `== != > < >= <=` and the unary operators `- abs` and `--` will attempt to convert arguments to integers. If both conversions are possible without loss of precision, and the operation can be performed without loss of precision then the integer result is used. Otherwise arguments are converted to floating point format and the floating point result is used. The caching of conversions (as described above) means that the integer conversion does not throw away fractional parts on floating point numbers.

`++`

`++` behaves as the other operators above, except that if it is a string matching the format `/^[a-zA-Z]*[0-9]*\z/` the string increment described in *perlop* is used.

Arithmetic operators during `use integer`

In scopes where `use integer;` is in force, nearly all the operators listed above will force their argument(s) into integer format, and return an integer result. The exceptions, `abs`, `++` and `--`, do not change their behavior with `use integer;`

Other mathematical operators

Operators such as `**`, `sin` and `exp` force arguments to floating point format.

Bitwise operators

Arguments are forced into the integer format if not strings.

Bitwise operators during `use integer`

forces arguments to integer format. Also shift operations internally use signed integers rather than the default unsigned.

Operators which expect an integer

force the argument into the integer format. This is applicable to the third and fourth arguments of `sysread`, for example.

Operators which expect a string

force the argument into the string format. For example, this is applicable to `printf "%s", $value`.

Though forcing an argument into a particular form does not change the stored number, Perl remembers the result of such conversions. In particular, though the first such conversion may be time-consuming, repeated operations will not need to redo the conversion.

Chapter 50

perlthrtut

Tutorial on threads in Perl

50.1 DESCRIPTION

NOTE: this tutorial describes the new Perl threading flavour introduced in Perl 5.6.0 called interpreter threads, or **ithreads** for short. In this model each thread runs in its own Perl interpreter, and any data sharing between threads must be explicit.

There is another older Perl threading flavour called the 5.005 model, unsurprisingly for 5.005 versions of Perl. The old model is known to have problems, deprecated, and will probably be removed around release 5.10. You are strongly encouraged to migrate any existing 5.005 threads code to the new model as soon as possible.

You can see which (or neither) threading flavour you have by running `perl -V` and looking at the `Platform` section. If you have `useithreads=define` you have ithreads, if you have `use5005threads=define` you have 5.005 threads. If you have neither, you don't have any thread support built in. If you have both, you are in trouble.

The user-level interface to the 5.005 threads was via the *Threads* class, while ithreads uses the *threads* class. Note the change in case.

50.2 Status

The ithreads code has been available since Perl 5.6.0, and is considered stable. The user-level interface to ithreads (the *threads* classes) appeared in the 5.8.0 release, and as of this time is considered stable although it should be treated with caution as with all new features.

50.3 What Is A Thread Anyway?

A thread is a flow of control through a program with a single execution point.

Sounds an awful lot like a process, doesn't it? Well, it should. Threads are one of the pieces of a process. Every process has at least one thread and, up until now, every process running Perl had only one thread. With 5.8, though, you can create extra threads. We're going to show you how, when, and why.

50.4 Threaded Program Models

There are three basic ways that you can structure a threaded program. Which model you choose depends on what you need your program to do. For many non-trivial threaded programs you'll need to choose different models for different pieces of your program.

50.4.1 Boss/Worker

The boss/worker model usually has one ‘boss’ thread and one or more ‘worker’ threads. The boss thread gathers or generates tasks that need to be done, then parcels those tasks out to the appropriate worker thread.

This model is common in GUI and server programs, where a main thread waits for some event and then passes that event to the appropriate worker threads for processing. Once the event has been passed on, the boss thread goes back to waiting for another event.

The boss thread does relatively little work. While tasks aren’t necessarily performed faster than with any other method, it tends to have the best user-response times.

50.4.2 Work Crew

In the work crew model, several threads are created that do essentially the same thing to different pieces of data. It closely mirrors classical parallel processing and vector processors, where a large array of processors do the exact same thing to many pieces of data.

This model is particularly useful if the system running the program will distribute multiple threads across different processors. It can also be useful in ray tracing or rendering engines, where the individual threads can pass on interim results to give the user visual feedback.

50.4.3 Pipeline

The pipeline model divides up a task into a series of steps, and passes the results of one step on to the thread processing the next. Each thread does one thing to each piece of data and passes the results to the next thread in line.

This model makes the most sense if you have multiple processors so two or more threads will be executing in parallel, though it can often make sense in other contexts as well. It tends to keep the individual tasks small and simple, as well as allowing some parts of the pipeline to block (on I/O or system calls, for example) while other parts keep going. If you’re running different parts of the pipeline on different processors you may also take advantage of the caches on each processor.

This model is also handy for a form of recursive programming where, rather than having a subroutine call itself, it instead creates another thread. Prime and Fibonacci generators both map well to this form of the pipeline model. (A version of a prime number generator is presented later on.)

50.5 What kind of threads are Perl threads?

If you have experience with other thread implementations, you might find that things aren’t quite what you expect. It’s very important to remember when dealing with Perl threads that Perl Threads Are Not X Threads, for all values of X. They aren’t POSIX threads, or DecThreads, or Java’s Green threads, or Win32 threads. There are similarities, and the broad concepts are the same, but if you start looking for implementation details you’re going to be either disappointed or confused. Possibly both.

This is not to say that Perl threads are completely different from everything that’s ever come before–they’re not. Perl’s threading model owes a lot to other thread models, especially POSIX. Just as Perl is not C, though, Perl threads are not POSIX threads. So if you find yourself looking for mutexes, or thread priorities, it’s time to step back a bit and think about what you want to do and how Perl can do it.

However it is important to remember that Perl threads cannot magically do things unless your operating systems threads allows it. So if your system blocks the entire process on sleep(), Perl usually will as well.

Perl Threads Are Different.

50.6 Thread-Safe Modules

The addition of threads has changed Perl's internals substantially. There are implications for people who write modules with XS code or external libraries. However, since perl data is not shared among threads by default, Perl modules stand a high chance of being thread-safe or can be made thread-safe easily. Modules that are not tagged as thread-safe should be tested or code reviewed before being used in production code.

Not all modules that you might use are thread-safe, and you should always assume a module is unsafe unless the documentation says otherwise. This includes modules that are distributed as part of the core. Threads are a new feature, and even some of the standard modules aren't thread-safe.

Even if a module is thread-safe, it doesn't mean that the module is optimized to work well with threads. A module could possibly be rewritten to utilize the new features in threaded Perl to increase performance in a threaded environment.

If you're using a module that's not thread-safe for some reason, you can protect yourself by using it from one, and only one thread at all. If you need multiple threads to access such a module, you can use semaphores and lots of programming discipline to control access to it. Semaphores are covered in §50.9.5.

See also §50.15.

50.7 Thread Basics

The core *threads* module provides the basic functions you need to write threaded programs. In the following sections we'll cover the basics, showing you what you need to do to create a threaded program. After that, we'll go over some of the features of the *threads* module that make threaded programming easier.

50.7.1 Basic Thread Support

Thread support is a Perl compile-time option - it's something that's turned on or off when Perl is built at your site, rather than when your programs are compiled. If your Perl wasn't compiled with thread support enabled, then any attempt to use threads will fail.

Your programs can use the Config module to check whether threads are enabled. If your program can't run without them, you can say something like:

```
    $Config{useithreads} or die "Recompile Perl with threads to run this program.";
```

A possibly-threaded program using a possibly-threaded module might have code like this:

```
    use Config;
    use MyMod;

    BEGIN {
        if ($Config{useithreads}) {
            # We have threads
            require MyMod_threaded;
           import MyMod_threaded;
        } else {
           require MyMod_unthreaded;
           import MyMod_unthreaded;
        }
    }
```

Since code that runs both with and without threads is usually pretty messy, it's best to isolate the thread-specific code in its own module. In our example above, that's what MyMod_threaded is, and it's only imported if we're running on a threaded Perl.

50.7.2 A Note about the Examples

Although thread support is considered to be stable, there are still a number of quirks that may startle you when you try out any of the examples below. In a real situation, care should be taken that all threads are finished executing before the program exits. That care has **not** been taken in these examples in the interest of simplicity. Running these examples "as is" will produce error messages, usually caused by the fact that there are still threads running when the program exits. You should not be alarmed by this. Future versions of Perl may fix this problem.

50.7.3 Creating Threads

The *threads* package provides the tools you need to create new threads. Like any other module, you need to tell Perl that you want to use it; `use threads` imports all the pieces you need to create basic threads.

The simplest, most straightforward way to create a thread is with new():

```
    use threads;

    $thr = threads->new(\&sub1);

    sub sub1 {
        print "In the thread\n";
    }
```

The new() method takes a reference to a subroutine and creates a new thread, which starts executing in the referenced subroutine. Control then passes both to the subroutine and the caller.

If you need to, your program can pass parameters to the subroutine as part of the thread startup. Just include the list of parameters as part of the `threads::new` call, like this:

```
    use threads;

    $Param3 = "foo";
    $thr = threads->new(\&sub1, "Param 1", "Param 2", $Param3);
    $thr = threads->new(\&sub1, @ParamList);
    $thr = threads->new(\&sub1, qw(Param1 Param2 Param3));

    sub sub1 {
        my @InboundParameters = @_;
        print "In the thread\n";
        print "got parameters >", join("<>", @InboundParameters), "<\n";
    }
```

The last example illustrates another feature of threads. You can spawn off several threads using the same subroutine. Each thread executes the same subroutine, but in a separate thread with a separate environment and potentially separate arguments.

`create()` is a synonym for `new()`.

50.7.4 Waiting For A Thread To Exit

Since threads are also subroutines, they can return values. To wait for a thread to exit and extract any values it might return, you can use the join() method:

```
    use threads;

    $thr = threads->new(\&sub1);
    @ReturnData = $thr->join;
    print "Thread returned @ReturnData";

    sub sub1 { return "Fifty-six", "foo", 2; }
```

In the example above, the join() method returns as soon as the thread ends. In addition to waiting for a thread to finish and gathering up any values that the thread might have returned, join() also performs any OS cleanup necessary for the thread. That cleanup might be important, especially for long-running programs that spawn lots of threads. If you don't want the return values and don't want to wait for the thread to finish, you should call the detach() method instead, as described next.

50.7.5 Ignoring A Thread

join() does three things: it waits for a thread to exit, cleans up after it, and returns any data the thread may have produced. But what if you're not interested in the thread's return values, and you don't really care when the thread finishes? All you want is for the thread to get cleaned up after when it's done.

In this case, you use the detach() method. Once a thread is detached, it'll run until it's finished, then Perl will clean up after it automatically.

```
    use threads;

    $thr = threads->new(\&sub1); # Spawn the thread

    $thr->detach; # Now we officially don't care any more

    sub sub1 {
        $a = 0;
        while (1) {
            $a++;
            print "\$a is $a\n";
            sleep 1;
        }
    }
```

Once a thread is detached, it may not be joined, and any return data that it might have produced (if it was done and waiting for a join) is lost.

50.8 Threads And Data

Now that we've covered the basics of threads, it's time for our next topic: data. Threading introduces a couple of complications to data access that non-threaded programs never need to worry about.

50.8.1 Shared And Unshared Data

The biggest difference between Perl ithreads and the old 5.005 style threading, or for that matter, to most other threading systems out there, is that by default, no data is shared. When a new perl thread is created, all the data associated with the current thread is copied to the new thread, and is subsequently private to that new thread! This is similar in feel to what happens when a UNIX process forks, except that in this case, the data is just copied to a different part of memory within the same process rather than a real fork taking place.

To make use of threading however, one usually wants the threads to share at least some data between themselves. This is done with the *threads::shared* module and the `: shared` attribute:

```
    use threads;
    use threads::shared;

    my $foo : shared = 1;
    my $bar = 1;
    threads->new(sub { $foo++; $bar++ })->join;

    print "$foo\n";  #prints 2 since $foo is shared
    print "$bar\n";  #prints 1 since $bar is not shared
```

In the case of a shared array, all the array's elements are shared, and for a shared hash, all the keys and values are shared. This places restrictions on what may be assigned to shared array and hash elements: only simple values or references to shared variables are allowed - this is so that a private variable can't accidentally become shared. A bad assignment will cause the thread to die. For example:

```
    use threads;
    use threads::shared;

    my $var           = 1;
    my $svar : shared = 2;
    my %hash : shared;

    ... create some threads ...

    $hash{a} = 1;       # all threads see exists($hash{a}) and $hash{a} == 1
    $hash{a} = $var     # okay - copy-by-value: same effect as previous
    $hash{a} = $svar    # okay - copy-by-value: same effect as previous
    $hash{a} = \$svar   # okay - a reference to a shared variable
    $hash{a} = \$var    # This will die
    delete $hash{a}     # okay - all threads will see !exists($hash{a})
```

Note that a shared variable guarantees that if two or more threads try to modify it at the same time, the internal state of the variable will not become corrupted. However, there are no guarantees beyond this, as explained in the next section.

50.8.2 Thread Pitfalls: Races

While threads bring a new set of useful tools, they also bring a number of pitfalls. One pitfall is the race condition:

```
    use threads;
    use threads::shared;

    my $a : shared = 1;
    $thr1 = threads->new(\&sub1);
    $thr2 = threads->new(\&sub2);

    $thr1->join;
    $thr2->join;
    print "$a\n";

    sub sub1 { my $foo = $a; $a = $foo + 1; }
    sub sub2 { my $bar = $a; $a = $bar + 1; }
```

What do you think $a will be? The answer, unfortunately, is "it depends." Both sub1() and sub2() access the global variable $a, once to read and once to write. Depending on factors ranging from your thread implementation's scheduling algorithm to the phase of the moon, $a can be 2 or 3.

Race conditions are caused by unsynchronized access to shared data. Without explicit synchronization, there's no way to be sure that nothing has happened to the shared data between the time you access it and the time you update it. Even this simple code fragment has the possibility of error:

```
use threads;
my $a : shared = 2;
my $b : shared;
my $c : shared;
my $thr1 = threads->create(sub { $b = $a; $a = $b + 1; });
my $thr2 = threads->create(sub { $c = $a; $a = $c + 1; });
$thr1->join;
$thr2->join;
```

Two threads both access $a. Each thread can potentially be interrupted at any point, or be executed in any order. At the end, $a could be 3 or 4, and both $b and $c could be 2 or 3.

Even `$a += 5` or `$a++` are not guaranteed to be atomic.

Whenever your program accesses data or resources that can be accessed by other threads, you must take steps to coordinate access or risk data inconsistency and race conditions. Note that Perl will protect its internals from your race conditions, but it won't protect you from you.

50.9 Synchronization and control

Perl provides a number of mechanisms to coordinate the interactions between themselves and their data, to avoid race conditions and the like. Some of these are designed to resemble the common techniques used in thread libraries such as `pthreads`; others are Perl-specific. Often, the standard techniques are clumsy and difficult to get right (such as condition waits). Where possible, it is usually easier to use Perlish techniques such as queues, which remove some of the hard work involved.

50.9.1 Controlling access: lock()

The lock() function takes a shared variable and puts a lock on it. No other thread may lock the variable until the variable is unlocked by the thread holding the lock. Unlocking happens automatically when the locking thread exits the outermost block that contains `lock()` function. Using lock() is straightforward: this example has several threads doing some calculations in parallel, and occasionally updating a running total:

```
use threads;
use threads::shared;

my $total : shared = 0;

sub calc {
    for (;;) {
        my $result;
        # (... do some calculations and set $result ...)
        {
            lock($total); # block until we obtain the lock
            $total += $result;
        } # lock implicitly released at end of scope
        last if $result == 0;
    }
}
```

```
    my $thr1 = threads->new(\&calc);
    my $thr2 = threads->new(\&calc);
    my $thr3 = threads->new(\&calc);
    $thr1->join;
    $thr2->join;
    $thr3->join;
    print "total=$total\n";
```

lock() blocks the thread until the variable being locked is available. When lock() returns, your thread can be sure that no other thread can lock that variable until the outermost block containing the lock exits.

It's important to note that locks don't prevent access to the variable in question, only lock attempts. This is in keeping with Perl's longstanding tradition of courteous programming, and the advisory file locking that flock() gives you.

You may lock arrays and hashes as well as scalars. Locking an array, though, will not block subsequent locks on array elements, just lock attempts on the array itself.

Locks are recursive, which means it's okay for a thread to lock a variable more than once. The lock will last until the outermost lock() on the variable goes out of scope. For example:

```
    my $x : shared;
    doit();

    sub doit {
        {
            {
                lock($x); # wait for lock
                lock($x); # NOOP - we already have the lock
                {
                    lock($x); # NOOP
                    {
                        lock($x); # NOOP
                        lockit_some_more();
                    }
                }
            } # *** implicit unlock here ***
        }
    }

    sub lockit_some_more {
        lock($x); # NOOP
    } # nothing happens here
```

Note that there is no unlock() function - the only way to unlock a variable is to allow it to go out of scope.

A lock can either be used to guard the data contained within the variable being locked, or it can be used to guard something else, like a section of code. In this latter case, the variable in question does not hold any useful data, and exists only for the purpose of being locked. In this respect, the variable behaves like the mutexes and basic semaphores of traditional thread libraries.

50.9.2 A Thread Pitfall: Deadlocks

Locks are a handy tool to synchronize access to data, and using them properly is the key to safe shared data. Unfortunately, locks aren't without their dangers, especially when multiple locks are involved. Consider the following code:

```
    use threads;
    my $a : shared = 4;
    my $b : shared = "foo";
    my $thr1 = threads->new(sub {
        lock($a);
        sleep 20;
        lock($b);
    });
    my $thr2 = threads->new(sub {
        lock($b);
        sleep 20;
        lock($a);
    });
```

This program will probably hang until you kill it. The only way it won't hang is if one of the two threads acquires both locks first. A guaranteed-to-hang version is more complicated, but the principle is the same.

The first thread will grab a lock on $a, then, after a pause during which the second thread has probably had time to do some work, try to grab a lock on $b. Meanwhile, the second thread grabs a lock on $b, then later tries to grab a lock on $a. The second lock attempt for both threads will block, each waiting for the other to release its lock.

This condition is called a deadlock, and it occurs whenever two or more threads are trying to get locks on resources that the others own. Each thread will block, waiting for the other to release a lock on a resource. That never happens, though, since the thread with the resource is itself waiting for a lock to be released.

There are a number of ways to handle this sort of problem. The best way is to always have all threads acquire locks in the exact same order. If, for example, you lock variables $a, $b, and $c, always lock $a before $b, and $b before $c. It's also best to hold on to locks for as short a period of time to minimize the risks of deadlock.

The other synchronization primitives described below can suffer from similar problems.

50.9.3 Queues: Passing Data Around

A queue is a special thread-safe object that lets you put data in one end and take it out the other without having to worry about synchronization issues. They're pretty straightforward, and look like this:

```
    use threads;
    use Thread::Queue;

    my $DataQueue = Thread::Queue->new;
    $thr = threads->new(sub {
        while ($DataElement = $DataQueue->dequeue) {
            print "Popped $DataElement off the queue\n";
        }
    });

    $DataQueue->enqueue(12);
    $DataQueue->enqueue("A", "B", "C");
    $DataQueue->enqueue(\$thr);
    sleep 10;
    $DataQueue->enqueue(undef);
    $thr->join;
```

You create the queue with `new Thread::Queue`. Then you can add lists of scalars onto the end with enqueue(), and pop scalars off the front of it with dequeue(). A queue has no fixed size, and can grow as needed to hold everything pushed on to it.

If a queue is empty, dequeue() blocks until another thread enqueues something. This makes queues ideal for event loops and other communications between threads.

50.9.4 Semaphores: Synchronizing Data Access

Semaphores are a kind of generic locking mechanism. In their most basic form, they behave very much like lockable scalars, except that thay can't hold data, and that they must be explicitly unlocked. In their advanced form, they act like a kind of counter, and can allow multiple threads to have the 'lock' at any one time.

50.9.5 Basic semaphores

Semaphores have two methods, down() and up(): down() decrements the resource count, while up increments it. Calls to down() will block if the semaphore's current count would decrement below zero. This program gives a quick demonstration:

```
use threads;
use Thread::Semaphore;

my $semaphore = new Thread::Semaphore;
my $GlobalVariable : shared = 0;

$thr1 = new threads \&sample_sub, 1;
$thr2 = new threads \&sample_sub, 2;
$thr3 = new threads \&sample_sub, 3;

sub sample_sub {
    my $SubNumber = shift @_;
    my $TryCount = 10;
    my $LocalCopy;
    sleep 1;
    while ($TryCount--) {
        $semaphore->down;
        $LocalCopy = $GlobalVariable;
        print "$TryCount tries left for sub $SubNumber (\$GlobalVariable is $GlobalVariable)\n";
        sleep 2;
        $LocalCopy++;
        $GlobalVariable = $LocalCopy;
        $semaphore->up;
    }
}

$thr1->join;
$thr2->join;
$thr3->join;
```

The three invocations of the subroutine all operate in sync. The semaphore, though, makes sure that only one thread is accessing the global variable at once.

50.9.6 Advanced Semaphores

By default, semaphores behave like locks, letting only one thread down() them at a time. However, there are other uses for semaphores.

Each semaphore has a counter attached to it. By default, semaphores are created with the counter set to one, down() decrements the counter by one, and up() increments by one. However, we can override any or all of these defaults simply by passing in different values:

```
    use threads;
    use Thread::Semaphore;
    my $semaphore = Thread::Semaphore->new(5);
                    # Creates a semaphore with the counter set to five

    $thr1 = threads->new(\&sub1);
    $thr2 = threads->new(\&sub1);

    sub sub1 {
        $semaphore->down(5); # Decrements the counter by five
        # Do stuff here
        $semaphore->up(5); # Increment the counter by five
    }

    $thr1->detach;
    $thr2->detach;
```

If down() attempts to decrement the counter below zero, it blocks until the counter is large enough. Note that while a semaphore can be created with a starting count of zero, any up() or down() always changes the counter by at least one, and so $semaphore->down(0) is the same as $semaphore->down(1).

The question, of course, is why would you do something like this? Why create a semaphore with a starting count that's not one, or why decrement/increment it by more than one? The answer is resource availability. Many resources that you want to manage access for can be safely used by more than one thread at once.

For example, let's take a GUI driven program. It has a semaphore that it uses to synchronize access to the display, so only one thread is ever drawing at once. Handy, but of course you don't want any thread to start drawing until things are properly set up. In this case, you can create a semaphore with a counter set to zero, and up it when things are ready for drawing.

Semaphores with counters greater than one are also useful for establishing quotas. Say, for example, that you have a number of threads that can do I/O at once. You don't want all the threads reading or writing at once though, since that can potentially swamp your I/O channels, or deplete your process' quota of filehandles. You can use a semaphore initialized to the number of concurrent I/O requests (or open files) that you want at any one time, and have your threads quietly block and unblock themselves.

Larger increments or decrements are handy in those cases where a thread needs to check out or return a number of resources at once.

50.9.7 cond_wait() and cond_signal()

These two functions can be used in conjunction with locks to notify co-operating threads that a resource has become available. They are very similar in use to the functions found in `pthreads`. However for most purposes, queues are simpler to use and more intuitive. See *threads::shared* for more details.

50.9.8 Giving up control

There are times when you may find it useful to have a thread explicitly give up the CPU to another thread. You may be doing something processor-intensive and want to make sure that the user-interface thread gets called frequently. Regardless, there are times that you might want a thread to give up the processor.

Perl's threading package provides the yield() function that does this. yield() is pretty straightforward, and works like this:

```
    use threads;
```

```
sub loop {
        my $thread = shift;
        my $foo = 50;
        while($foo--) { print "in thread $thread\n" }
        threads->yield;
        $foo = 50;
        while($foo--) { print "in thread $thread\n" }
}

my $thread1 = threads->new(\&loop, 'first');
my $thread2 = threads->new(\&loop, 'second');
my $thread3 = threads->new(\&loop, 'third');
```

It is important to remember that yield() is only a hint to give up the CPU, it depends on your hardware, OS and threading libraries what actually happens. **On many operating systems, yield() is a no-op.** Therefore it is important to note that one should not build the scheduling of the threads around yield() calls. It might work on your platform but it won't work on another platform.

50.10 General Thread Utility Routines

We've covered the workhorse parts of Perl's threading package, and with these tools you should be well on your way to writing threaded code and packages. There are a few useful little pieces that didn't really fit in anyplace else.

50.10.1 What Thread Am I In?

The `threads->self` class method provides your program with a way to get an object representing the thread it's currently in. You can use this object in the same way as the ones returned from thread creation.

50.10.2 Thread IDs

tid() is a thread object method that returns the thread ID of the thread the object represents. Thread IDs are integers, with the main thread in a program being 0. Currently Perl assigns a unique tid to every thread ever created in your program, assigning the first thread to be created a tid of 1, and increasing the tid by 1 for each new thread that's created.

50.10.3 Are These Threads The Same?

The equal() method takes two thread objects and returns true if the objects represent the same thread, and false if they don't.

Thread objects also have an overloaded == comparison so that you can do comparison on them as you would with normal objects.

50.10.4 What Threads Are Running?

`threads->list` returns a list of thread objects, one for each thread that's currently running and not detached. Handy for a number of things, including cleaning up at the end of your program:

```
# Loop through all the threads
foreach $thr (threads->list) {
    # Don't join the main thread or ourselves
    if ($thr->tid && !threads::equal($thr, threads->self)) {
        $thr->join;
    }
}
```

If some threads have not finished running when the main Perl thread ends, Perl will warn you about it and die, since it is impossible for Perl to clean up itself while other threads are running

50.11 A Complete Example

Confused yet? It's time for an example program to show some of the things we've covered. This program finds prime numbers using threads.

```
 1 #!/usr/bin/perl -w
 2 # prime-pthread, courtesy of Tom Christiansen
 3
 4 use strict;
 5
 6 use threads;
 7 use Thread::Queue;
 8
 9 my $stream = new Thread::Queue;
10 my $kid    = new threads(\&check_num, $stream, 2);
11
12 for my $i ( 3 .. 1000 ) {
13     $stream->enqueue($i);
14 }
15
16 $stream->enqueue(undef);
17 $kid->join;
18
19 sub check_num {
20     my ($upstream, $cur_prime) = @_;
21     my $kid;
22     my $downstream = new Thread::Queue;
23     while (my $num = $upstream->dequeue) {
24         next unless $num % $cur_prime;
25         if ($kid) {
26            $downstream->enqueue($num);
27                   } else {
28            print "Found prime $num\n";
29                $kid = new threads(\&check_num, $downstream, $num);
30         }
31     }
32     $downstream->enqueue(undef) if $kid;
33     $kid->join           if $kid;
34 }
```

This program uses the pipeline model to generate prime numbers. Each thread in the pipeline has an input queue that feeds numbers to be checked, a prime number that it's responsible for, and an output queue into which it funnels numbers that have failed the check. If the thread has a number that's failed its check and there's no child thread, then the thread must have found a new prime number. In that case, a new child thread is created for that prime and stuck on the end of the pipeline.

This probably sounds a bit more confusing than it really is, so let's go through this program piece by piece and see what it does. (For those of you who might be trying to remember exactly what a prime number is, it's a number that's only evenly divisible by itself and 1)

The bulk of the work is done by the check_num() subroutine, which takes a reference to its input queue and a prime number that it's responsible for. After pulling in the input queue and the prime that the subroutine's checking (line 20), we create a new queue (line 22) and reserve a scalar for the thread that we're likely to create later (line 21).

The while loop from lines 23 to line 31 grabs a scalar off the input queue and checks against the prime this thread is responsible for. Line 24 checks to see if there's a remainder when we modulo the number to be checked against our prime. If there is one, the number must not be evenly divisible by our prime, so we need to either pass it on to the next thread if we've created one (line 26) or create a new thread if we haven't.

The new thread creation is line 29. We pass on to it a reference to the queue we've created, and the prime number we've found.

Finally, once the loop terminates (because we got a 0 or undef in the queue, which serves as a note to die), we pass on the notice to our child and wait for it to exit if we've created a child (lines 32 and 37).

Meanwhile, back in the main thread, we create a queue (line 9) and the initial child thread (line 10), and pre-seed it with the first prime: 2. Then we queue all the numbers from 3 to 1000 for checking (lines 12-14), then queue a die notice (line 16) and wait for the first child thread to terminate (line 17). Because a child won't die until its child has died, we know that we're done once we return from the join.

That's how it works. It's pretty simple; as with many Perl programs, the explanation is much longer than the program.

50.12 Different implementations of threads

Some background on thread implementations from the operating system viewpoint. There are three basic categories of threads: user-mode threads, kernel threads, and multiprocessor kernel threads.

User-mode threads are threads that live entirely within a program and its libraries. In this model, the OS knows nothing about threads. As far as it's concerned, your process is just a process.

This is the easiest way to implement threads, and the way most OSes start. The big disadvantage is that, since the OS knows nothing about threads, if one thread blocks they all do. Typical blocking activities include most system calls, most I/O, and things like sleep().

Kernel threads are the next step in thread evolution. The OS knows about kernel threads, and makes allowances for them. The main difference between a kernel thread and a user-mode thread is blocking. With kernel threads, things that block a single thread don't block other threads. This is not the case with user-mode threads, where the kernel blocks at the process level and not the thread level.

This is a big step forward, and can give a threaded program quite a performance boost over non-threaded programs. Threads that block performing I/O, for example, won't block threads that are doing other things. Each process still has only one thread running at once, though, regardless of how many CPUs a system might have.

Since kernel threading can interrupt a thread at any time, they will uncover some of the implicit locking assumptions you may make in your program. For example, something as simple as `$a = $a + 2` can behave unpredictably with kernel threads if $a is visible to other threads, as another thread may have changed $a between the time it was fetched on the right hand side and the time the new value is stored.

Multiprocessor kernel threads are the final step in thread support. With multiprocessor kernel threads on a machine with multiple CPUs, the OS may schedule two or more threads to run simultaneously on different CPUs.

This can give a serious performance boost to your threaded program, since more than one thread will be executing at the same time. As a tradeoff, though, any of those nagging synchronization issues that might not have shown with basic kernel threads will appear with a vengeance.

In addition to the different levels of OS involvement in threads, different OSes (and different thread implementations for a particular OS) allocate CPU cycles to threads in different ways.

Cooperative multitasking systems have running threads give up control if one of two things happen. If a thread calls a yield function, it gives up control. It also gives up control if the thread does something that would cause it to block, such as perform I/O. In a cooperative multitasking implementation, one thread can starve all the others for CPU time if it so chooses.

Preemptive multitasking systems interrupt threads at regular intervals while the system decides which thread should run next. In a preemptive multitasking system, one thread usually won't monopolize the CPU.

On some systems, there can be cooperative and preemptive threads running simultaneously. (Threads running with realtime priorities often behave cooperatively, for example, while threads running at normal priorities behave preemptively.)

Most modern operating systems support preemptive multitasking nowadays.

50.13 Performance considerations

The main thing to bear in mind when comparing ithreads to other threading models is the fact that for each new thread created, a complete copy of all the variables and data of the parent thread has to be taken. Thus thread creation can be quite expensive, both in terms of memory usage and time spent in creation. The ideal way to reduce these costs is to have a relatively short number of long-lived threads, all created fairly early on - before the base thread has accumulated too much data. Of course, this may not always be possible, so compromises have to be made. However, after a thread has been created, its performance and extra memory usage should be little different than ordinary code.

Also note that under the current implementation, shared variables use a little more memory and are a little slower than ordinary variables.

50.14 Process-scope Changes

Note that while threads themselves are separate execution threads and Perl data is thread-private unless explicitly shared, the threads can affect process-scope state, affecting all the threads.

The most common example of this is changing the current working directory using chdir(). One thread calls chdir(), and the working directory of all the threads changes.

Even more drastic example of a process-scope change is chroot(): the root directory of all the threads changes, and no thread can undo it (as opposed to chdir()).

Further examples of process-scope changes include umask() and changing uids/gids.

Thinking of mixing fork() and threads? Please lie down and wait until the feeling passes. Be aware that the semantics of fork() vary between platforms. For example, some UNIX systems copy all the current threads into the child process, while others only copy the thread that called fork(). You have been warned!

Similarly, mixing signals and threads should not be attempted. Implementations are platform-dependent, and even the POSIX semantics may not be what you expect (and Perl doesn’t even give you the full POSIX API).

50.15 Thread-Safety of System Libraries

Whether various library calls are thread-safe is outside the control of Perl. Calls often suffering from not being thread-safe include: localtime(), gmtime(), get{gr,host,net,proto,serv,pw}*(), readdir(), rand(), and srand() – in general, calls that depend on some global external state.

If the system Perl is compiled in has thread-safe variants of such calls, they will be used. Beyond that, Perl is at the mercy of the thread-safety or -unsafety of the calls. Please consult your C library call documentation.

On some platforms the thread-safe library interfaces may fail if the result buffer is too small (for example the user group databases may be rather large, and the reentrant interfaces may have to carry around a full snapshot of those databases). Perl will start with a small buffer, but keep retrying and growing the result buffer until the result fits. If this limitless growing sounds bad for security or memory consumption reasons you can recompile Perl with PERL_REENTRANT_MAXSIZE defined to the maximum number of bytes you will allow.

50.16 Conclusion

A complete thread tutorial could fill a book (and has, many times), but with what we’ve covered in this introduction, you should be well on your way to becoming a threaded Perl expert.

50.17 Bibliography

Here’s a short bibliography courtesy of Jürgen Christoffel:

50.17.1 Introductory Texts

Birrell, Andrew D. An Introduction to Programming with Threads. Digital Equipment Corporation, 1989, DEC-SRC Research Report #35 online as http://gatekeeper.dec.com/pub/DEC/SRC/research-reports/abstracts/src-rr-035.html (highly recommended)

50.18 Acknowledgements

Thanks (in no particular order) to Chaim Frenkel, Steve Fink, Gurusamy Sarathy, Ilya Zakharevich, Benjamin Sugars, Jürgen Christoffel, Joshua Pritikin, and Alan Burlison, for their help in reality-checking and polishing this article. Big thanks to Tom Christiansen for his rewrite of the prime number generator.

50.19 AUTHOR

Dan Sugalski <dan@sidhe.org<gt>

Slightly modified by Arthur Bergman to fit the new thread model/module.

Reworked slightly by Jörg Walter <jwalt@cpan.org<gt> to be more concise about thread-safety of perl code.

Rearranged slightly by Elizabeth Mattijsen <liz@dijkmat.nl<gt> to put less emphasis on yield().

Chapter 51

perlothrtut

Old tutorial on threads in Perl

51.1 DESCRIPTION

WARNING: This tutorial describes the old-style thread model that was introduced in release 5.005. This model is now deprecated, and will be removed, probably in version 5.10. The interfaces described here were considered experimental, and are likely to be buggy.

For information about the new interpreter threads ("ithreads") model, see the *perlthrtut* tutorial, and the *threads* and *threads::shared* modules.

You are strongly encouraged to migrate any existing threads code to the new model as soon as possible.

51.2 What Is A Thread Anyway?

A thread is a flow of control through a program with a single execution point.

Sounds an awful lot like a process, doesn't it? Well, it should. Threads are one of the pieces of a process. Every process has at least one thread and, up until now, every process running Perl had only one thread. With 5.005, though, you can create extra threads. We're going to show you how, when, and why.

51.3 Threaded Program Models

There are three basic ways that you can structure a threaded program. Which model you choose depends on what you need your program to do. For many non-trivial threaded programs you'll need to choose different models for different pieces of your program.

51.3.1 Boss/Worker

The boss/worker model usually has one 'boss' thread and one or more 'worker' threads. The boss thread gathers or generates tasks that need to be done, then parcels those tasks out to the appropriate worker thread.

This model is common in GUI and server programs, where a main thread waits for some event and then passes that event to the appropriate worker threads for processing. Once the event has been passed on, the boss thread goes back to waiting for another event.

The boss thread does relatively little work. While tasks aren't necessarily performed faster than with any other method, it tends to have the best user-response times.

51.3.2 Work Crew

In the work crew model, several threads are created that do essentially the same thing to different pieces of data. It closely mirrors classical parallel processing and vector processors, where a large array of processors do the exact same thing to many pieces of data.

This model is particularly useful if the system running the program will distribute multiple threads across different processors. It can also be useful in ray tracing or rendering engines, where the individual threads can pass on interim results to give the user visual feedback.

51.3.3 Pipeline

The pipeline model divides up a task into a series of steps, and passes the results of one step on to the thread processing the next. Each thread does one thing to each piece of data and passes the results to the next thread in line.

This model makes the most sense if you have multiple processors so two or more threads will be executing in parallel, though it can often make sense in other contexts as well. It tends to keep the individual tasks small and simple, as well as allowing some parts of the pipeline to block (on I/O or system calls, for example) while other parts keep going. If you're running different parts of the pipeline on different processors you may also take advantage of the caches on each processor.

This model is also handy for a form of recursive programming where, rather than having a subroutine call itself, it instead creates another thread. Prime and Fibonacci generators both map well to this form of the pipeline model. (A version of a prime number generator is presented later on.)

51.4 Native threads

There are several different ways to implement threads on a system. How threads are implemented depends both on the vendor and, in some cases, the version of the operating system. Often the first implementation will be relatively simple, but later versions of the OS will be more sophisticated.

While the information in this section is useful, it's not necessary, so you can skip it if you don't feel up to it.

There are three basic categories of threads-user-mode threads, kernel threads, and multiprocessor kernel threads.

User-mode threads are threads that live entirely within a program and its libraries. In this model, the OS knows nothing about threads. As far as it's concerned, your process is just a process.

This is the easiest way to implement threads, and the way most OSes start. The big disadvantage is that, since the OS knows nothing about threads, if one thread blocks they all do. Typical blocking activities include most system calls, most I/O, and things like sleep().

Kernel threads are the next step in thread evolution. The OS knows about kernel threads, and makes allowances for them. The main difference between a kernel thread and a user-mode thread is blocking. With kernel threads, things that block a single thread don't block other threads. This is not the case with user-mode threads, where the kernel blocks at the process level and not the thread level.

This is a big step forward, and can give a threaded program quite a performance boost over non-threaded programs. Threads that block performing I/O, for example, won't block threads that are doing other things. Each process still has only one thread running at once, though, regardless of how many CPUs a system might have.

Since kernel threading can interrupt a thread at any time, they will uncover some of the implicit locking assumptions you may make in your program. For example, something as simple as `$a = $a + 2` can behave unpredictably with kernel threads if $a is visible to other threads, as another thread may have changed $a between the time it was fetched on the right hand side and the time the new value is stored.

Multiprocessor Kernel Threads are the final step in thread support. With multiprocessor kernel threads on a machine with multiple CPUs, the OS may schedule two or more threads to run simultaneously on different CPUs.

This can give a serious performance boost to your threaded program, since more than one thread will be executing at the same time. As a tradeoff, though, any of those nagging synchronization issues that might not have shown with basic kernel threads will appear with a vengeance.

In addition to the different levels of OS involvement in threads, different OSes (and different thread implementations for a particular OS) allocate CPU cycles to threads in different ways.

Cooperative multitasking systems have running threads give up control if one of two things happen. If a thread calls a yield function, it gives up control. It also gives up control if the thread does something that would cause it to block, such as perform I/O. In a cooperative multitasking implementation, one thread can starve all the others for CPU time if it so chooses.

Preemptive multitasking systems interrupt threads at regular intervals while the system decides which thread should run next. In a preemptive multitasking system, one thread usually won't monopolize the CPU.

On some systems, there can be cooperative and preemptive threads running simultaneously. (Threads running with realtime priorities often behave cooperatively, for example, while threads running at normal priorities behave preemptively.)

51.5 What kind of threads are perl threads?

If you have experience with other thread implementations, you might find that things aren't quite what you expect. It's very important to remember when dealing with Perl threads that Perl Threads Are Not X Threads, for all values of X. They aren't POSIX threads, or DecThreads, or Java's Green threads, or Win32 threads. There are similarities, and the broad concepts are the same, but if you start looking for implementation details you're going to be either disappointed or confused. Possibly both.

This is not to say that Perl threads are completely different from everything that's ever come before–they're not. Perl's threading model owes a lot to other thread models, especially POSIX. Just as Perl is not C, though, Perl threads are not POSIX threads. So if you find yourself looking for mutexes, or thread priorities, it's time to step back a bit and think about what you want to do and how Perl can do it.

51.6 Threadsafe Modules

The addition of threads has changed Perl's internals substantially. There are implications for people who write modules–especially modules with XS code or external libraries. While most modules won't encounter any problems, modules that aren't explicitly tagged as thread-safe should be tested before being used in production code.

Not all modules that you might use are thread-safe, and you should always assume a module is unsafe unless the documentation says otherwise. This includes modules that are distributed as part of the core. Threads are a beta feature, and even some of the standard modules aren't thread-safe.

If you're using a module that's not thread-safe for some reason, you can protect yourself by using semaphores and lots of programming discipline to control access to the module. Semaphores are covered later in the article. Perl Threads Are Different

51.7 Thread Basics

The core Thread module provides the basic functions you need to write threaded programs. In the following sections we'll cover the basics, showing you what you need to do to create a threaded program. After that, we'll go over some of the features of the Thread module that make threaded programming easier.

51.7.1 Basic Thread Support

Thread support is a Perl compile-time option-it's something that's turned on or off when Perl is built at your site, rather than when your programs are compiled. If your Perl wasn't compiled with thread support enabled, then any attempt to use threads will fail.

Remember that the threading support in 5.005 is in beta release, and should be treated as such. You should expect that it may not function entirely properly, and the thread interface may well change some before it is a fully supported, production release. The beta version shouldn't be used for mission-critical projects. Having said that, threaded Perl is pretty nifty, and worth a look.

Your programs can use the Config module to check whether threads are enabled. If your program can't run without them, you can say something like:

```
  $Config{usethreads} or die "Recompile Perl with threads to run this program.";
```

A possibly-threaded program using a possibly-threaded module might have code like this:

```
    use Config;
    use MyMod;

    if ($Config{usethreads}) {
        # We have threads
        require MyMod_threaded;
        import MyMod_threaded;
    } else {
        require MyMod_unthreaded;
        import MyMod_unthreaded;
    }
```

Since code that runs both with and without threads is usually pretty messy, it's best to isolate the thread-specific code in its own module. In our example above, that's what MyMod_threaded is, and it's only imported if we're running on a threaded Perl.

51.7.2 Creating Threads

The Thread package provides the tools you need to create new threads. Like any other module, you need to tell Perl you want to use it; use Thread imports all the pieces you need to create basic threads.

The simplest, straightforward way to create a thread is with new():

```
    use Thread;

    $thr = new Thread \&sub1;

    sub sub1 {
        print "In the thread\n";
    }
```

The new() method takes a reference to a subroutine and creates a new thread, which starts executing in the referenced subroutine. Control then passes both to the subroutine and the caller.

If you need to, your program can pass parameters to the subroutine as part of the thread startup. Just include the list of parameters as part of the `Thread::new` call, like this:

```
    use Thread;
    $Param3 = "foo";
    $thr = new Thread \&sub1, "Param 1", "Param 2", $Param3;
    $thr = new Thread \&sub1, @ParamList;
    $thr = new Thread \&sub1, qw(Param1 Param2 $Param3);

    sub sub1 {
        my @InboundParameters = @_;
        print "In the thread\n";
        print "got parameters >", join("<>", @InboundParameters), "<\n";
    }
```

The subroutine runs like a normal Perl subroutine, and the call to new Thread returns whatever the subroutine returns.

The last example illustrates another feature of threads. You can spawn off several threads using the same subroutine. Each thread executes the same subroutine, but in a separate thread with a separate environment and potentially separate arguments.

The other way to spawn a new thread is with async(), which is a way to spin off a chunk of code like eval(), but into its own thread:

```
    use Thread qw(async);

    $LineCount = 0;

    $thr = async {
        while(<>) {$LineCount++}
        print "Got $LineCount lines\n";
    };

    print "Waiting for the linecount to end\n";
    $thr->join;
    print "All done\n";
```

You'll notice we did a use Thread qw(async) in that example. async is not exported by default, so if you want it, you'll either need to import it before you use it or fully qualify it as Thread::async. You'll also note that there's a semicolon after the closing brace. That's because async() treats the following block as an anonymous subroutine, so the semicolon is necessary.

Like eval(), the code executes in the same context as it would if it weren't spun off. Since both the code inside and after the async start executing, you need to be careful with any shared resources. Locking and other synchronization techniques are covered later.

51.7.3 Giving up control

There are times when you may find it useful to have a thread explicitly give up the CPU to another thread. Your threading package might not support preemptive multitasking for threads, for example, or you may be doing something compute-intensive and want to make sure that the user-interface thread gets called frequently. Regardless, there are times that you might want a thread to give up the processor.

Perl's threading package provides the yield() function that does this. yield() is pretty straightforward, and works like this:

```
    use Thread qw(yield async);
    async {
        my $foo = 50;
        while ($foo--) { print "first async\n" }
        yield;
        $foo = 50;
        while ($foo--) { print "first async\n" }
    };
    async {
        my $foo = 50;
        while ($foo--) { print "second async\n" }
        yield;
        $foo = 50;
        while ($foo--) { print "second async\n" }
    };
```

51.7.4 Waiting For A Thread To Exit

Since threads are also subroutines, they can return values. To wait for a thread to exit and extract any scalars it might return, you can use the join() method.

```
use Thread;
$thr = new Thread \&sub1;

@ReturnData = $thr->join;
print "Thread returned @ReturnData";

sub sub1 { return "Fifty-six", "foo", 2; }
```

In the example above, the join() method returns as soon as the thread ends. In addition to waiting for a thread to finish and gathering up any values that the thread might have returned, join() also performs any OS cleanup necessary for the thread. That cleanup might be important, especially for long-running programs that spawn lots of threads. If you don't want the return values and don't want to wait for the thread to finish, you should call the detach() method instead. detach() is covered later in the article.

51.7.5 Errors In Threads

So what happens when an error occurs in a thread? Any errors that could be caught with eval() are postponed until the thread is joined. If your program never joins, the errors appear when your program exits.
Errors deferred until a join() can be caught with eval():

```
use Thread qw(async);
$thr = async {$b = 3/0};   # Divide by zero error
$foo = eval {$thr->join};
if ($@) {
    print "died with error $@\n";
} else {
    print "Hey, why aren't you dead?\n";
}
```

eval() passes any results from the joined thread back unmodified, so if you want the return value of the thread, this is your only chance to get them.

51.7.6 Ignoring A Thread

join() does three things: it waits for a thread to exit, cleans up after it, and returns any data the thread may have produced. But what if you're not interested in the thread's return values, and you don't really care when the thread finishes? All you want is for the thread to get cleaned up after when it's done.
In this case, you use the detach() method. Once a thread is detached, it'll run until it's finished, then Perl will clean up after it automatically.

```
use Thread;
$thr = new Thread \&sub1; # Spawn the thread

$thr->detach; # Now we officially don't care any more

sub sub1 {
    $a = 0;
    while (1) {
        $a++;
        print "\$a is $a\n";
        sleep 1;
    }
}
```

Once a thread is detached, it may not be joined, and any output that it might have produced (if it was done and waiting for a join) is lost.

51.8 Threads And Data

Now that we've covered the basics of threads, it's time for our next topic: data. Threading introduces a couple of complications to data access that non-threaded programs never need to worry about.

51.8.1 Shared And Unshared Data

The single most important thing to remember when using threads is that all threads potentially have access to all the data anywhere in your program. While this is true with a nonthreaded Perl program as well, it's especially important to remember with a threaded program, since more than one thread can be accessing this data at once.

Perl's scoping rules don't change because you're using threads. If a subroutine (or block, in the case of async()) could see a variable if you weren't running with threads, it can see it if you are. This is especially important for the subroutines that create, and makes `my` variables even more important. Remember–if your variables aren't lexically scoped (declared with `my`) you're probably sharing them between threads.

51.8.2 Thread Pitfall: Races

While threads bring a new set of useful tools, they also bring a number of pitfalls. One pitfall is the race condition:

```
    use Thread;
    $a = 1;
    $thr1 = Thread->new(\&sub1);
    $thr2 = Thread->new(\&sub2);

    sleep 10;
    print "$a\n";

    sub sub1 { $foo = $a; $a = $foo + 1; }
    sub sub2 { $bar = $a; $a = $bar + 1; }
```

What do you think $a will be? The answer, unfortunately, is "it depends." Both sub1() and sub2() access the global variable $a, once to read and once to write. Depending on factors ranging from your thread implementation's scheduling algorithm to the phase of the moon, $a can be 2 or 3.

Race conditions are caused by unsynchronized access to shared data. Without explicit synchronization, there's no way to be sure that nothing has happened to the shared data between the time you access it and the time you update it. Even this simple code fragment has the possibility of error:

```
    use Thread qw(async);
    $a = 2;
    async{ $b = $a; $a = $b + 1; };
    async{ $c = $a; $a = $c + 1; };
```

Two threads both access $a. Each thread can potentially be interrupted at any point, or be executed in any order. At the end, $a could be 3 or 4, and both $b and $c could be 2 or 3.

Whenever your program accesses data or resources that can be accessed by other threads, you must take steps to coordinate access or risk data corruption and race conditions.

51.8.3 Controlling access: lock()

The lock() function takes a variable (or subroutine, but we'll get to that later) and puts a lock on it. No other thread may lock the variable until the locking thread exits the innermost block containing the lock. Using lock() is straightforward:

```
use Thread qw(async);
$a = 4;
$thr1 = async {
    $foo = 12;
    {
        lock ($a); # Block until we get access to $a
        $b = $a;
        $a = $b * $foo;
    }
    print "\$foo was $foo\n";
};
$thr2 = async {
    $bar = 7;
    {
        lock ($a); # Block until we can get access to $a
        $c = $a;
        $a = $c * $bar;
    }
    print "\$bar was $bar\n";
};
$thr1->join;
$thr2->join;
print "\$a is $a\n";
```

lock() blocks the thread until the variable being locked is available. When lock() returns, your thread can be sure that no other thread can lock that variable until the innermost block containing the lock exits.

It's important to note that locks don't prevent access to the variable in question, only lock attempts. This is in keeping with Perl's longstanding tradition of courteous programming, and the advisory file locking that flock() gives you. Locked subroutines behave differently, however. We'll cover that later in the article.

You may lock arrays and hashes as well as scalars. Locking an array, though, will not block subsequent locks on array elements, just lock attempts on the array itself.

Finally, locks are recursive, which means it's okay for a thread to lock a variable more than once. The lock will last until the outermost lock() on the variable goes out of scope.

51.8.4 Thread Pitfall: Deadlocks
